(Dated: September 24, 2020)

A constant Early Dark Energy (EDE) component contributing a fraction \( f_{\text{EDE}}(z_e) \sim 10\% \) of the energy density of the universe around \( z_e \approx 3500 \) and diluting as or faster than radiation afterwards, can provide a simple resolution to the Hubble tension, the \( \sim 5\sigma \) discrepancy – in the ΛCDM context – between the \( H_0 \) value derived from early- and late-universe observations. However, it has been pointed out that including Large-Scale Structure (LSS) data, which are in \( \sim 3\sigma \) tension with ΛCDM and EDE cosmologies, might break some parameter degeneracy and alter these conclusions. We reassess the viability of the EDE against a host of high- and low-redshift measurements, by combining LSS observations from recent weak lensing (WL) surveys with CMB, Baryon Acoustic Oscillation (BAO), growth function (FS) and Supernova Ia (SNIa) data. Introducing a model whose only parameter is \( f_{\text{EDE}}(z_e) \), we report in agreement with past work a \( \sim 2\sigma \) preference for non-zero \( f_{\text{EDE}}(z_e) \) from PLANCK CMB data alone, while the tension with the local \( H_0 \) measurement from SH0ES is reduced below 2\( \sigma \). Adding BAO, FS and SNIa does not affect this conclusion, while the inclusion of a prior on \( H_0 \) from SH0ES increase the preference for EDE over ΛCDM to the \( \sim 3.6\sigma \) level. After checking the EDE non-linear matter power spectrum as predicted by standard semi-analytical algorithms via a dedicated set of \( N \)-body simulations, we test the 1-parameter EDE cosmology against WL data. We find that it does not significantly worsen the fit to the \( S_8 \) measurement as compared to ΛCDM, and that current WL observations do not exclude the EDE resolution to the Hubble tension. We also caution against the interpretation of constraints obtained from combining statistically inconsistent data sets within the ΛCDM cosmology. In light of the CMB lensing anomalies, we show that the lensing-marginalized CMB data also favor non-zero \( f_{\text{EDE}}(z_e) \) at \( \sim 2\sigma \), predicts \( H_0 \) in 1.4\( \sigma \) agreement with SH0ES and \( S_8 \) in 1.5\( \sigma \) and 0.8\( \sigma \) agreement with KiDS-VIKING and DES respectively. There still exists however a \( \sim 2.5\sigma \) tension with the joint results from KiDS-VIKING and DES. With an eye on Occam’s razor, we finally discuss promising extensions of the EDE cosmology that could allow to fully restore cosmological concordance.

I. INTRODUCTION

In recent years, several tensions between probes of the early- and late-universe have emerged. First and foremost, there exists a strong mismatch between the prediction of the current expansion rate of the universe (known as Hubble constant) in the Λ cold dark matter (ΛCDM) model calibrated onto Planck CMB data, and its direct measurement using low redshift data (i.e., the classical distance ladder) [1, 2]. Originally, this “Hubble tension” was limited to the determination of the Hubble constant using type Ia supernovae by the SH0ES collaboration, whose latest determination is \( H_0 = 74.03 \pm 1.42 \) km/s/Mpc [3], while the prediction from the ΛCDM model inferred from Planck CMB data is \( H_0 = 67.4 \pm 0.5 \) km/s/Mpc [4]. In the last few years, tremendous progress have been made in measuring \( H_0 \) with alternative methods, such that nowadays there exist five other methods to measure \( H_0 \) with few percent accuracy. Remarkably, various averages over these measurements (excluding correlated data) leads to \( H_0 \) values that ranges from 72.8 ± 1.1 and 74.3 ± 1.0, in 4.5 to 6.3\( \sigma \) discrepancy with the prediction from ΛCDM [1, 2]. Similarly, it has been shown that the prediction from ΛCDM calibrated on any ‘early-universe’ data (e.g. BAO+SNIa+BBN [12–15], WMAP+SPT and/or ACT [13, 16]) is always in good agreement with that of Planck. A number of possible systematic effects affecting some of these measurements have been discussed (see e.g. [5, 17–20]), yet the existence of several vastly different methods yielding relatively high \( H_0 \) have triggered a wide range of theoretical activities to resolve the Hubble tension (see in particular [21] for a recent review). Indeed, this tension between different measurements of the Hubble constant could point to a major failure of the ΛCDM scenario, and hence to a new cosmological paradigm: that would be a new and unexpected breakthrough in cosmology.

CMB data do not provide an absolute measurement of \( H_0 \). Rather, the value of \( H_0 \) is inferred within a given cosmological model from a measurement of the angular scale of sound horizon \( \theta_s \equiv r_s(z_e)/d_A(z_e) \), where \( r_s(z_e) \) is the emission in four galaxies at great distances [11] and Surface Brightness Fluctuations of distant galaxies [1].
sound horizon at recombination and $d_A(z_r)$ is the angular diameter distance to recombination. The great challenge lies in that $\theta_s$ is nowadays measured at sub-percent-level accuracy with the latest CMB data [4]. This suggests two main ways of resolving the Hubble tension through new physics – based on the requirement to keep the key angular scale $\theta_s$ fixed – usually called late- and early-universe solutions. The first way boils down to changing the redshift evolution of the angular diameter distance in the late-universe, i.e. $z \ll z_*$, so as to force a higher $H_0$, without changing $d_A(z_*)$ nor $r_s(z_*)$. The second way amounts in reducing $r_s(z_*)$ in the early-universe, which automatically requires to reduce $d_A(z_*)$ by the same amount to keep $\theta_s$ fixed, that is most naturally done by increasing the value of $H_0$. A final, more subtle, way of resolving the $H_0$ tension comes from the fact that the position of the peaks receives an additional phase-shift from various effects, in particular from the gravitational pulling of CMB photons out of the potential wells by free-streaming neutrinos [22, 23]. Suppressing this phase-shift can change the value of $\theta_s$ deduced from a CMB power spectra analysis and in turn significantly increase $H_0$.

There have been many attempts to find extensions of the standard cosmological model, $\Lambda$CDM, which bring these estimates into agreement. However, theoretical explanations for the Hubble tension are not easy to come by. Late-time observables, especially BAO and luminosity-distance to SNIa, place severe limitations on late-time resolutions [13, 24, 25]. On the other hand, early-time resolutions affect the physics that determines the fluctuations in the CMB. At first sight, given the precision measurements of the CMB from Planck, this might appear to be even more constraining than the late-time probes of the expansion rate. Excitingly, there are a few early-time resolutions which do not spoil the fit to current CMB temperature measurements [26, 40], sometimes even improving it over $\Lambda$CDM.

EDE representing $\sim 10\%$ of the total energy density of the universe around matter-radiation equality and diluting faster than radiation afterwards has been shown to provide a very good resolution to this tension. However, taken at face value, this model triggers a number of questions. On the theoretical side, it suffers from a strong coincidence problem as the fluid needs to become dynamical around a key era of the universe. This is not without reminding the standard coincidence problem of DE that such models were originally introduced to resolve. However, this coincidence might be the sign of a very specific dynamics to be uncovered; in fact there exist models in which the field becomes dynamical precisely around matter-radiation equality, either because of a phase-transition triggered by some other process (e.g. the neutrino mass becoming of the order of the neutrino bath temperature [41]) or because of a non-minimal coupling to the Ricci curvature [42]. There exist also more concrete issues with Large-Scale Structure (LSS) observables, and in particular weak lensing (WL) surveys, which this article aims to address. Indeed, a number of cosmic shear surveys (CFHTLenS [43], KiDS/VIKING [44], DES [45], HSC [46]) have provided accurate measurements of the cosmological parameter $S_8 \equiv \sigma_8(\Omega_m/0.3)^{0.5}$ – where $\sigma_8$ measures the amplitude of fluctuations in a sphere of radius 8 Mpc/$h$ – which are systematically lower than the $\Lambda$CDM prediction. The significance of this “$S_8$ tension” oscillates between 2 and $4\sigma$ depending on the experiments, such that the discrepancy cannot easily be attributed to a statistical fluke. The problem for EDE cosmologies lies in the fact that the prediction for the value of $S_8$ is somewhat higher than that of $\Lambda$CDM. Therefore, taken at face values, these experiments pose a challenge to EDE cosmologies, and could exclude these models as a resolution to the Hubble tension [47]. A similar conclusion was reached in Refs [48, 49] with the inclusion of BOSS data in the effective field theory (EFT) of LSS framework.

In this paper, we analyze the EDE cosmology resolving the Hubble tension in light of the latest PLANCK data (and the more precise polarization measurement) and confront it to the KiDS-VIKING measurement of the cosmic shear power spectrum [50] and the joint measurement of $S_8$ from KiDS-VIKING+DES [4]. The KiDS-VIKING+DES measurements however rely on modelling the non-linear matter power spectrum on relatively small scales. This is done within numerical Einstein-Boltzmann solvers such as CAMB [52] or CLASS [53, 54], through the halofit [55, 56] or HMcode [57] algorithms, which have not been calibrated for EDE cosmologies. We thus check the predictions of these algorithms against the results of a set of dedicated cosmological $N$-body simulations, confirming that the qualitative departures from $\Lambda$CDM arising in the EDE cosmology are small enough to make use of these standard algorithms. We perform a series of Monte Carlo Markov Chain (MCMC) analyses with various combination of the latest Planck, BAO, growth factor and SNIa Luminosity distance measurements, the SH0ES measurement of $H_0$, and KiDS/Viking/DES data, in order to assess whether current observations exclude the EDE resolution to the Hubble tension.

We find that, while the $S_8$ prediction from the best fit EDE cosmology is indeed $\sim 2.5\sigma$ higher than the measurement, KiDS data currently provide very little constraining power on the EDE parameters. Yet, it has been found in Ref. [50, 58] that a combination of KiDS and DES-Y1 (after re-calibration of the DES photo-metric redshifts) and yields $S_8 = 0.755_{-0.019}^{+0.019}$, a result that is in $3.2\sigma$ tension with Planck $\Lambda$CDM prediction [4]. At such a level of discrepancy, one should be cautious when interpreting results obtained from combining Planck and WL

---

[1] The re-analysis of BOSS data in the EFT of LSS is performed elsewhere [51].

[2] The joint analysis of KIDS1000+BOSS+2dfLenS has determined $S_8 = 0.766_{-0.014}^{+0.020}$ in $3\sigma$ tension with Planck. Making use of these data would not affect our conclusions.
data, even within ΛCDM. Indeed, we show that despite the inclusion of a Gaussian $S_8$ likelihood, the resulting cosmological model yields a very bad fit to the $S_8$ data, while providing very strong constraints on any parameter correlated with $S_8$ (e.g. $\omega_{cdm}, A_s, f_{EDE}(\omega_c)$). It is easily conceivable that the resolution to the $S_8$ tension lies elsewhere (whether new physics related – or not – to the EDE, or systematic effects), such that any constraints derived from these combined data are artificial.

It is also possible that this anomaly comes from CMB measurements. Interestingly, it has been found that there exists a lensing anomaly in Planck data (strengthened in the latest data released despite extensive efforts from the Planck team to pin down a possible systematic effect) [4, 61], which could be related to the $S_8$ tension [62, 63]. Indeed, the amplitude of the CMB lensing power spectrum deduced from the smoothing of the acoustic peaks at high-$\ell$ is higher than that predicted by the ΛCDM cosmology obtained from the ‘unlensed’ part of the CMB power spectrum [3]. Moreover, it is also higher than that deduced from the lensing reconstruction such that, while this anomaly looks like lensing, it cannot be attributed to some extra source of CMB lensing. Once marginalizing over the lensing information (which by itself is an interesting consistency check of the ΛCDM cosmology), it has been shown that the reconstructed cosmology has a smaller $A_s$ and $\omega_{cdm}$ (as well as a higher $H_0$) and it shows no $S_8$ tension, but a remnant $\sim 3.5\sigma$ Hubble tension [62, 63]. Interestingly, the cosmology deduced once marginalizing over the lensing information is in better agreement with the recent results from the SPTPol [61, 64, 65], which shows no tension with the LSS measurement of $S_8$, a weaker $H_0$ tension, and no lensing anomaly. Pin-pointing the source of such lensing anomaly (perhaps a simple statistical fluke, although quantifying is likelihood and how to treat it is complicated) is therefore of utmost importance to understand whether the $S_8$ tension derives from it.

Motivated by this fact, we perform an analysis of the ΛCDM and EDE cosmology against Planck and a prior on $S_8$ from the joint DES-Y1 and KiDS results, while marginalizing over the lensing information. We find that both the unlensed ΛCDM and EDE cosmology spectrum agrees better with LSS data, and that the presence of EDE does not affect the amount of anomalous lensing. This means that the anomalous lensing is not due to the EDE, and also that the success of EDE is not due to opening up a new degeneracy direction with some exotic lensing parameters.

The paper is structured as follows. In sec. II, we present the phenomenological EDE models studied in this work and compare it to other models from the literature. In sec. III, we perform an ‘anatomy’ of the EDE resolution to the Hubble tension, to understand how each data set reacts to the presence of EDE. We additionally introduce the new baseline 1-parameter EDE model that is favored by PLANCK 2018 data. We present our N-Body simulations validating the HMcode prediction and confront the 1-parameter EDE model against WL data in sec. IV. We discuss the $H_0$ and $S_8$ tension in light of the lensing-marginalized CMB spectrum in sec. V and suggest some promising ways of restoring cosmological concordance in an extended EDE cosmology. Finally, we conclude in sec. VI.

II. THE PHENOMENOLOGICAL EARLY DARK ENERGY MODEL RESOLVING THE HUBBLE TENSION

The possible presence of a dark energy component before last-scattering has been studied for more than a decade [66, 67]. These alternative cosmological realizations have little to do with that under study here, as they typically assume tracking equation of state at early times. The idea of an anomalous era of expansion triggered by a frozen scalar field as a resolution to the Hubble tension was introduced in Ref. [68], where a background-only computation was shown to alleviate the Hubble tension. However, it is the work of Ref. [36] that showed through a fluid approximation the key role played by perturbations in the scalar field to allow for a resolution of the Hubble tension. Since this work, the treatment of the EDE component has been improved [69, 71], and augmented to deal with alternative potentials and better motivated underlying fundamental models [38, 41, 69, 71–76]. In particular, it has been shown that Planck data not only provide a detection of the background dynamics of the EDE component, but also severely restricts the dynamics of perturbations [70, 71]. As such, Planck data allows for pinning down directly properties of the EDE, making the choice of model crucial. They favor either non-canonical kinetic term whereby the equation of state $w$ is approximately equal to the effective sound speed $c_s^2$ [72], or potential that flattens close to the initial field value [70].

In this work, we study the modified axion potential introduced in Refs. [36, 68, 70, 71, 75],

$$V_n(\Theta) = m^2 f^2 [1 - \cos(\Theta)]^n,$$

where $m$ represent the axion mass, $f$ the decay constant and $\Theta \equiv \phi/f$ is a re-normalized field variable, so that $-\pi \leq \Theta \leq \pi$. We assume that the field always starts in slow-roll the background dynamics and without loss of generality we restrict $0 \leq \Theta_0 \leq \pi$.

This potential is a phenomenological generalization of the well motivated axion-like potential (which can be recovered by setting $n = 1$) that arise generically in string theory [73, 82]. Such a potential may be generated by higher-order instanton corrections [83], but taken at face
values would suffer from a strong fine-tuning issues necessary to the cancelling of the lowest orders instantons. Therefore, it should not be interpreted beyond a phenomenological description. We note that similar forms of potential, with power law minima and flattened “wings” have been used in the context of inflationary physics, as well as dark energy (see, e.g., Refs. [54][84]). Still, this form was devised to allow for flexibility in the background dynamics after the field becomes dynamical, and it also provides an excellent fit to both Planck and SH0ES data. In fact, to the best of our knowledge, it corresponds to the EDE scenario that leads to the best combined $\chi^2$ of the cosmological data-sets under study (although the better theoretically motivated model studied in Ref. [54][70] seems to perform equally well).

We refer to Refs. [70][78] for all necessary details about the model. However, the key features can be summarized as follows: at early times the scalar field is frozen due to Hubble friction, until the Hubble rate drops below its mass value; the field then starts moving in the potential, and eventually oscillating around the minimum, at which point the energy density dilutes at a rate dictated by the asymptotic equation of state $w(n) = (n - 1)/(n + 1)$ (e.g., Refs. [78][87][88]).

We can trade three out of the four model parameters $\{m, f, n, \Theta_i\}$ for phenomenological parameters: the first two of them describing the fractional energy density $f_{\text{EDE}}(z_c)$ at the critical redshift $z_c$ where the field becomes dynamical and the asymptotic equation of states after the field becomes dynamical $w(n) = (n - 1)/(n + 1)$, respectively; the last degree of freedom lies in the dynamics of linear perturbations, whose phenomenology is captured by the effective sound speed $c_s^2$. However, within the EDE scalar field scenario under study, such freedom is intrinsically encoded in the choice of the initial field value $\Theta_i$, once the other phenomenological parameters have been fixed.

To perform our analyses, we use the modified version of the Einstein-Boltzmann code CLASS [53][54] presented in Ref. [70]. The code is publicly available at https://github.com/PoulinV/AxCLASS (the latest version, used for this study, can be found in the “devel” branch).

III. CONFRONTING EDE TO PLANCK 2018, BOSS AND PANTHEON DATA

In this section, we test the EDE scenario with various combinations of data-sets, in order to extract the cosmology that would resolve the Hubble tension, and compare with results from past literature making use of Planck 2015 data. We will test our phenomenological model against:

- **Planck TTTTTE+σ**: the high-ℓ TT,TE,EE, low-ℓ TT and EE data from Planck 2018 through the baseline PLIK, COMMANDER and SMALL likelihoods [89][90], alone and combined with the lensing amplitude reconstruction (SIMC likelihood); we make use of a Cholesky decomposition as implemented in MONTEPYTHON-V3 to handle the large number of nuisance parameters [91].

- **BAO**: the measurements from 6dFGS at $z = 0.106[25]$, SDSS MGS at $z = 0.15[26]$, and BOSS DR12 data at $z = 0.38, 0.51$ and 0.61 [31]. In practice, we make use of the “conensus” BAO and FS result that combines both in a single likelihood.

- **PANtheon**: the Pantheon SN1a catalogue, spanning redshifts $0.01 < z < 2.3$; we marginalize over the nuisance parameter $M$ describing the SN1a calibration.

- **SH0ES**: the SH0ES result, modelled with a Gaussian likelihood centered on $H_0 = 74.03 \pm 1.42$ km/s/Mpc [3]; however, choosing a different value that combines various direct measurements would not affect the result, given their small differences.

A. Baseline analysis: anatomy of the 3-parameter EDE model resolving the Hubble tension

Our baseline cosmology consists in the following combination of the six ΛCDM parameters $\{\omega_s, \omega_{\text{cdm}}, H_0, n_s, A_s, \tau_{\text{reio}}\}$, plus three parameters describing the EDE sector, namely $\{f_{\text{EDE}}(a_c), \log_{10}(a_c), \Theta_i\}$. We use wide flat priors on all these parameters. We follow the Planck convention and assume two massless neutrinos and one massive with $m_\nu = 0.06$ eV. We perform our MCMC analyses using MONTEPYTHON-V3, and consider chains to be converged with the Gelman-Rubin criterion $\bar{R} < 1 < 0.1[92]$. To extract best-fit parameters, we make use of the MINUIT algorithm [93] through the iMINUIT python package. Starting from Planck only, we now discuss the impact of adding data-sets on the reconstructed EDE parameters. We compare the evolution of the $\chi^2$
in the EDE cosmology as we add data-sets, to that of the ΛCDM model in the same combined fit, with and without SH0ES data. The results are presented in Tab. 1 and we show the 1D and 2D posterior distributions of \{H_0, f_{\text{EDE}}(z_c), \Theta_1, \log_{10}(z_c), \omega_{\text{cdm}}, n_s, S_8\} in Fig. 1. All relevant \(\chi^2\) information is given in App. A.

Planck TT,TE,EE only: with \textsc{Planck}\textsuperscript{TT,TE,EE} data only and three free parameters, the EDE model under study is not detected. In agreement with Refs. 17, 76, we find that the fraction of EDE at \(z_c\) is limited to \(f_{\text{EDE}}(z_c) < 0.088\), while \(\log_{10}(z_c)\) and \(\Theta_1\) are unconstrained. Interestingly, we also find that the best fit within \textsc{Planck} data only has \(f_{\text{EDE}}(z_c) \sim 8.5\%\), \(\log_{10}(z_c) \sim 3.56\), \(\Theta_1 \sim 2.8\), \(H_0 \sim 70.5\) km/s/Mpc\} and a \(\Delta \chi^2_{\text{min}} \equiv \chi^2_{(\Lambda\text{CDM})} - \chi^2(\text{EDE}) \simeq -5\) in favor of the EDE model\textsuperscript{10}. One can already note a curiosity: the best fit value of \(f_{\text{EDE}}(z_c)\) is very close to the 2σ bound that we obtain. This, as we will discuss later, is due to the choice of flat, uninformative prior on \(\log_{10}(z_c)\) and \(\Theta_1\).

Planck TT,TE,EE+SH0ES: Once a prior on \(H_0\) given by SH0ES is included in the analysis, the sampler explores more easily a part of parameter space with higher \(H_0\) values, and the EDE is now well detected: \((f_{\text{EDE}}(z_c) \simeq 0.11^{+0.036}_{-0.031}, \log_{10}(z_c) = 3.6^{+0.14}_{-0.039}, \Theta_1 = 2.569^{+0.36}_{-0.032}\), with \(H_0 = 71.4 \pm 1\) km/s/Mpc\}. This is in excellent agreement with results from past literature 36, 70, 71, 76. Remarkably, the best fit values of both \(\Theta_1\) and \(\log_{10}(z_c)\) are in perfect agreement with that obtained \textsc{Planck} only. This is highly non-trivial, and seem to indicate that \textsc{Planck} does favor the region of the \{\log_{10}(z_c), \Theta_1\}-space that resolves the Hubble tension. However, the best fit fraction reaches 15%, a value that one naively consider to be strongly excluded by the \textsc{Planck} only analysis. In fact, that is not the case, as the the fit to \textsc{Planck} data is barely affected by the additional \(H_0\) prior, while one can get a perfect fit of SH0ES data. Concretely, the \(\chi^2_{\text{min}}(\text{EDE})\) when fitting \textsc{Planck}+SH0ES increases by \(\sim 3\), such that even in this combined fit, the \(\chi^2\) of \textsc{Planck} data is smaller than that of ΛCDM fitted on \textsc{Planck} data only. This indicates that the limit on \(f_{\text{EDE}}(z_c)\) derived in a \textsc{Planck} only analysis is not robust, as it is entirely driven by our choice of flat priors. This was also discussed in Refs. 70, 76, and the reason for that is clear\textsuperscript{12}.

Planck TT,TE,EE+PP+BAO+SNIa+SH0ES: We now add to our analysis the lensing reconstruction \textsc{Planck}\textsuperscript{pp}, the PANTHEON SNIa data-set, and the BAO data from BOSS. Strikingly, the addition of these three data-sets has almost no impact on the reconstructed posteriors, nor on the best fit. This is far from a trivial test to pass, as many of the suggested resolutions to the Hubble tension are strongly constrained by the addition of these data-sets 13, 25, 35. However, as noted in Refs. 36, 70, 76, we find that the reconstructed \(\omega_{\text{cdm}}\) and \(n_s\) in the EDE cosmology are somewhat higher than in ΛCDM, such that the \(S_8\) tension is slightly increased. As suggested in past literature 17, 39, this opens up the possibility of constraining the EDE resolution using LSS data, and in particular the \(S_8\) measurement from weak gravitational lensing surveys. However, combining KiDS+VIKING/HSC data with \textsc{Planck} to constrain extension to ΛCDM can be problematic as: i) they require the ability to predict the non-linear power spectrum at relatively small scales in models beyond ΛCDM; ii) the ΛCDM best fit model from \textsc{Planck} is not a good fit to these data.

All Data: As a starter, we add the ‘consensus’ \(f_{\sigma_8}\) BOSS likelihood to the analysis, which is consistent with the ΛCDM model from \textsc{Planck}; we find a mild \(\sim 0.4\sigma\) decrease in the reconstructed mean, now being \(H_0 \simeq 71 \pm 1\) km/s/Mpc and \(f_{\text{EDE}} \simeq 0.1 \pm 0.03\). This is consistent with the fact that the \(f_{\sigma_8}\) measurements are sensibly lower than the ΛCDM prediction, while the EDE cosmology leads to slightly larger values. Still, the \(\chi^2\) of the FS data is barely affected; in fact, as before, ΛCDM provides a slightly worse fit to the joint data-set, even when the SH0ES prior is not included in the analysis. Before including weak lensing measurements to the analysis, we therefore conclude that the 3-parameter EDE model under study performs very well in resolving the Hubble tension, but future measurement of \(f_{\sigma_8}\) will certainly put the model under crucial tests.

\textsuperscript{10} Hereinafter, we quote 1-sided constraints at 95\%C.L., and two-sided ones at 68\%C.L.
\textsuperscript{11} To guide the reader, we mention that a 1σ shift in the quality of the fit to \textsc{Planck} data roughly corresponds to a \(\Delta \chi^2\) of \(\sim 3\) (see the distribution of \textsc{Planck}’s \(\chi^2\) in the tables available\textsuperscript{14} this link).

\textsuperscript{12} Here, let us mention that Ref. 18 make the comment that such degeneracy does not exist. It is of course only true because they include the 3σ discrepant \(S_8\) data to their analysis. The degeneracy is very clear within \textsc{Planck} data.
TABLE I. The mean (best-fit) ±1σ error of the cosmological parameters reconstructed from the combined analysis of various data sets (from left to right, each column adds a set of data to the previous one). We also report the Δχ²_min with respect to a ΛCDM fit to the same data-sets, with and without a prior on H₀ from SH0ES.

| Parameter | PLANCK+Planck+BAO+Pantheon | +SH0ES | +Planck+BAO+Pantheon | +FS |

B. Towards a 1-parameter resolution to the Hubble tension

Before turning to the inclusion of WL data, we show that the apparently tight bounds obtained when the SH0ES prior on H₀ is not included is due to our choice of uninformative priors for Θ₁ & Log₁₀ (z_c). In fact, one can strongly weaken the bound on f_ede by reducing the EDE parameter space to a suitable choice of Log₁₀ (z_c) and Θ₁. This might sound counter-intuitive: in principle, one expects to relax constraints on a given parameter by enlarging the parameter space such as to introduce a new degeneracy. Hence however, it is the poor prior choice which leads to a strong bound on f_ede(z_c) independently of the data combination. Fixing Log₁₀ (z_c) and Θ₁ to some fiducial values surely rises the question of what values should one choose. In a realistic scenario, one might know these values a priori; one example is the scenario discussed in Ref. [41] in which a scalar field experiences a phase-transition around the redshift at which neutrinos become non-relativistic, such that the critical redshift is specified by the value of the neutrino mass, while Θ₁ is set by the dynamics of the phase-transition (see also Refs. [73, 74, 75] for different EDE models with fewer free parameters). Here however, we have been considering a phenomenological model whose primary characteristics is to have enough freedom to extract information from the data to resolve the tension – we will therefore make use of that information and fix Θ₁ & Log₁₀ (z_c) to their best fit value from PLANCK data only –, which we recall, are close-to-identical to that obtained in the combined fit. We report in Table I the reconstructed cosmological parameters from PLANCK only and from the combined fit of all data, with and without including SH0ES. We show the reconstructed 2D posteriors of {f_ede (z_c), H₀, S₈} in Figure 3. Notice how the degeneracy direction f_ede (z_c) – H₀ clearly opens up. Furthermore, the mild Δχ² preference

in favor of the EDE cosmology now leads to reconstructing f_ede(z_c) = 0.082 ± 0.037, i.e., a ~ 2σ preference for non-zero EDE from PLANCK data only. The inferred H₀ = 70.1 ± 1.4 km/s/Mpc is now in agreement with the SH0ES determination at better than 2σ. The addition of BAO, FS and SH0ES measurements has little impact; the reconstructed EDE fraction shifts downward by ~ 0.3σ, slightly degrading the success of the resolution to the Hubble tension, while the 2σ preference for non-zero EDE is still present. These results are in excellent agreement with these presented in Ref. [72] for a different EDE model. Finally, the inclusion of a prior from SH0ES pulls up the fraction of EDE to f_ede(z_c) = 0.118 ± 0.029 and the value of H₀ = 71.7 ± 1 km/s/Mpc, at the cost of a small degradation in χ²_min (Δχ² ~ +6). Yet, as before, the χ²_min of the combined fit PLANCK+BAO+FS+SH0ES in the 1-parameter EDE cosmology is slightly lower than a ΛCDM fit to PLANCK+BAO+FS+SH0ES (no SH0ES). This attests that, despite this small degradation in χ²_min, the goodness of fit is still excellent. However, as discussed previously, the values of S₈ are in significant tension with weak lensing measurements, and one might expect that it is possible to strongly constrain the EDE model by including LSS data. We study this possibility in detail in Section IV following Refs. [77, 78, 79].

IV. CONFRONTING EDE TO WEAK LENSING SURVEYS

In order to make use of weak gravitational lensing data to perform LSS analyses, one needs to accurately model the matter power spectrum in the late-time non-linear regime. To this purpose, one can adopt the HALOFIT semi-analytical prescription [59], as revised by [60], which has been shown to be accurate at 5% level in reproducing the non-linear power spectra of ΛCDM models up to
wavenumbers $k \leq 10\,h$/Mpc. However, the version developed by authors of Ref. [56] does not consider the impact of baryon feedback. A further improvement, dubbed as HMcode, has been developed in Ref. [57], its main advantage being its flexibility to account for the effects of baryon physics on the small-scale clustering of matter, particularly important at very low redshifts. Both HALOFIT and HMcode have been shown to be suitable to describe the $\Lambda$CDM scenario, as well as some common extensions beyond it, such as models with varying DE EoS or massive neutrinos [94]. In Section IV A we confront the non-linear matter power spectra produced by using HALOFIT/HMcode in the EDE framework, against the outputs of dedicated cosmological N-Body simulations, to explicitly demonstrate the accuracy of our LSS data analyses. In Section IV B we discuss the results of our
MCMC analysis against weak lensing data.

A. Non-linear matter power spectrum: a comparison with \textit{N-Body} simulations

The goal of this Section is to show that the impact on the non-linear matter power spectrum due to the presence of EDE is mainly due to changes in the standard $\Lambda$CDM free parameters with respect to their reference values, and therefore such impact can be safely studied without further modifying or re-calibrating \textsc{halofit}/\textsc{hmcode}. To this end, we perform two sets of \textit{N-Body} DM-only simulations (one set for the EDE and one for the $\Lambda$CDM scenarios), as reported in Table \ref{tab:table3} by using the \textit{N-body} code \textsc{GADGET-3}, a modified version of the publicly available numerical code \textsc{GADGET-2} \cite{95,96}. The initial conditions have been produced by displacing the DM particles from a cubic Cartesian grid according to second-order Lagrangian Perturbation Theory, with the
TABLE II. The mean (best-fit) ±1σ error of the cosmological parameters reconstructed from the combined analysis of various data-sets (from left to right, each column adds a sets of data to the previous one). We also report the Δχ² with respect to a ΛCDM fit to the same data-sets. In the last row, we also report the Δχ² with respect to ΛCDM fit to the combined data without SH0ES in parenthesis.

TABLE III. Summary of the properties of the cosmological simulations used in this work. Notice that the Figures shown in this Section have been obtained by splicing together (for each redshift and model) the non-linear matter power spectra extracted from the first two simulations listed here, by using the third one to correct for finite-volume and resolution effects (see Appendix B for details). The labels listed in the last column stand for High Resolution, Large Box, and Low Resolution, respectively.

| Model | Particles (N) | Box size (L) | Mass resolution | Label |
|-------|---------------|-------------|-----------------|-------|
| ΛCDM/EDE | 1024^7 | 250 h⁻¹ Mpc | 1.2 · 10⁹ h⁻¹ M⊙ | HR |
| ΛCDM/EDE | 1024^3 | 1000 h⁻¹ Mpc | 7.5 · 10¹⁰ h⁻¹ M⊙ | LB |
| ΛCDM/EDE | 256^6 | 250 h⁻¹ Mpc | 7.5 · 10¹⁰ h⁻¹ M⊙ | LR |

2LPTic public code [27], at redshift z = 99. The corresponding input linear matter power spectra, for both the EDE and ΛCDM cases, were computed with AxiClass, the aforementioned modified version [40] of the publicly available code CLASS [54]. For all of the simulations, we kept the cosmological parameters fixed to their EDE best fit values from Ref. [40] (very close to ours), namely H₀ = 72.81, Ω_m = 0.2915, A_s = 2.191 · 10⁻⁹, n_s = 0.986 for both cosmological simulations; plus the additional parameters log_{10}(z_c) = 1.04106, f_EDE(z_c) = 0.132, Θ_c = 2.72, n = 2.6 for the EDE model. To bind together the matter power spectra extracted from simulations with different resolutions we adopt a splicing technique described in detail in Appendix B. Our results are summarized in Fig. B and we refer to Appendix B for a deeper technical discussion.

In the top panel of Fig. B we compare the matter power spectra extracted from our simulations, with the ones computed with HALOFIT/HMCode, at redshift z = 0. The blue curves refer to the ΛCDM scenario — dubbed hereafter as ΛCDM “equivalent” — while the red ones refer to the EDE best fit model. As a reference, we also report the best fit ΛCDM case from Planck 2018. The spliced power spectra are denoted by thick dotted lines. Symbols stand for the output power spectra of the “non-spliced” LB and HR simulations. The solid/dotted lines are the non-linear power spectra from HALOFIT/HMCode, while the dashed lines are the corresponding linear power spectra used to set the initial conditions for the simulations. In the right panel, we adopt the same linear-stable-color and code-color to show the ratio between the non-linear power spectra produced by HALOFIT/HMCode with respect to the ones extracted from our simulations. The thick horizontal lines highlight ±5% deviations. In Appendix B we extend the analysis to three additional redshift bins — z = 0.5, 1.5, 2 — obtaining analogous results. We can thus conclude that the differences between HALOFIT/HMCode predictions with respect to the outputs of our N-Body simulations are below 5% level, for scales 10⁻² ≤ k ≤ 10 h/Mpc, at redshifts 0 ≤ z ≤ 2, for both ΛCDM and EDE models. Whereas this is a very well established result for the ΛCDM paradigm, this is not often the case for alternative cosmological scenarios, such as the one considered in this work. Let us note that the exponential increase in the difference between the outputs by simulations and HALOFIT at k ∼ 10 h/Mpc is absent when one compares the outputs from simulations with the predictions by HMCode. As expected, the latter method is more accurate than HALOFIT in modelling the very small-scale and very low-z regime. In this work, we therefore make use of HMCode to model the non-linear evolution of perturbations, following the approach adopted by the KiDS collaboration.

We also present our results in terms of ratios between the matter power spectra in the EDE and the ΛCDM models in Fig. B bottom panel. The comparison between the EDE best fit and the ΛCDM equivalent confirms that
FIG. 3. In the top left panel we show the matter power spectra extracted from our simulations, and the ones computed with HALOFIT/HMcode. The blue curves refer to the ΛCDM scenario, while the red ones refer to the EDE best fit model. We also report the best fit ΛCDM case from Planck 2018. The spliced power spectra are reported as thick dot-dashed lines. Symbols stand for the outputs of the LB and HR simulations. The solid/dotted lines are the non-linear power spectra from HALOFIT/HMCODE, whereas the dashed lines are the corresponding linear power spectra used to produce the initial conditions for the simulations. The cyan shaded band roughly corresponds to the scales probed by DES-Y1. In the top right panel, we show the ratio between the non-linear matter power spectra from our simulations and the ones computed with HALOFIT/HMCODE, for both the ΛCDM “equivalent” and the EDE best fit models, adopting the same linestyle-code and color-code. In the bottom right panel we compare departures from the ΛCDM model in terms of ratios of non-linear matter power spectra, adopting the same linestyle-code and color-code.

it is not the intrinsic presence of EDE that enhances the matter power spectrum on small scales, exacerbating the $S_8$ tension. Rather, the EDE reduces the growth of perturbations at fixed $\omega_{\text{cdm}}$. As already pointed out, such power enhancement is instead due to variations in the standard ΛCDM parameters – mostly an increase in $\omega_{\text{cdm}}$ – induced to balance the EDE impact on the CMB. This suggests that the limitations of the EDE are not intrinsic to its presence, but rather to an accidental degeneracy that could be alleviated in an extended model. This will be the starting point of Section V B, where we will outline possible paths towards restoring the agreement with WL measurements in (extended) EDE cosmologies.

In view of these considerations, it is straightforward to conclude that LSS surveys constitute an ideal counterpart to CMB data, given the complementarity between the regimes that they probe. However, in section IV B we will show that currently available weak lensing data are not sensitive enough to unequivocally capture the signature of EDE. This will clearly not be the case when more precise data (e.g. from Euclid [98]) will become available. As also our results suggest, it will soon be necessary to go beyond the HALOFIT/HMCODE prescription for modelling the non-linear power spectrum.
We stress that they can see that the degradation in the combined results should be roughly the sum of \(\chi^2_{\text{min}}\) for the individual fits. While one might naively expect that the \(\chi^2_{\text{min}}\) of the global fit should be roughly the sum of the \(\chi^2_{\text{min}}\) of individual fits, we find that the global \(\chi^2_{\text{min}}\) is degraded by \(\sim +6.5\). Similarly, the inclusion of a tight Gaussian likelihood on \(S_8\) as measured by KiDS-VIKING+DES leads to a degradation in the combined \(\chi^2\) by \(\sim +15.5\), while one expects \(\sim +1\) for a good fit. In Fig. 4 we show the reconstructed 2D posteriors of \(\{f_{\text{EDE}}(z), H_0, S_8, \Omega_m\}\) in the 1-parameter EDE realization for various data combinations. We start by performing an analysis of EDE against KiDS-VIKING data only; as expected we find that the KiDS-VIKING data have no constraining power on the fraction of E. However, the reconstructed \(S_8 = 0.738^{+0.041}_{-0.038}\) is \(\sim 2.4\sigma\) discrepant with that obtained from previous analyses, suggesting a potential discordance between the cosmologies. For comparison, the prediction for \(S_8\) in the ΛCDM model obtained from \(\text{PLANCK}\) data is \(2.3\sigma\) discrepant with that from KiDS-VIKING data [44]. Therefore, although the mean value has increased, the level of the \(S_8\) tension in the EDE cosmology is similar to that in ΛCDM because of larger error bars. Combining KiDS-VIKING to \(\text{PLANCK+BAO+PANTHEON+FS}\), a non-zero EDE contribution is still favored at \(\sim 1.5\sigma\), but the reconstructed mean fraction has moved downwards by \(\sim 0.7\sigma\). This was expected, given the positive correlation between \(f_{\text{EDE}}(z)\) and \(S_8\). In this cosmology, \(\text{PLANCK}\) data are still slightly better fitted (\(\Delta\chi^2_{\text{min}} \sim +6\)) than in ΛCDM, while the fit to KiDS-VIKING data is degraded by \(\sim +2\). Once a prior on \(H_0\) from SH0ES is added, we find again \(f_{\text{EDE}}(z) \sim 10 \pm 3\%\), at the cost of increasing the total \(\chi^2_{\text{min}}\) by \(\sim 5.5\). The increase in \(\chi^2\) is partly due to the inclusion of SH0ES (\(\chi^2 \sim 1.62\), a reasonably good fit), and also to a mild degradation in the fit to \(\text{PLANCK}\) (\(\sim +3\)) and BAO (\(\sim +1.6\)). The reason is that the inclusion of KiDS-VIKING data reduces the degeneracy between \(f_{\text{EDE}}(z)\) and the ΛCDM parameters, in particular the one with \(\omega_{\text{cdm}}\). Note that the goodness of \(\text{PLANCK}\) fit is not sensibly degraded as compared to ΛCDM, since the \(\chi^2\) stays better than that from ΛCDM fitted on \(\text{PLANCK}\) only. In fact, when compared to ΛCDM, the combined \(\chi^2\) is improved by \(\sim -13\) (for one extra parameter), indicating a significant preference for EDE despite the presence of KiDS-VIKING data. Looking at the individual \(\chi^2_{\text{min}}\), we find indeed that the quality of the fit to KiDS-VIKING data in the EDE cosmology that resolves the Hubble tension is barely changed (\(\Delta\chi^2 \sim +1.6\) for 195 data points [44]) compared to the ΛCDM fit to the same data set.

**Results for EDE against Planck+KiDS+DES:** We now trade KiDS-VIKING data for a split-normal likelihood on \(S_8\) as inferred from the joint KiDS-VIKING+DES data. We note that the tension between the value of this joint \(S_8\) measurement and that predicted by our fiducial EDE model (obtained from the global fit of \(\text{PLANCK+BAO+FS+PANTHEON+SH0ES}\)) is at the \(\sim 3.8\sigma\) level (slightly increased from \(3.2\sigma\) tension in ΛCDM). It would be interesting to quantify the level of tension between these data sets in the ΛCDM framework using more robust statistical tools than the ‘difference in the mean’ used here, as done for instance in Refs. [106] [107]. However, we note that authors from Ref. [106] found that the less precise KiDS-VIKING data available at that time were already in sig-

---

13 We stress that \(S_8\) is a model-dependent quantity, and it is particularly sensitive to the treatment of the neutrino mass. We therefore make use of the value that was derived following our convention, i.e. at fixed \(\sum m_\nu = 0.06\) eV.
significant statistical disagreement with the prediction from ΛCDM. We anticipate that this more robust approach would strengthen the case for a statistically significant discrepancy, even in ΛCDM, and therefore the need to apply caution when drawing conclusions from the combined analysis. We show the reconstructed 2D posteriors of \( \{ f_{EDE}(z_c), H_0, S_8, \Omega_m \} \) in the 1-parameter EDE model in Fig. 6. Without the SH0ES prior, \( f_{EDE}(z_c) \) is compatible with 0 at 1σ, and we find an upper limit on \( f_{EDE}(z_c) < 0.094 \) at 95% C.L. This constraint is significantly weaker than that derived in Refs [47], despite the fact that we have reduced the parameter space. We have simply adopted a different ‘prior’ choice on \( \Theta_i \) and \( \log_{10}(z_c) \) (i.e. here we fix them), demonstrating that the current constraints from WL – besides being derived from statistically inconsistent data set – are not robust. Looking at \( \chi^2_{\text{min}} \), we find that the resulting best fit cosmology degrades the fit to Planck by \( \sim +6 \) while providing a poor fit to the \( S_8 \) likelihood (\( \chi^2 = 8.3 \) for a single data point). Still, the best-fit

TABLE V. The mean (best-fit) ±1σ error of the cosmological parameters reconstructed from the combined analysis of the KIDS/Viking/DES data with other data discussed in the text, with and without a prior on $H_0$ from SH0ES. The ‘Base’ dataset refers to PLANCK+BAO/FS+PANTHEON. We also report the $\chi^2_{min}$ for each model and data set combination.

is marginally better than that of $\Lambda$CDM adjusted on the same sets of data ($\Delta \chi^2_{min} \sim -1.5$). Once we include the SH0ES prior, we find again $f_{EDE}(z_c)$ to be non-zero at more than 3σ, $f_{EDE}(z_c) \simeq 9 \pm 3\%$, with a global
\[ \Delta \chi^2_{\text{min}} \simeq -11.6. \] Looking at individual \( \chi^2_{\text{min}} \) values, we find that the fit to PlanckTTTEEE, Planck\( \phi \phi \), BAO and FS data is somewhat degraded compared to the best fit EDE cosmology obtained without \( S_8 \) prior, as a consequence of the breaking of the \( f_{\text{EDE}}(z_t) - \omega_{\text{cdm}} \) degeneracy. However, as expected, we note that the \( S_8 \) likelihood has a \( \chi^2 \simeq 9 \), which is not particularly worst that the one obtained in the \( \Lambda \)CDM case without SH0ES (\( \chi^2 \simeq 8.3 \)). This indicates that any constraint on the EDE derived from this combined analysis should be regarded with caution, as the cosmology reconstructed from the analysis does not provide a good fit to the \( S_8 \) data. This naturally impacts the reconstructed \( H_0 \), which is \( \sim 0.6\sigma \) lower than without the \( S_8 \) likelihood, although the fit to SH0ES is still reasonably good (\( \chi^2 \simeq 2.4 \)). We therefore conclude that current \( S_8 \) measurements do not exclude the EDE resolution to the Hubble tension; however, they do call for new physics beyond EDE – or unknown systematics – to explain the intriguingly low measured \( S_8 \) values.

V. A COMMON RESOLUTION TO THE \( H_0 \) AND \( S_8 \) TENSIONS IN THE EDE COSMOLOGY?

A. EDE and the \( S_8 \) tension in light of Planck unlensed CMB spectrum

It has been noted that there exists a number of ‘curiosities’ in Planck that can potentially shed light on cosmological tensions. In particular, there is a residual oscillatory feature in the Planck TT data at \( 1100 < \ell < 2000 \) compared to the best fit \( \Lambda \)CDM prediction \[4, 61\]. This feature can be captured by an extra source of smoothing of the acoustic peaks, as modelled by the \( A^{\phi \phi} \) parameter which is used to re-scale the amplitude of the lensing potential power spectrum \( C_{\ell}^{\phi \phi} \rightarrow A^{\phi \phi}_{\text{lens}} C_{\ell}^{\phi \phi} \) at every point in parameter space. However, the amplitude of the lensing potential power spectrum can also be estimated directly from the lensing-reconstruction and is compatible with the \( \Lambda \)CDM expectation, such that while this extra smoothing looks like lensing, it cannot be attributed to actual gravitational lensing.

A thorough investigation of the lensing-like tensions in the Planck legacy release was performed in Refs. \[61-63\]. It has been noted in particular that, once marginalizing over the lensing information, the ‘unlensed’ CMB temperature and polarization power spectra favor a cosmology with a lower \( A_s \) and \( \omega_{\text{cdm}} h^2 \). Indeed, these parameters are strongly correlated with the amplitude of the lensing power spectrum, such that the lensing-like anomaly pull up these parameters. Additionally, since the acoustic feature of the CMB tightly constrains the parameter combination \( \Omega_m h^2 \), a lower \( \Omega_{\text{cdm}} h^2 \) is compensated by a higher \( H_0 \). As a consequence, the unlensed \( \Lambda \)CDM cosmology shows no \( S_8 \) tension, and a milder (although still > 3.5\( \sigma \) significant) \( H_0 \) tension. It was also pointed out that this ‘unlensed’ cosmology is in good agreement with the \( \Lambda \)CDM cosmology reconstructed from the SPTPol data \[61, 63\].

It is therefore reasonable to ask what is the impact of such anomalies on extensions to \( \Lambda \)CDM like the EDE under study. To that end, we introduce two additional parameters \( A_{\text{lens}} \) and \( A^{\phi \phi}_{\text{lens}} \) whose goal is to marginalize over the lensing information in Planck\[7\]. The latter parameter re-scales the amplitude of the theory lensing potential power spectrum, while the former only re-scales the amplitude of the acoustic peak smoothing. In practice, the amplitude of the acoustic peak smoothing is then determined by the product \( A^{\text{TTTEEE}}_{\text{lens}} \equiv A_{\text{lens}} A^{\phi \phi}_{\text{lens}} \). We first perform MCMC analysis of the \( \Lambda \)CDM and EDE cosmologies against Planck data. In a second step, we perform a global analysis combining all the data considered in this work. As before, the joint KiDS-VIKING+DES results is modelled via a split-normal likelihood distribution on \( S_8 \). The results of these analysis are reported in Tab. \[VI\] and shown in Figs. \[7\] and \[8\].

Results for \( \Lambda \)CDM: We start by analyzing the \( \Lambda \)CDM cosmology in light of the ‘unlensed’ Planck spectrum. We confirm the results of Refs. \[4, 63\]: we find that the amount of lensing determined from the peak smoothing \( A^{\text{TTTEEE}}_{\text{lens}} \) is \( \sim 2.8\sigma \) higher than the expectation from the \( \Lambda \)CDM model deduced from the ‘unlensed’ CMB power spectrum. Moreover, the difference between the reconstructed \( A^{\phi \phi}_{\text{lens}} \simeq 1.07 \pm 0.04 \) and \( A^{\text{TTTEEE}}_{\text{lens}} \simeq 1.2 \pm 0.07 \) illustrates the fact that this extra smoothing component cannot be due to actual gravitational lensing. Still, this \( \Lambda \)CDM ‘unlensed’ cosmology is now in much better agreement with the \( S_8 \) measurements from KiDS and DES, as can be seen in Fig. \[7\]. This is due to the fact that the reconstructed \( A_s \) and \( \omega_{\text{cdm}} \) are lower than in the analysis including lensing information. We then perform a global analysis, including all data sets considered in this work. We find that the ‘unlensed’ \( \Lambda \)CDM cosmology can indeed accommodate a low \( S_8 \), however this is at the cost of worsening somewhat the fit to BAO+FS data (\( \Delta \chi^2 \simeq +3.5 \)), when compared to the ‘concordance’ \( \Lambda \)CDM model obtained from a fit to the full Planck data, BAO and FS (without \( S_8 \) priors). Additionally, we note that accommodating such a low \( S_8 \) requires a somewhat smaller \( \omega_{\text{cdm}} \) and \( A_s \) (by a little less than 1\( \sigma \)), which are compensated for by pulling up the \( A^{\phi \phi}_{\text{lens}} \) and \( A^{\text{TTTEEE}}_{\text{lens}} \) by a similar amount. The fit to SH0ES on the other hand is still very poor, \( \chi^2_{\text{min}} \simeq 10 \), suggesting that the global unlensed cosmology is still in strong tension with SH0ES.

Results for EDE: Turning now to the 1-parameter EDE model, we wish to check whether the EDE cosmology deduced from ‘unlensed’ Planck spectra only is

---

14 An alternative, more thorough, way is to use CMB lensing principal components as introduced in Ref. \[62, 63\]. As we will show shortly, our reconstructed ‘unlensed’ cosmologies are in good agreement. Our approach follows that introduced in Refs. \[105, 109\].
in better agreement with both $S_8$ and $H_0$ direct measurements\textsuperscript{15}. As one can see from Fig. 8, the lensing-marginalized CMB data does favor non-zero $f_{\text{EDE}}(z_e)$ at $\sim 2\sigma$ ($\Delta\chi^2_{\text{min}} \simeq -4$ with respect to ΛCDM) and predicts $H_0 \simeq 71.2 \pm 1.5$ and $S_8 \simeq 0.81 \pm 0.02$. Compared to the EDE cosmology reconstructed from the full Planck data, the ‘tension’ with $H_0$ and $S_8$ has therefore decreased by $\sim 1\sigma$ due to a shift in the mean of the reconstructed posterior in the unlensed cosmology. It is now in 1.4σ agreement with SH0ES but stays in mild ($\sim 2.7\sigma$) tension with the combined $S_8$ measurement. The $S_8$ prediction is however in very good agreement with the KiDS-VIKING and DES measurements when considered individually (an important note since the combined low $S_8$ value relies on a re-calibration of DES photometric redshift by the KiDS-VIKING team). Additionally, the $A^\phi_{\text{eff}}$ and $A^{\text{TTTEEE}}_{\text{lens}}$ parameters are unchanged with respect to that reconstructed in the ACDM cosmology, while the anomalous amount of lensing in Planck data is not an effect due to the presence of the EDE, these parameters do not correlate with a non-zero $f_{\text{EDE}}(z_e)$, i.e., they do not take values different from the ACDM ones to ‘hide’ the effect of the EDE.

Once all data sets are included in the analysis, a non-zero fraction of EDE is favored at $\sim 3.5\sigma$. Interestingly, most of the reconstructed parameters do not shift by more than $\sim 0.5\sigma$; rather, the uncertainty on the reconstructed parameters tighten significantly, as one would expect from making use of additional data. However, similarly to what happens in the ACDM cosmology, the inclusion of the tight-and-low $S_8$ value does force a slightly (~1σ) smaller $A_s$, that is compensated by slightly higher $A^{\phi}_{\text{eff}}$ and $A^{\text{TTTEEE}}_{\text{lens}}$ parameters. The fit to SH0ES is good ($\chi^2 \sim 1.9$) and stable when compared to that obtained including Planck lensing information. On the other hand, as expected, the fit to the joint KiDS-VIKING+DES $S_8$ is better than in the ‘lensed’ cosmology ($\Delta\chi^2 \sim -4.3$), but its value is still somewhat poor ($\chi^2 \sim 4$). We emphasize again that the fit to individual $S_8$ measurements, on the other hand, is excellent. If future $S_8$ measurements stay low while becoming more precise, they will be in tension even with the ‘lensed’ cosmology (whether ACDM or EDE), confirming the need for new physics beyond EDE (or an unknown systematic effect).

### TABLE VI

The mean (best-fit) ±1σ error of the cosmological parameters reconstructed from the lensing-marginalized Planck data only and in combination with BAO/FS+PANTHEON+KiDS-VIKING-DES. We also report the $\chi^2_{\text{min}}$ for each model and data set combination.

15 A similar study was performed in Ref. [63] for $N_{\text{eff}}$. There, it was found that polarization and BAO data exclude $N_{\text{eff}}$ as a resolution to the Hubble tension, even after marginalizing over the lensing anomaly in Planck.
FIG. 7. Reconstructed 1- and 2D-posteriors of a subset of parameters in the ΛCDM and 1-parameter EDE cosmology for various data sets (see legend), once marginalizing over $A_{\text{lens}}$ and $A_{\phi\phi\text{lens}}$.

which should make the extension less ‘ad-hoc’.

As was discussed extensively in this paper (see sec. IV A), it is interesting to note that at fixed $\omega_{\text{cdm}}$, the EDE leads to a decrease in power at small scales that goes in the right direction to resolve the $S_8$ tension. However, the problem of EDE cosmologies is that they exploit a degeneracy with $\omega_{\text{cdm}}$ to counteract the effect of the EDE on the gravitational potential wells as seen in the CMB. Taken at face value, this poses both a concrete experimental problem—it is at odds with $S_8$ measurements—and a theoretical ‘tuning’ issue—why should these two apparently unrelated sectors ‘conspire’ to hide the EDE in CMB data? This logic should also be applied when considering sensible extension to a model. One of the less ‘theoretically costly’ possible explanation of the $S_8$ values is to invoke the fact that neutrinos are massive, and lead to a power suppression at small scales which decreases the value of $\sigma_8$. Unfortunately it seems as though in practice the required sum of neutrino masses $\sum m_\nu \sim 0.3\text{eV}$ is excluded by PLANCK data. Moreover, neither DES nor
KiDS-VIKING seems to have a preference for non-zero $\sum m_\nu$. However, it is interesting to note that constraints on the sum of neutrino masses can be strongly relaxed in extended cosmologies (e.g. [4, 110, 111]). In fact, in models attempting at resolving the Hubble tension with strongly interacting neutrinos [37, 112–114], it has been noted that Planck temperature 2015 data are in good agreement with $H_0 \approx 72$ km/s/Mpc and neutrino masses $\sum m_\nu \approx 0.4$eV, but polarization data seems to restrict this resolution. In the EDE context, we have already mentioned that in Ref. [41], it was suggested that the non-relativistic transition of neutrinos could trigger a phase-transition in the EDE. It would therefore be very interesting in the future to study further the possible connection between EDE and neutrino masses. Along this idea, we have performed a MCMC run in the 1-parameter EDE model against all data-sets with the sum of neutrino masses let free to vary. We find that marginalizing over the neutrino mass does not affect the result presented here. The $S_8$ value shifts downward only by $\sim 0.3\sigma$. 

**FIG. 8.** Reconstructed 1- and 2D-posterior of a subset of parameters in the 1-parameter EDE cosmology for various data sets (see legend), once marginalizing over $A_{lens}$ and $A_{\phi\phi}$. 

Please note that the diagram is not accurately rendered here and should be referred to in the document for full visibility.
This is because, while $\sigma_8$ does get suppressed, a non-zero $\sum m_8$ increases $\Omega_m$, resulting only in a mild decrease in $S_8$.

Another promising category of solutions to the $S_8$ tension invokes interaction between DM and an additional dark radiation (DR) component. These models are particularly interesting because, by themselves and similarly to EDE, an additional radiation component leads to an increase in $S_8$. This is due to the fact that increasing the radiation density requires a simultaneous increase in the matter density to avoid a shift in matter radiation equality. As a consequence, $\Omega_m$ is higher in this model, leading to a higher $S_8$. However, the introduction of an interaction between DM and DR leads to a power-suppression at small-scales and therefore to a smaller $\sigma_8$, resulting in a net decrease in $S_8$. Alternatively, there exists a number of model leading to interactions between DM and DE at late-times. Introducing an interaction between DM and EDE is a straight-forward extension of the model whose dynamics is dictated by an interaction with dark gauge bosons was recently proposed in Ref. [73]. Interestingly, the parameter space is not enlarged in this model- rather, the critical redshift $z_c$ at which the field starts to move is dictated by the ratio of the interaction rate over the Hubble rate. It will be interesting to generalize the model studied there (i.e., consider different type of interactions) and include linear cosmological perturbations, to check whether the presence of the additional interaction could open a new degeneracy direction (alternative to the $f_{\text{ede}} - \omega_{\text{cdm}}$ one), which would prevent an increase in $S_8$. Speculating further, if the presence of EDE is confirmed in the future, it is likely that it is connected to the existence of DE today, and perhaps even inflation. As a matter of fact, EDE models were introduced over a decade ago to alleviate the cosmological coincidence problem – the fact that the dark energy density and the matter density are very close from one another just today \cite{77, 87}. Therefore, it is quite natural to ask whether the current epoch of accelerated expansion (and inflation) could be due to a dynamical scalar-field similar to the EDE, if more eras of such type can have occurred at other moments in the history of the Universe, and what would be the impact on the cosmic structure growth. In fact, in Ref. \cite{94}, it was shown that a time-evolving equation of state for DE is favored over $\Lambda$CDM from a combination of PLANCK, KiDS-450 and SH0ES data. However, these simple solutions are severely constrained by BAO and PANThEON data. In future work, it will be interesting to check whether these constraints can be affected by the presence of EDE, and whether a more complete picture for early and late dark energy can help restoring cosmological concordance.

VI. CONCLUSIONS

In this paper, we have reassessed the viability of the EDE against a host of high- and low-redshift measurements, by combining LSS observations from recent weak lensing surveys KiDS-VIKING and DES with PLANCK 2018 CMB data, BOSS-DR12 BAO and growth function measurements, and the PANThEON compilation of luminosity distance to SNIa. Our results can be summarized as follows:

- Within a phenomenological 3-parameters EDE model, we confirm that PLANCK+BAO+FS+PANThEON+SH0ES favor $f_{\text{EDE}}(z_c) \simeq 0.1 \pm 0.03$, $z_c \simeq 4000^{+1400}_{-500}$ and $\Theta_i = 2.6^{+0.4}_{-0.3}$, with a $\Delta \chi^2 = -18.7$ compared to $\Lambda$CDM fitted on the same data set (i.e. a $\sim 3.6\sigma$ preference over $\Lambda$CDM). The inclusion of the latest PLANCK data (and in particular the more precise polarization measurements) does not spoil the success of the EDE resolution to the Hubble tension. When compared to the `concordance' $\Lambda$CDM model (i.e. obtained from analysis without SH0ES data), the EDE cosmology fits PLANCK+BAO+FS+PANThEON equally well, but can additionally accommodate the high local $H_0$ values.

- Following the approach of Ref. \cite{76}, we have then shown that reducing the parameter space to a 1-parameter EDE model by fixing $\log_{10}(z_c)$ and $\Theta_i$ to their best fit values as obtained from a PLANCK data only analysis – which strikingly coincide with those from the combined analysis with SH0ES – leads to a $\sim 2\sigma$ preference for non-zero EDE, namely $f_{\text{EDE}}(z_c) \simeq 0.08 \pm 0.04$ from PLANCK CMB data alone. In this cosmology, the inferred $H_0 \simeq 70 \pm 1.5$ km/s/Mpc is in agreement at better than $2\sigma$ with its local measurement from SH0ES. The addition of BAO, FS and PANThEON data has no significant impact on the result. Including a prior on $H_0$ from SH0ES pulls up the reconstructed fraction to the $\sim 10\%$ level, with $H_0 \simeq 71.7 \pm 1$, while the fit to PLANCK is slightly better than in the concordance $\Lambda$CDM cosmology ($\Delta \chi^2 \sim -5$).

- To justify the inclusion of LSS data in our analyses, we have confronted the EDE non-linear matter power spectrum as predicted by standard semi-analytical algorithms against a dedicated set of $N$-body simulations. We have then tested the 1-parameter EDE cosmology against WL data, finding that it does not significantly worsen the fit to

\footnote{We assume Gaussian posteriors with 3 additional parameters for simplicity.}
the $S_8$ measurements as compared to ΛCDM, and that current WL observations do not exclude the EDE resolution to the Hubble tension.

• We also caution against the interpretation of constraints obtained from combining Planck with KiDS-VIKING+DES. As we showed, the ‘compromise’ cosmology that is obtained is a poor fit to KiDS-VIKING+DES and degrades the fit to Planck data, even in ΛCDM. This illustrates that these data sets are statistically inconsistent in a ΛCDM framework, and it is easily conceivable that the resolution of this tension lies elsewhere (whether systematic effect or new physics).

• In light of the CMB lensing anomaly, we have shown that the lensing-marginalized CMB data favor non-zero EDE at $\sim 2\sigma$, predicts $H_0$ in $1.4\sigma$ agreement with SH0ES and $S_8$ in $1.5\sigma$ and $0.8\sigma$ agreement with KiDS-VIKING and DES, respectively. There still exists however a $\sim 2.5\sigma$ tension with the joint results from KiDS-VIKING and DES. Moreover, the presence of EDE does not affect the amount of anomalous lensing. This suggests that the anomalous lensing is not due to the presence of EDE, but also that the success of EDE is not due to opening up a new degeneracy direction with some exotic lensing parameters.

• With an eye on Occam’s razor, we finally discussed extensions of the EDE cosmology that could allow to accommodate the low $S_8$ values. In particular, we argue that EDE models which are coupled to neutrinos; include interaction with an extra dark radiation bath or dark matter; or are connected to dynamical dark energy at late time (and perhaps inflation), are all worth exploring in future work as promising ways to fully restore cosmological concordance.

In another study [51], we confronted BOSS data to the 1-param EDE cosmology within the EFT of LSS framework [48, 49], finding that the constraints on $f_{\text{EDE}}$ largely weaken and that LSS current data do not exclude the EDE resolution to the Hubble tension (in good agreement with Ref. [119] for a slightly different model). An important follow-up to these studies will be to see whether the new ACT data [10], compatible with Planck (although see Ref. [119]), support – or restrict – the EDE resolution to the Hubble tension (see e.g. Ref. [120] for the recent study of a similar model). Looking forward, future CMB experiment (such as Simons Observatory [121] and CMB-S4 [122]) and LSS data (from Euclid [98], LSST [123], JWST and DESI [124]) will be crucial in testing prediction of the EDE cosmology (and its potential extensions) [70, 99] and firmly confirm – or exclude – the presence of EDE.

Appendix A: $\chi^2$ tables

We report all $\chi^2_{\text{min}}$’s obtained with the MINUIT algorithm [93] through the MINUIT python package for the various model and data-set combination considered in this work.

Appendix B: a closer look to $N$-Body simulations

The main systematical uncertainties in numerical simulations come from their limited box size and resolution, as it has been thoroughly discussed in past literature (see, e.g., [125, 128]). In order to minimize the missing large-scale modes, potentially affecting small-box simulations, and to overcome the impossibility of capturing the very non-linear scales in our large-box simulations, we adopted a splicing technique to bind together the matter power spectra extracted from simulations with different resolutions, for each redshift and model, as in Refs. [129, 130].

For both the ΛCDM model and the EDE best fit model from [70], we indeed performed: i) one Large Box (LB hereafter) simulation with $N = 1024^3$ DM particles and box size $L = 250 \, h^{-1}\text{Mpc}$; ii) one High Resolution (HR hereafter) simulation with $N = 1024^3$ DM particles and box size $L = 1000 \, h^{-1}\text{Mpc}$; iii) one Low Resolution (LR hereafter) simulation with the same box size of the HR one and the same resolution of the LB, namely $N = 256^3$ and $L = 250 \, h^{-1}\text{Mpc}$, to be used as a transition simulation. The spliced non-linear matter power spectrum

### TABLE X. Best-fit $\chi^2$ per experiment (and total) in $\Lambda$CDM and the 1-parameter EDE model when marginalizing over the lensing information in Planck.

$P(k)$ is given by [139]

$$P(k) = \begin{cases} P_{LB}(k) & \text{if } k \leq k_{\text{MIN}}^{250} \\ P_{HR}(k) & \text{if } k_{\text{MIN}}^{250} < k < \frac{1}{2} k_{\text{NYQ}}^{L}\,k_{\text{MIN}}^{L} \\ P_{HR}(0.5 \cdot k_{\text{NYQ}}^{L}) & \text{if } k \geq 0.5 \cdot k_{\text{NYQ}}^{L} \end{cases}$$

where $k_{\text{MIN}}^{250}$ is the minimum $k$-mode in our small-box simulations (HR and LR), while $k_{\text{NYQ}}^{L}$ is the Nyquist wave-number of the LB one.

Besides the aforementioned systematical uncertainties, numerical simulations are also affected by two primary sources of statistical errors: the cosmic variance, affecting
FIG. 9. Here we compare the matter power spectra extracted from our simulations, with the ones computed with halofit/HMCODE, in three different redshift bins from $z = 1.5$ to $z = 0.5$. The blue curves refer to the ΛCDM scenario, whereas the red ones refer to the EDE best fit model. As a reference, we also report the best fit ΛCDM case from Planck 2018. The spliced power spectra are denoted by thick dot-dashed lines. Symbols stand for the output power spectra of the “non-spliced” LB and HR simulations. The solid/dotted lines are the non-linear power spectra from halofit/HMCODE, while the dashed lines are the corresponding linear power spectra used to set the initial conditions for the simulations. The cyan shaded band approximately corresponds to the scales probed by DES-Y1.

Concerning the shot noise term, its contribution to the power spectrum is simply given by $P_{SN} = (L/N)^3$. It is straightforward to see that it is largely subdominant at the scales and redshifts considered in this work, from Fig. 9 where we compare the matter power spectra extracted from our simulations with the ones computed with HALOFIT/HMCODE, in three different redshift bins from $z = 1.5$ to $z = 0.5$ — given that we have already discussed the $z = 0$ case in Section IV A. In Fig. 10 we plot the ratio between the power spectrum predicted by HALOFIT or HMCODE and that extracted from the numerical simulation in order to explicitly demonstrate that the differences are below 5% level, for scales $10^{-2} \lesssim k \lesssim 10 h/\text{Mpc}$, at redshifts $0.5 \leq z \leq 2$, for both ΛCDM and EDE models. This extends the $z = 0$ result presented in the main text to cover the full redshift range from KiDS-VIKING.

It is also informative to compare the prediction from algorithm with N-body at larger scales than that depicted in Figs. 9 and 10. Indeed, these are affected by higher statistical noise, due to cosmic variance, as one might already guess from the lower–$k$ part of both figures. To beat down cosmic variance, one should run several statistical realizations of the same simulation, by producing initial conditions starting from different random seeds. To circumvent this issue and save computational time, we adopted the simple solution to run the two sets of simula-
FIG. 10. Here we show the ratio between the non-linear matter power spectra from our simulations and the ones computed with halofit/HMcode, for both the ΛCDM equivalent and the EDE best-fit models. We have adopted the same linestyle-code and color-code of Figure 9.

sions (EDE and ΛCDM) with identical random seeds for the realization of their initial conditions, and to present our results in terms of ratios in the matter power spectra between the EDE and the ΛCDM models, in Figs. 11 and 12. Any scatter related to the cosmic variance is now removed, allowing us to go down one order of magnitude in terms of wave-numbers $k$’s. We show in both figures by vertical dashed lines the scales corresponding to $k_{250\,\text{MIN}}$ and $k_{\text{LB}\,\text{Nyq}}/2$. One can clearly see again that the EDE by itself lead to a decrease in power. However, the increase in $\omega_{\text{cdm}}$, leads the EDE best-fit model to predict $\mathcal{O}(20\%)$ increase in power, when compared to the best-fit ΛCDM model. Note how the differences become even more manifest at higher redshift. This illustrates that high-$z$ LSS measurements have the potential to put EDE under crucial tests.

Another way of presenting our results is in terms of the accuracy at which halofit/HMcode can predict deviations in the non-linear power spectrum of EDE models with respect to the ΛCDM ‘equivalent’ case (as opposed to predicting the absolute power spectrum). This is what we show in Fig. 12 where we now compare the ratio between the EDE and ΛCDM power spectra from halofit/HMcode against the same ratio extracted from simulations. The thick horizontal lines highlight ±5% deviations. In light of all of this, we conclude that, in the EDE framework, halofit/HMcode predictions on ΛCDM departures are reliable at ≤5% level with respect to the outputs of N-Body simulations, for scales $10^{-2} \lesssim k \lesssim 10\ h/\text{Mpc}$, at redshifts $0 \leq z \leq 2$.
