ABSTRACT

Following the discovery of SAGE0536AGN (z ~ 0.14), with the strongest 10-μm silicate emission ever observed for an Active Galactic Nucleus (AGN), we discovered SAGE0534AGN (z ~ 1.01), a similar AGN but with less extreme silicate emission. Both were originally mistaken as evolved stars in the Magellanic Clouds. Lack of far-infrared emission, and therefore star-formation, implies we are seeing the central engine of the AGN without contribution from the host galaxy. They could be a key link in galaxy evolution. We used a dimensionality reduction algorithm, t-SNE (t-distributed Stochastic Neighbourhood Embedding) with multi-wavelength data from Gaia EDR3, VISTA survey of the Magellanic Clouds, AllWISE and the Australian SKA Pathfinder to find these two unusual AGN are grouped with 16 other objects separated from the rest, suggesting a rare class. Our spectroscopy at SAAO/SALT and literature data confirm at least 14 of these objects are extragalactic (0.13 < z < 1.23), all hosting AGN. Using spectral energy distribution fitter CIGALE we find that the majority of dust emission (~70%) in these sources is due to the AGN. Host galaxies appear to be either in or transitioning into the green valley. There is a trend of a thinning torus, increasing X-ray luminosity and decreasing Eddington ratio as the AGN transition through the green valley, implying that as the accretion supply depletes, the torus depletes and the column density reduces. Also, the near-infrared variability amplitude of these sources correlates with attenuation by the torus, implying the torus plays a role in the variability.

Key words: quasars: emission lines – galaxies: evolution – Magellanic Clouds

1 INTRODUCTION

Active Galactic Nuclei (AGN) preside in the centre of some galaxies, resulting from the accretion of gas by a supermassive black hole at the galaxy’s centre. The accretion of gas leads to the formation of a disk, from which the central supermassive black hole can draw in material and accrete, releasing energy in the form of radiation. This process is known as the accretion disk model, and it is fundamental to understanding the formation and evolution of galaxies. AGN play a crucial role in galaxy evolution, as they can significantly influence their host galaxies through feedback processes, such as the ejection of material and energy into the surrounding region. The discovery of SAGE0536AGN and SAGE0534AGN, with their unique properties and positions in the t-SNE plot, suggests the existence of a rare class of AGN that are not associated with the host galaxy but are instead seen as isolated central engines. The study of these objects provides insights into the central engines of AGN and their role in galaxy evolution.

hole. The mass of supermassive black holes is known to correlate with the mass of the galaxy bulge, implying the formation and evolution of bulges and supermassive black holes are intertwined (Magorrian et al. 1998; Ferrarese & Merritt 2000; Gebhardt et al. 2000; Tremaine et al. 2002). It is thought that AGN play a significant role in galaxy evolution by creating large outflows that quench (Kormendy & Ho 2013) and/or trigger bursts of star formation (Xue et al. 2010; Mullaney et al. 2011; Rosario et al. 2015; Cowley et al. 2016), making them an ideal laboratory for studying the evolution and formation of galaxies.

AGN emit across the entire electromagnetic spectrum. The diversity of observed AGN can be explained by a small number of physical parameters, such as the mass of the central supermassive black hole (SMBH), the rate of gas accretion onto the black hole, the orientation of the accretion disk with respect to our line-of-sight, the degree of obscuration of the nucleus by dust, and the presence or absence of jets. This is called the unified model of AGN (Antonucci 1993; Urry & Padovani 1995). This model is however an oversimplification of observed variety of AGN evolving through cosmic time (see Cowley et al. 2016, 2018). Finding the more unusual of these diverse objects could be the key to unlocking the evolution of AGN, such as an AGN without interstellar gas to feed it or AGN hosted by bulgeless galaxies (e.g. Simmons et al. 2017), implying no history of major mergers.

Emission from hot dust is associated with the torus of gas and dust surrounding the central engine of the AGN and most often observed in the mid-infrared (mid-IR) (Antonucci 1982, 1984; Sanders et al. 1988). The distribution (smooth, clumpy or polar) and kinematics (static, inflowing or outflowing) of this hot dust are however still uncertain. For instance, at parsec scales in the polar regions there exist grains, thought to be irradiated by the AGN almost directly (Raban et al. 2009; Hönig et al. 2012, 2013; Tristram et al. 2014; Asmus et al. 2016; López-Gonzaga et al. 2016; Leffey et al. 2018; Hönig 2019), which may be associated with an AGN-driven outflow (Schartmann et al. 2014). The properties of these grains observed in the torus and polar regions appear to be different from those observed in the interstellar medium (ISM), with a dearth of smaller grains such as small graphite grains and/or polycyclic aromatic hydrocarbon (PAH) nanoparticles, indicated by the absence of a 2175 Å bump (Czerny et al. 2004; Gaskell et al. 2004; Gaskell & Benker 2007), whilst retaining larger grains such as silicate.

Silicate features in emission are expected for AGN seen face-on (type 1 AGN), where dust in the surface of the inner torus will be heated by radiation from the central engine to sufficient temperatures to allow for direct detection of the 10 \( \mu m \) and 18 \( \mu m \) silicate bands emitted from this hot dust. The Spitzer space telescope has been used to detect this emission in type 1 AGN (Hao et al. 2005; Siebenmorgen et al. 2005; Sturm et al. 2005; Weedman et al. 2005; Shi et al. 2006; Hatziminaoglou et al. 2015) as well as in type 2 AGN (Hao et al. 2007), where it would be expected to be detected in absorption. Silicate emission detected in type 2 AGN breaks the relation between orientation and AGN characteristics; this is explained by clumpiness in the torus seen in the radiative transfer models of Henkova et al. (2008) and Nikutta et al. (2009).

The originator of the strongest 10 \( \mu m \) silicate emission of any known AGN, is the hot dust near the SMBH of SAGE1C J053544.78–722658.5 (hereafter referred to as ‘SAGE0536AGN’) that was discovered serendipitously behind the LMC by Hony et al. (2011) in the Spitzer Space Telescope Survey of the Agents of Galaxy Evolution Spectroscopic follow-up of IR sources seen towards the LMC (SAGE-Spec: Kemper et al. 2010; Woods et al. 2011). It lies behind the Large Magellanic Cloud (LMC) and was found to be a type 1 AGN with a negligible amount of far-IR emission meaning a lack of star formation, confirmed by spectra obtained with the Southern African Large Telescope (SALT) (van Loon & Sansom 2015). Finding more of these could provide valuable insight into this stage of galaxy/AGN evolution.

Our new spectroscopic observations using the South African Astronomical Observatory (SAAO) 1.9m telescope, reveals SSTIS-AGE1C J053444.17–673750.1 is one such source that shows similarities to SAGE0536AGN. This source has also been referred to as 4XMM J053444.1–673751, 2MASS J05344418–6737501, SHP LMC 256 or [KWV2015] J053444.17–673750.1 (identifier for post-AGB star candidate), in this paper it shall be referred to as SAGE0534AGN. Both of these sources have been confused as evolved stars, have silicate emission and a lack of star formation. Can more be found? Are they an unusual type, or a short and therefore rarely seen stage of galaxy evolution?

As these sources mimic evolved stars in the Magellanic Clouds, we therefore needed to adopt a more systematic approach in finding more of them. Unsupervised machine learning has been used to great effect to cluster objects together and reveal patterns in large datasets (e.g., Lochner et al. 2016; Anders et al. 2018; Reis et al. 2018; Zhang et al. 2020). This can be used to find objects with similar properties to those already discovered, such as SAGE0536AGN and SAGE0534AGN.

AGN are most readily identified within combinations of multi-wavelength photometric survey data. The Magellanic Clouds span ~100 sq. degrees on the sky that have been studied, in parts or as a whole, in the UV (e.g. Thilker et al. 2014), optical (e.g. Gaia, SMASH; Gaia Collaboration et al. 2021; Nidever et al. 2017), IR (e.g. SAGE, AllWISE; Lacy et al. 2004; Cutri et al. 2021), radio (e.g. MOST, ATCA; Mauch et al. 2003; Murphy et al. 2010) and X-ray (XMM-Newton; Sturm et al. 2013), which makes them an ideal location to search for AGN behind them. The combination of all these data has great potential for discovery of the more unusual and extreme cases of AGN, such as SAGE0536AGN. The new and deeper surveys towards the Magellanic Clouds, such as the near-IR VISTA Magellanic Clouds (VMC; Cioni et al. 2011) and radio Evolutionary Map of the Universe all-sky (EMU; Joseph et al. 2019a; Pennock et al. 2021) surveys greatly enhance such attempts.

The paper is laid out as follows: Section 2 describes the data used and machine learning tool used to create the sample. In Section 3 we describe the light curves (Section 3.1) and spectra, calculation of black hole masses (Section 3.2), spectral energy distribution (SED) fitting with CIGALE (Section 3.3), X-ray observations (Section 3.4) and modelling of those sources where we can see their host galaxies with GALFIT (Section 3.5). In Section 4 we discuss the selection techniques of AGN (Section 4.1) and where this sample and sources mistaken for AGN fall within them. This is followed by a discussion of the sample galaxies’ identity as either star-forming, quiescent or green valley galaxy and how their properties change as they transition from star-forming to green valley (Section 4.2). The radio properties and how they link to the evolutionary stage of the sample are then discussed (Section 4.3) followed by a discussion of the AGN dust and its effect on observed properties such as variability and the 10 \( \mu m \) silicate emission (Section 4.4).
2 THE DATA

2.1 Photometry

2.1.1 VISTA Magellanic Clouds Survey

The VISTA Survey of the Magellanic Clouds (VMC; Cioni et al. 2011) is a near-IR deep, multi-epoch and wide-field study of the Magellanic Clouds. It has a spatial resolution of < 1” in the $YJK_s$ filters, reaching a sensitivity of about 21 mag (Vega). Its depth and coverage can be compared to the VISTA Deep Extragalactic Observations (VIDEO; Jarvis et al. 2013) survey, which was specifically designed to study galaxy and cluster/structure evolution. The VMC data provide an opportunity to double the effort of the VIDEO survey and cover more volume and cosmic variance, and has already proven successful in discovering more AGN (e.g. Ivanov et al. 2016). This however comes with the caveat of increased stellar confusion with the presence of the LMC and SMC.

2.1.2 Radio EMU–ASKAP survey

The Australian Square Kilometre Array Pathfinder (ASKAP) observed the LMC (Pennock et al. 2021) at 888 MHz (54,612 sources) and the SMC at 960 MHz and 1320 MHz (7,736 sources; Joseph et al. 2019) with a bandwidth of 288 MHz and beam size of 13′′9 × 12′′1, and the SMC at 960 MHz and 1320 MHz (7,736 sources; Joseph et al. 2019a) with a bandwidth of 192 MHz and beam sizes of 30′′ × 30′′ and 16′′3 × 15′′1, respectively. The majority of these sources were found to be extragalactic.

2.1.3 Other survey data

Other data used in this work include optical Gaia EDR3 survey (Gaia Collaboration et al. 2021) photometry and astrometry; the optical Survey of the Magellanic Stellar History (SMASH; Nidever et al. 2017) photometry; mid-IR AllWISE (Cutri et al. 2021) and Spitzer SAGE (Lacy et al. 2004) photometry and XMM-Newton (Sturm et al. 2013) X-ray photometry.

2.2 Spectroscopy

2.2.1 SAAO 1.9m spectra

Eight new optical spectra of SAGE0534AGN and Source 1, 2, 3, 4, 6, 11 and 14 (see Table 1 for sample list) were obtained at the South African Astronomical Observatory (SAAO) 1.9m telescope with SpUpNIC (Spectrograph Upgrade: Newly Improved Cassegrain; Crause et al. 2019). Grating 7 (grating angle of 16°) and the order blocking ‘BG38’ filter were used, delivering a resolving power $R = \frac{1}{\Delta \lambda} \approx 500$ over a wavelength range of 3800 Å – 9000 Å. The CuAr lamp was used for wavelength calibration. Three 600s exposures were obtained for each source. The standard stars (EG 21, Feige 110 or LTT 1020; Hamuy et al. 1994) were observed on the same night under the same conditions for 30s. The data were processed using the standard IRAF1 tools (Tody 1986, 1993).

1 IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

2.2.2 SALT spectra

Supplementary optical spectroscopic observations were made of three sources (SAGE0534AGN and Source 13 and 16, see Table 1 for sample list) using SALT (Buckley et al. 2006) under programmes 2021-1-SCI-018 (PI: Jacquy van Loon), 2021-1-SCI-029 (PI: Jacquy van Loon), 2021-1-SCI-032 (PI: Jacquy van Loon) and 2021-2-SCI-017 (PI: Joy Anih). We used the Robert Stobie Spectrograph (RSS; Burgh et al. 2003; Koulbizky et al. 2003), a combination of three CCD detectors with total 3172 × 2052 pixels and spatial resolution of 0′′1267 per pixel. We used the long-slit with width 1′′5, grating PG0300 and an Argon arc lamp. These data were also processed using the standard IRAF tools (Tody 1986, 1993).

Prior to this study SAGE0536AGN had been observed with SALT by van Loon & Sansom (2015). Further observations of SAGE0536AGN were obtained with SALT RSS in 2017 (programme 2017-1-SCI-001) but were unfortunately affected by focus issues. These spectra covered ~ 534 to 623 nm, with PG2300 grating, including Hb, Mg b and Fe5335 spectral features. Two of the five exposures (observed on 20/10/2017) were of sufficiently good quality and high spectral resolution to attempt kinematic measurements. Using Python PPXF2 and INDO-US star spectral templates (Valdes et al. 2004) the measured velocity dispersion was $\sigma \approx 202 \pm 15$ km s$^{-1}$, with overall errors from PXPXF uncertainty and spectral resolution uncertainty added in quadrature. This measurement was within the central ~ 1′′ along the major axis of SAGE0536AGN and is larger than previously found, $\sigma \approx 123 \pm 15$ km s$^{-1}$, in van Loon & Sansom (2015). This may be because of the focus problems with the 2017 data but could also result from measurement in a better spectral range, less affected by a particular (NaD) spectral feature and along the major axis. IFU data would be needed to more accurately determine the kinematics across SAGE0536AGN.

2.2.3 Other optical spectra

Prior to this study, three sources (Source 7, 9 and 10, see Table 1 for sample list) had been observed as part of the Magellanic Quasars Survey (MQS, Kozlowski et al. 2013) and one source (Source 12) as part of a search for variability-selected quasars in the Magellanic Field (Geha et al. 2003).

Another (Source 15) had been observed with European Southern Observatory’s 3.6m telescope with EFOOSC as part of a survey to find polarized quasars (see Kishimoto et al. 2008, Kishimoto et al. in prep.). For all frames, the CCD was read out with 2 × 2 binning, giving a spatial sampling of 0′′316 per pixel. The grism Gr#1 was used at a dispersion of 13 Å per pixel (after the binning). The target was observed with 1′′5 slit width, giving a spectral resolution of ~ 60 Å. The data were reduced in a standard manner. Averaged bias frame was subtracted, and each frame was flat-fielded. The wavelengths were calibrated using arc frames, and the spectra were extracted with 2′′8 window and flux-calibrated.

2.3 Target sample

2.3.1 SAGE0536AGN

SAGE1C J053634.78–722658.5 is a peculiar and rare AGN at $z = 0.14$ (van Loon & Sansom 2015), which was discovered serendipitously, as its colours indicated it was most likely a dusty evolved star.

https://www-astro.physics.ox.ac.uk/~cappellari/software/ppxf
It was discovered by Hony et al. (2011) in the SAGE-Spec survey (Kemper et al. 2010; Woods et al. 2011) to be an AGN and further characterised by van Loon & Sansom (2015).

2.3.2 SAGE0534AGN

This source was spectroscopically observed as part of SAGE-Spec (Woods et al. 2011). The classification was based on a combination of infrared spectral features, continuum and spectral energy distribution shape, bolometric luminosity, cluster membership and variability information. It was described as an unusual object as it demonstrates a very broad 20 μm emission and a very broad but weak 10 μm emission. It also has a double peaked SED, which is often taken as indicative of a post-Asymptotic Giant Branch (AGB) object, though it was considered bluer than expected for a post-AGB object. This study also considered X-ray counterparts. It was identified as an X-ray source of unknown physical nature by Sasaki et al. (2000), source ID 256, when it was observed by the ROSAT High Resolution Imager (HRI; Zombeck et al. 1995), as well as detected by the X-ray Multi-Mirror Mission (XMM/2XMMi; Watson et al. 2009) where it showed an SED that peaks around 1 keV. This, combined with the unusual Spitzer IRS spectrum, led to a classification of ‘Unknown’. This source was also detected five times serendipitously in the field of view of XMM-Newton observations (Webb et al. 2020, 2022) and is designated as 4XMM J053444.1−673751.

SAGE0534AGN was first spectroscopically observed in the optical as part of a search for optically bright post-AGB stars in the LMC (van Aarle et al. 2011). On the basis of a low resolution spectrum this object was determined to be a post-AGB star of spectral-type G. A later optical spectroscopic study by Kamath et al. (2015) revealed this source to be a quasi-stellar object (QSO) instead. As this source was not stellar in nature it was not further explored in that study and the spectrum was not published.

Comparison of the full SEDs of SAGE0536AGN and SAGE0534AGN is shown in Figure 1. From this we can see that they share a lack of far-IR emission, indicating a lack of emission from star formation. At the optical/UV end there is a lack of emission for SAGE0536AGN, whereas SAGE054AGN is bright, implying more dust extinction in SAGE0536AGN. We can also see the silicate emission, which is much stronger for SAGE0536AGN than SAGE0534AGN.
3 RESULTS

The sample (including SAGE0536AGN and SAGE0534AGN) is made up of 18 sources, 16 of which are spectroscopically confirmed extragalactic sources (see next subsection). Source 8 has no current spectroscopic confirmation of it being an extragalactic source, but has been previously identified as a potential Hα emission line star (Meyssonnier & Azzopardi 1993, identified an emission line and no underlying continuum), a far-infrared (far-IR) object (Boyer et al. 2011; Srinivasan et al. 2016) and an emission line object (Grweneugen et al. 2020).

Source 5 is a near-superposition of a carbon star in front of the true extragalactic radio source, which can be seen from the spectrum and the annotated spectral lines (Barnbaum et al. 1996; van Loon et al. 1998) that is included in the online appendix.

3.1 VMC light curves

The VMC survey is comprised of multi-epoch observations, which allows for the detection of variability. The light curves of the sample can be seen in Figure 3. The amplitudes of variation in $K_s$ were calculated by selecting the highest and lowest set of points. At these points of time the median value is selected as the highest/lowest value. The amplitude is calculated as the difference between these values. For some of these sources we are not seeing the full amplitude, such as for Source 14, where the source becomes brighter without reaching a noticeable peak. The amplitudes calculated from the VMC light curves in $K_s$ can be seen in Table 2.

Source 5 shows large-amplitude, semi-regular variability that corroborates its identity as a carbon star. The variability of the other sources combined with their extragalactic spectroscopic confirma-
Figure 3. Light curves from the VMC survey of all sources in our t-SNE selected sample.
tion, confirms the presence of an AGN. However, Sources 3, 4, and 6 show little to no variability.

3.2 Optical line identifications and spectral analysis

The spectra of SAGE0536AGN, SAGE0534AGN and 14 out of 16 t-SNE sample sources that were observed with SALT, SAAO’s 1.9m telescope or with other facilities prior to this study are shown in Figure 4. Sources that were observed as part of other surveys are also shown in Figure 4. Only Sources 5 (Star) and 8 (no available spectrum) are not shown. The spectra of Source 5 and sources with multiple available spectra that are not shown in Figure 4 can be found in the online appendix. Redshifts are listed in Table 3. The redshift for Source 8 was estimated from photometry (Flesch 2015, 2021).

The Full Width at Half Maximum (FWHM) is calculated by modelling the continuum surrounding the emission line and then subtracting the continuum from the spectra. After this the half maximum height of the emission line is calculated from the line profile and then subsequently the width of the emission to get the observed FWHM. The intrinsic FWHM is then calculated from $\text{FWHM}_{\text{intrinsic}} = \sqrt{(\text{FWHM}_{\text{observed}})^2 - (\text{FWHM}_{\text{instrument}})^2}$, where FWHM$_{\text{instrument}}$ is the FWHM of the instrument used to obtain the spectrum.

The continuum of the optical spectra was modelled using Python’s Astropy module (Astropy Collaboration et al. 2013, 2018). This facilitated the use of a low order polynomial to model the continuum. The most notable emission line is the Mg II λ2798 line, observed in all but four of the sources.

3.2.1 Black hole masses

The sample showcases emission lines from either Mg II/α, 11 had FWHM that were too close to the instrumental FWHM to modelled as a two phase torus (Stalevski et al. 2012, 2016), where $\epsilon$ is the delayed SFH with optional exponential burst which provides the dust torus is mainly made of dusty clumps (e.g. Nikutta et al. 2009; Stalevski et al. 2012). Recently, Yang et al. (2022) developed an updated version of Cigale, which allows for the modelling of the X-ray emission to account for X-ray fluxes in the fits of the SED. This version also includes a more recent AGN model, with a clumpy two-phase torus model derived from a radiative-transfer method (SKIRTOR model; Stalevski et al. 2012, 2016). This model also accounts for the presence of AGN polar dust extinction that has been observed in type 1 AGN (Gandhi & Hoenig 2015). Furthermore, the radio models now account for radio emission from an AGN, not just star formation as it did previously. It is this version of the code that we use in this work.

The SKIRTOR model is a library of AGN dusty torus emission models that were calculated with SKIRT, a radiative transfer code based on a Monte Carlo technique. In this model the dust distribution of the torus is modelled as a two phase medium. This medium consists of a large number of high-density clumps embedded in a smooth dusty component of low density. The advantage of this model is that it can produce both attenuated silicate features and pronounced near-IR emission at the same time, which both smooth and clumpy models find challenging. Since SKIRTOR’s creation evidence, both simulated (Roseboom et al. 2013) and observational (Ponti et al. 2013; Markowitz et al. 2014; Leighly et al. 2015), have shown that the dusty torus is a multi-phase structure.

The Cigale fit is made of a maximum of eight modules. The first is the star formation history (SFH) module, the one used here is the delayed SFH with optional exponential burst which provides efficient modelling of early-type and late-type galaxies. The second is the simple stellar population module that computes the intrinsic stellar spectrum, for which we selected the standard Bruzual & Charlot (2003) model. The modified dust attenuation law from Calzetti et al. (2000) is our third module, which controls the UV attenuation with the colour excess E(B−V), and also the power-law slope (δ) that modifies the attenuation curve. We included the nebular emission module, though we kept default parameters. The module to model the dust emission in the SED uses a modified blackbody spectrum following Dale et al. (2014). Next is the AGN module, modelled as a two phase torus (Stalevski et al. 2012, 2016), where

SAGE0536AGN’s black hole mass was previously reported as $M_{\text{BH}} = (3.5 \pm 0.8) \times 10^8 M_\odot$, and $L_{\text{bol}} = (5.5 \pm 1.3) \times 10^{45} \text{ erg s}^{-1} (= 12 \%$ of the Eddington luminosity (van Loon & Sansom 2015). In this work the black hole mass of SAGE0536AGN is calculated from the Hα line to be $M_{\text{BH}} = (5.5 \pm 1.3) \times 10^8 M_\odot$ with an Eddington ratio of $\sim 6 \%$. This mass combined with the calculated velocity dispersion, $\sigma \sim 202 \pm 15 \text{ km s}^{-1}$, puts SAGE0536AGN in agreement with the known correlation between velocity dispersion and black hole mass (e.g. Graham 2008).

3.3 Cigale modelling

3.3.1 The code and models

The AGN model of Cigale is from Fritz et al. (2006) and assumes that the dusty torus is a smooth structure. However, more recent theoretical and observational works find that the torus is mainly made of dusty clumps (e.g. Nikutta et al. 2009; Stalevski et al. 2012). Recently, Yang et al. (2022) developed an updated version of Cigale, which allows for the modelling of the X-ray emission to account for X-ray fluxes in the fits of the SED. This version also includes a more recent AGN model, with a clumpy two-phase torus model derived from a radiative-transfer method (SKIRTOR model; Stalevski et al. 2012, 2016). This model also accounts for the presence of AGN polar dust extinction that has been observed in type 1 AGN (Gandhi & Hoenig 2015). Furthermore, the radio models now account for radio emission from an AGN, not just star formation as it did previously. It is this version of the code that we use in this work.

The SKIRTOR model is a library of AGN dusty torus emission models that were calculated with SKIRT, a radiative transfer code based on a Monte Carlo technique. In this model the dust distribution of the torus is modelled as a two phase medium. This medium consists of a large number of high-density clumps embedded in a smooth dusty component of low density. The advantage of this model is that it can produce both attenuated silicate features and pronounced near-IR emission at the same time, which both smooth and clumpy models find challenging. Since SKIRTOR’s creation evidence, both simulated (Roseboom et al. 2013) and observational (Ponti et al. 2013; Markowitz et al. 2014; Leighly et al. 2015), have shown that the dusty torus is a multi-phase structure.

The Cigale fit is made of a maximum of eight modules. The first is the star formation history (SFH) module, the one used here is the delayed SFH with optional exponential burst which provides efficient modelling of early-type and late-type galaxies. The second is the simple stellar population module that computes the intrinsic stellar spectrum, for which we selected the standard Bruzual & Charlot (2003) model. The modified dust attenuation law from Calzetti et al. (2000) is our third module, which controls the UV attenuation with the colour excess E(B−V), and also the power-law slope (δ) that modifies the attenuation curve. We included the nebular emission module, though we kept default parameters. The module to model the dust emission in the SED uses a modified blackbody spectrum following Dale et al. (2014). Next is the AGN module, modelled as a two phase torus (Stalevski et al. 2012, 2016), where

- $M_{\text{BH}} = 10^{6.748} \left( \frac{L_{\text{3000}}}{10^{42} \text{ erg s}^{-1}} \right)^{0.620} \left( \frac{\text{FWHM}_{\text{Mg II}}}{10^3 \text{ km s}^{-1}} \right)^2 M_\odot \tag{1}$
- $M_{\text{BH}} = 10^{6.910} \left( \frac{L_{\text{5100}}}{10^{44} \text{ erg s}^{-1}} \right)^{0.500} \left( \frac{\text{FWHM}_{\text{H}\alpha}}{10^3 \text{ km s}^{-1}} \right)^2 M_\odot \tag{2}$
- $M_{\text{BH}} = \epsilon 10^{6.90} \left( \frac{L_{\text{5000}}}{10^{44} \text{ erg s}^{-1}} \right)^{0.54} \left( \frac{\text{FWHM}_{\text{Mg I}}}{10^3 \text{ km s}^{-1}} \right)^{2.06} M_\odot \tag{3}$

where $L_{\text{3000}}$ and $L_{\text{5100}}$ are the monochromatic continuum luminosities at rest-frame 3000 Å and 5100 Å respectively in erg s$^{-1}$ derived from SED fitting (see Section 3.3 for more information). Calculated black hole masses are shown in Table 4. The constant $\epsilon = 1.075$ (Reines & Volonteri 2015) was adopted. Error on the monochromatic continuum luminosities were calculated by the SED fitter, errors on the FWHM is the standard error of the mean measurement from the line profile and error of the black hole masses is propagated from these two errors.
Table 3. Table of sources investigated in this work. Redshifts are calculated from spectroscopy, except for source 8 (indicated with an * ) for which the redshift was calculated from photometry. (1) van Loon & Sansom (2015); (2) Kozłowski et al. (2013); (3) Flesch (2015, 2021); (4) Geha et al. (2003); (5) Kishimoto et al. (in prep.). Source 5 was found to be a carbon star in the SMC dominating in the optical/IR.

| Source Name         | 𝑧    | Emission Lines — FWHM (km s⁻¹) — | Date                 | Ref.         |

Figure 4. Spectra of t-SNE selected sample, excluding Source 5 (carbon star, spectrum shown in online appendix) and 8 (no spectrum available). Spectral flux has been normalised. Black indicates sources that were observed with SAAO 1.9m telescope and blue indicates sources observed with SALT. Orange indicates sources that were observed prior to this study with other facilities.

we set the extinction law of the polar dust to the SMC values (Prevot et al. 1984), the temperature to 100 K (e.g. Buat et al. 2021) and the emissivity index of the polar dust to 1.6 (Casey 2012). The radio module is also included as all the sources have radio observations, as the recent update to CIGALE (Yang et al. 2022) now models radio emission from an AGN. Where there is only one radio observation, the spectral index, 𝛼, is set to the default of −0.7, typical of synchrotron emission. Where the sources have X-ray observations the X-ray module was implemented.
3.3.2 Inputs

The known redshifts and photometry from SMASH, Gaia EDR3, VMC, SAGE, ADBWSE and HERITAGE (Meixner et al. 2013) were used to model the SEDs of the 17 objects. Not all sources had far-IR fluxes, due to either being outside of the HERITAGE survey field of the Magellanic Clouds or the fluxes being too faint. Where far-IR fluxes were not found in images an upper limit on the flux was calculated from the HERITAGE images. For Source 8, where there was no spectroscopically determined redshift, the photometric redshift, calculated by Flesch (2015, 2021) was used.

Models used and the parameters that were varied over the fit are shown in Table 5. Each AGN was initially fit without extragalactic redshift, calculated by Flesch (2015, 2021) was used. Where there was no spectrophotometrically determined redshift, the photometric redshift, calculated by Flesch (2015, 2021) was used.

Models used and the parameters that were varied over the fit are shown in Table 5. Each AGN was initially fit without extragalactic redshift, calculated by Flesch (2015, 2021) was used. Where there was no spectrophotometrically determined redshift, the photometric redshift, calculated by Flesch (2015, 2021) was used.

Table 4. Black hole masses calculated using equations 1, 2 and 3. \( L_{\text{bol}}(\text{AGN}) \) is the AGN bolometric luminosity calculated during SED fitting (see Section 3.3). Eddington Ratio is defined as the \( L_{\text{bol}}(\text{AGN})/\dot{M}_{\text{edd}} \), where the \( \dot{M}_{\text{edd}}=1.25\times10^{38}M_{\odot}\text{erg s}^{-1} \). Sources that are not listed here either have a noisy spectrum or emission lines that are smaller or close to the FWHM of the instrument.

| Source Name         | \( \log H\alpha \) | \( M_{\text{BH}}(\text{MB}) \) | \( M_{\text{ng}} \) | \( L_{\text{bol}}(\text{AGN}) \) \( \left(10^{38}\text{erg s}^{-1}\right) \) | Edd. Ratio |

| 15                  | \((5.7\pm1.9)\times10^{8}\) | \((5.0\pm0.5)\times10^{8}\) | -               | \((6.5\pm3.0)\times10^{35}\) | 9.7\pm 3.7 |
| 16                  | \((1.7\pm0.8)\times10^{7}\) | \((3.1\pm0.7)\times10^{7}\) | -               | \((5.7\pm3.0)\times10^{34}\) | 19.1\pm 8.2 |

3.3.3 

Cigale SED fits of SAGE0534AGN and SAGE0536AGN are shown in Figure 5 and the calculated parameters can be found in Table 6.

The fit of SAGE0536AGN shows that the emission from this object is not solely due to the AGN, as expected from the visible galaxy seen in survey images (see top left in Figure 6), ~11% is from the host galaxy. Extinction due to polar dust is the highest for SAGE0536AGN compared to the rest of the sample. Accretion power is smallest for SAGE0536AGN.

The fit of SAGE0534AGN however shows that the emission is almost solely due to the AGN. Compared to SAGE0536AGN, SAGE0534AGN shows similar \( \tau, i \) and \( R \) (radial thickness of torus) values. Extinction in polar dust is minimal compared to SAGE0536AGN. The opening angle is expected to be \( \approx 40^\circ \) from observations (e.g. Stalevski et al. 2016). SAGE0534AGN has the expected opening angle, whilst SAGE0536AGN has the largest opening angle of the sample, implying a thinner torus.

3.3.4 

Cigale models of the r-SNE sample

The majority of sources show a lack of host galaxy contribution, \( f_{\text{AGN}} > 70\% \), which implies differences in the dusty torus (shape, density, etc.) are causing the differences. This is shown by the ranges of the other parameters such as \( R, \tau, p_l, q \) and polar dust extinction.

All the sources, except Source 7, show an inclination angle between \( 0 < i < 45^\circ \), implying the central engine of the AGN is seen for all sources. All the sources, except Source 2, show \( R > 20 \), implying a sample with a thick torus, some of which may be thicker than the models allow (\( 10 > R > 30 \)).

3.4 X-ray observations

Seven of these sources have been detected at X-ray energies with the XMM-Newton telescope (Jansen et al. 2001) (Table 7).

Comparing with the Cigale parameters calculated, the overall luminosity of the AGN increases with X-ray luminosity as expected. Also, the X-ray luminosities decrease with both the AGN inclination angle, polar extinction and AGN dust percentage, as expected, as when the central engine becomes more obscured, X-ray emission decreases. Overall, from looking at Table 6, the X-ray luminosities of the sources with \( f_{\text{AGN}} < 99\% \) are in general lower than for \( f_{\text{AGN}} > 99\% \) sources.

3.5 The host galaxies

The host galaxy of SAGE0536AGN is resolved in VMC images, giving the appearance of a red galaxy. The fits of Cigale also show that ~11% of this object’s total dust emission is due to the host galaxy. Cigale also calculated Sources 7, 8, 10, 15 and 16 to have emission contributed by the host galaxy. Of these, only Sources 10 and 16 have host galaxies that are resolved in the VMC images.

The appearance of the host galaxies provides insight into what step of evolution they are in, be they red dead elliptical, blue and star-forming, or intermediate as a green valley galaxy (Salim 2014).

3.5.1 Galfit

Galfit (Peng et al. 2002) is a well-known software used for galaxy decomposition and by using it we hoped to shed some light on the structure of the three host galaxies. It uses parametric functions to model objects as they appear in 2D images, i.e. modelling their light distributions. It can be used to determine the global morphology or to dissect a galaxy into its separate components such as bulge, disk, bar, etc.

We used the Sérsic profile function, as varying the Sérsic exponent (which determines the light profile) can match the other
Table 5. Modules and parameter values used to model the sample in CIGALE. For the parameter values not listed the default values were used.

| Parameter | Model/Values | Description |
|-----------|--------------|-------------|
| Star formation history (SFH) | delayed SFH with optional exponential burst | |
| \( \tau_{\text{main}} \) | 100 – 4000 | e-folding time of main stellar population model (Myr). |
| \( t \) | 100 – 6000 | Age of oldest stars in the galaxy (Myr). |
| Simple stellar population (SSP) | Bruzual & Charlot (2003) | |
| IMF | 0 | Initial Mass Function from Chabrier (2003) |
| Metallicity | 0.0001, 0.01, 0.02, 0.05 | Metallicity, where solar metallicity 0.02. |
| Separation age | 1, 5, 10 | Separation between young and old star populations (Myr). |
| Galactic dust attenuation | Modified Calzetti et al. (2000) attenuation law | |
| \( E(B-V) \) | 0.4 | Colour excess of nebular lines (mag). |
| Ext-law_emission_lines | LMC, SMC | Extinction law for attenuating emission lines flux (Pei 1992). |
| Galactic dust emission | Dale et al. (2014) | |
| \( \beta \) | 0.0625 – 4 | Slope in \( dM_{\text{dust}} \propto U^{-\beta} dU \) |
| AGN | SKIRTOR UV-to-IR, from Stalevski et al. (2012, 2016) | |
| \( \tau \) | 3, 5, 7, 9, 11 | Optical depth at 9.7 \( \mu \)m. |
| \( pl \) | 0, 0.5, 1, 1.5 | Torus radial density parameter, such that \( \rho \propto r^{-pl} e^{-q|\cos(\theta)|} \), where \( \rho \) is the torus density and \( r \) is the radius of the torus. |
| \( q \) | 0, 0.5, 1, 1.5 | Torus density angular parameter. |
| Opening Angle | 10, 20, 30, 40, 50, 60, 70, 80 | Angle between the equatorial plane and edge of the torus. |
| \( R \) | 10, 20, 30 | Ratio of the outer to inner radii of the dust torus, \( R_{\text{out}}/R_{\text{in}} \). |
| \( i \) | 0, 10, 20, 30, 40, 50, 60, 70, 80, 90 | Viewing angle where face-on: \( i = 0^\circ \), edge-on: \( i = 90^\circ \). |
| \( f_{\text{AGN}} \) | 0.6, 0.7, 0.8, 0.9, 0.999 | AGN fraction, \( f_{\text{AGN}} = L_{\text{dust,AGN}}/L_{\text{dust,galaxy}} \), where \( L_{\text{dust,AGN}} \) and \( L_{\text{dust,galaxy}} \) are AGN and galaxy dust luminosity integrated over all wavelengths, respectively. |
| \( \delta \) | 0.36 – 0.36 | Power-law modifying the optical slope of the disk. |
| Law_polar | SMC | Extinction law of polar dust. |
| \( E(B-V)_{\text{polar}} \) | 0, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0 | Polar-dust colour excess (mag). |
| \( T_{\text{polar}} \) | 100 K | Temperature of polar dust. |
| Emissivity_polar | 1.6 | Emissivity index of polar dust (see equation (10) of Yang et al. 2020). |

X-ray

| Parameter | Model/Values | Description |
|-----------|--------------|-------------|
| \( \Gamma \) | 1.5 – 2.0 | Photon index, \( \Gamma \), of the AGN intrinsic X-ray spectrum. |
| \( \alpha_{\text{ox}} \) | \( -1.9, -1.8, -1.7, -1.6, -1.5, -1.4 \) | UV/X-ray slope calculated at \( \lambda = 300 \AA \). |

Radio

| Parameter | Model/Values | Description |
|-----------|--------------|-------------|
| \( \alpha_{\text{SF}} \) | 0.8 | Slope of the power-law synchrotron emission related to SF, which is a free power-law slope. |
| \( \alpha_{\text{AGN}} \) | 0.01 – 2 | Slope of the power-law AGN radio emission, defined as \( L_{\nu,\text{AGN}} \propto \nu^{-\alpha_{\text{AGN}}} \). |
| \( R_{\text{AGN}} \) | 0.1 – 300 | Radio-loudness parameter, defined as \( L_{\nu,\text{AGN}}/L_{\nu,\text{2500}} \), where \( L_{\nu,\text{AGN}} \) and \( L_{\nu,\text{2500}} \) are the monochromatic AGN luminosities per frequency at rest-frame 5 GHz and 2500 \( \AA \). |

The host galaxies of Sources 10 and 16 display rotation as a function of radius, as is seen in spiral galaxies. GALFIT allows for coordinate rotation in the light profile, and in this case we use the powerlaw spiral function in conjunction with the Sérsic function to account for the spiral arms. The residuals of SAGE0536AGN also suggest the presence of spiral arms, though they were not fit here.

When the Sérsic exponent, \( n \), is large, it has a steep inner profile (cusp), and a highly extended outer wing. When \( n \) is small, it has a shallow inner profile (core) and a steep truncation at large radius. For the host galaxies of these three AGN, SAGE0536AGN has \( n = 0.62 \), implying a form between a Gaussian function \( (n \sim 0.5) \) and an exponential disk \( (n \sim 1) \). Source 10 has \( n = 0.71 \) and Source 16...
Table 6. AGN properties calculated with CIGALE. AGN fraction is the fraction of IR luminosity from the object that is due to the AGN. \( \tau \) is the torus optical depth at 9.7 \( \mu m \). The inclination angle, \( i \), is the viewing angle, where \( i = 0^\circ \) is face-on and \( i = 90^\circ \) is edge-on. \( R \) is the ratio between the maximum and minimum radii of the torus. The opening angle, \( \alpha \), is the angle between the equatorial plane and edge of the torus. \( p_l \) is the torus radial density parameter and \( q \) is the torus density angular parameter, such that \( \rho = r^{-p_l}e^{-q\cos(\theta)} \), where \( \rho \) is the torus density and \( r \) is the radius of the torus. \( E(B-V) \) is the extinction caused by polar dust. Accretion power is the intrinsic AGN disk luminosity averaged over all directions. AGN luminosity is the sum of the observed AGN disk luminosity (some might be extincted) and the observed AGN dust re-emitted luminosity. AGN torus fraction is the fraction of the AGN luminosity that is re-emitted by the torus disk.

| Source   | AGN fraction | \( \tau \) (degrees) | \( i \) (degrees) | \( R \) | \( \alpha \) (degrees) | \( p_l \) | \( q \) | \( E(B-V) \) | Accretion power \((10^{37}W)\) | AGN luminosity \((10^{48}W)\) | Torus fraction |

Quasars dominated by nuclear dust emission

Combining the AGN and bulge components of each source provides a total magnitude brighter than the host galaxy, as expected. The AGN appears unresolved in the images, so the \( R_\text{AGN} \) calculated by GALFIT for the Sérsic profile are not true values. A Sérsic exponent, \( n \sim 0.5 \) gives a Gaussian component, and a Gaussian component with \( R_\text{AGN} \sim 0.5 \) pixels is an alternative for fitting a PSF profile and therefore an unresolved source, such as an AGN. Source 10 AGN has \( R_\text{AGN} \sim 0.5 \) pixels, showing it as is expected an unresolved source. SAGE0536AGN and Source 16 both have \( R_\text{AGN} \sim 1.5 \) pixels, implying the AGN bulge is slightly resolved.

All three galaxies are brighter at redder wavelengths, implying dust and/or lack of star formation. However, these three galaxies also have the appearance of spiral galaxies. This could imply a recent shut-down of star formation and that the galaxy has yet to transition morphologically into an elliptical galaxy. This could mean green-valley galaxies.

4 DISCUSSION

4.1 IR properties and selection criteria

The infrared has proven to be an effective wavelength regime to select AGN in and therefore many selection criteria for AGN have been created for IR wavebands based on previously spectroscopically identified AGN.

AGN selection criteria have been created for Spitzer IRAC and...

Figure 6. **GAOFIT** models of SAGE0536AGN (top), Source 10 (centre) and Source 16 (bottom). The cyan line represents 10 kpc based off of the respective redshift of each source. The input images are \( K_s \) band VMC images.

WISE wavebands by Lacy et al. (2004), Stern et al. (2005), Mateos et al. (2012) and Donley et al. (2012). The Donley et al. (2012) wedge, shown in Figure 7, was designed to be an improvement on the Lacy et al. (2004) and Stern et al. (2005) wedges, as it excludes high-redshift star-forming galaxies whilst incorporating the best aspects of the previous AGN selection wedges. All but SAGE0536AGN fall within the Donley et al. (2012) wedge. SAGE0536AGN, however, does still fall within the Lacy et al. (2004) wedge. This implies that sources similar to SAGE0536AGN could potentially be missed by the Donley et al. (2012) wedge.

The Mateos et al. (2012) wedge, shown in the left panel of Figure 8 (right) shows that all sources fall well within the expected area in the colour–colour diagram. Also, as expected, Source 5 (the carbon star) falls outside this area. All the sources fall well within the criteria from Stern et al. (2005), except SAGE0536AGN which is only just within its bounds.

Cioni et al. (2013) created AGN selection criteria which are shown in Figure 8 (left). It separates the colour–colour space into four regions. Regions A and B are where most known AGN are found where point-like AGN dominate region A and AGN with visible host galaxies dominate region B. The average redshift was found to be \( z = 1.22 ± 0.25 \) in region A and \( z = 0.44 ± 0.25 \) in region B. Region C was found to contain reddened Magellanic sources and region D was found to contain stars and low-confidence AGN. As expected, none of our sources are found in region C. Source 9, however, was found unexpectedly in region D, where stars dominate. The three sources with clear host galaxies, Source 10, 16 and SAGE0536AGN are found, as expected, in region B. All sources that have \( f_{\text{AGN}} \) < 0.99 are found in region B and all of the sources found in region A have \( f_{\text{AGN}} = 0.99 \). Sources 11, 13 and 14 are also found in region B, despite the predicted \( f_{\text{AGN}} = 0.99 \). Source 5 is found at \( Y - J = 1.4 \) and \( J - K_s = 4.6 \) (not on the diagram), when it would be expected to be found in region C or D. From the sample the average redshifts for A and B are, \( z \sim 1.02 \) and \( z \sim 0.35 \), respectively, as expected.

AGB and post-AGB/RGB stars, classes known for being confused with AGN, have been added to the plots. These stars have all been spectroscopically observed (Groenewegen & Blommaert 1998; van Loon et al. 1998, 1999a,b, 2005, 2006, 2008; Kamath et al. 2014) and are all in the Magellanic Clouds. In Figure 7 the locus of the AGB stars is outside the two AGN selection criteria, however some are still found within the Lacy wedge, some of which are avoided with the Donley wedge. In Figure 8 (right) most of the stars are outside the Mateos wedge. Of those that encroach on the AGN criteria, AGB stars are in the top of the wedge, whilst post-AGB/RGB stars are at the bottom of the wedge. In Figure 8 (left) AGB stars can be mostly found in region B, whilst post-AGB/RGB stars can be found in region A. For all colour–colour diagrams AGB and post-AGB/RGB stars can be found amongst the AGN sample. It is known that combining near-IR and mid-IR selection techniques can efficiently select a high number of AGN Bornancini et al. (2022), and the combination of WISE and VMC colour selection techniques has the potential to efficiently remove the AGB and post-AGB/RGB sources.

4.2 Green-valley

To determine whether the sources of the t-SNE selected sample are blue star-forming, green-valley or quiescent galaxies, they can be plotted on a diagram of star-formation rate (SFR) versus stellar mass of the host galaxy (e.g. Chen et al. 2016; Belfiore et al. 2018).
Table 8. The functions fitted to SAGE0536AGN, Source 10 and Source 16 in GALFIT and their parameters. All sources were fitted with one Sérsic function for the host galaxy and two Sérsic functions for the central AGN. A sky background object was also fitted, the only parameter of that used was sky background at centre of fitting region [ADUs], fitted prior to fitting the other models by setting an estimate of the background and allowing GALFIT to iterate and find the best value for the background. The magnitude is the total $K_s$ Vega magnitude from the VMC survey. $R_e$ is the effective radius in kpc (calculated from the redshift, conversion factors are 2.49 kpc arcsec$^{-1}$ for SAGE0536AGN, 3.34 kpc arcsec$^{-1}$ for Source 10 and 2.26 kpc arcsec$^{-1}$ for Source 16), such that half of the total flux is within $R_e$. $R_e$ for AGN is not meaningful since the AGN is not resolved. $n$ is the Sérsic exponent. $b/a$ is the axis ratio. The position angle is the angle the major axis, $a$, is orientated to. To account for the presence of spiral arms the Sérsic components of the host galaxy include PA rotation angle function. The bar radius is the radius where the rotation reaches roughly 20$^\circ$. The 96% asymptotic radius is the radius at 96% tanh rotation. Rotation is the cumulative coordinate rotation out to the asymptotic radius. The asymptotic spiral arm powerlaw is related to the rotation, $\theta \propto r^\alpha$, where $r$ is the radius and $\alpha$ is the powerlaw.

| Object type | SAGE0536AGN | Source 10 | Source 16 |
|-------------|-------------|-----------|-----------|
| Magnitude   | 13.1        | 13.2      | 12.7      |
| $R_e$ (kpc) | 1.3         | 2.3       | 7.8       |
| $n$         | 0.6         | 0.6       | 0.6       |
| $b/a$       | 0.9         | 1.0       | 0.7       |
| Position angle (degrees) | $-6.5$ | $51.7$ | $77.8$ |
| PA rotation func. | none | none | none |
| Bar radius (kpc) | - | - | 16.1 |
| 96 % asymp. radius (pixels) | - | - | $106.9$ |
| Rotation (degrees) | - | - | $126.7$ |
| Asymp. spiral arm powerlaw | - | - | $-3.3$ |
| Inclination to L.o.S. (degrees) | - | - | $7.7$ |
| Sky Position Angle (degrees) | - | - | - |

The SFR was calculated using the CIGALE best fits (after subtracting the AGN components) by using the correlation between total luminosity between 8 $\mu$m and 1000 $\mu$m and SFR as shown in Bell (2003):

$$SFR(M_\odot yr^{-1}) = \begin{cases} 
1.57 \times 10^{-10} L_{\text{TIR}} \left(1 + \sqrt{\frac{10^8}{L_{\text{TIR}}}}\right), & L_{\text{TIR}} > 10^{11} \\
1.17 \times 10^{-10} L_{\text{TIR}} \left(1 + \sqrt{\frac{10^8}{L_{\text{TIR}}}}\right), & L_{\text{TIR}} \leq 10^{11} 
\end{cases}$$

where $L_{\text{TIR}}$ is the total luminosity between 8 $\mu$m and 1000 $\mu$m in solar luminosities. The stellar mass was calculated by using the correlation between black hole mass and stellar mass as described in Haring & Rix (2004):

$$\log(M_{\text{BH}}) = -4.12 + 1.12 \log(M_*)$$

where $M_*$ is the stellar mass. The resulting diagram can be seen in Figure 9 (centre). The CIGALE output for SFR was not used as most of the sources are dominated by the AGN, meaning the host
galaxy, and therefore the SFR, could not be modelled accurately. For these sources the calculated SFR is an upper limit.

This plot shows that 12 out of 17 of the sources are green-valley galaxies. However, the far-IR fluxes from these galaxies are upper limits, meaning the SFR could possibly be lower and therefore in the quiescent region. SAGE0536/AGN and Source 16 show spiral arm structure, meaning star formation shut off recently and they are at least more likely to be green-valley galaxies rather than quiescent.

Of the sources in the star-forming region, Source 6 may be a green-valley galaxy as its SFR is an upper limit. Of the other galaxies it is possible that the far-IR emission is not due to star formation. The far-IR from these galaxies could instead be accounted for by dust heated by the AGN beyond the torus. It has been shown that for torus opening angles of 20–70° (Zhuang et al. 2018) the AGN emission will heat dust in the narrow-line region (where the polar dust is) if the black hole accretion disk is aligned with the galaxy plane (Baron et al. 2016), or the dust in the host galaxy if the accretion disk and the galaxy plane are misaligned (Viaene et al. 2020).

We compare other observed characteristics of these sources and CIGALE model outputs with the distance along the evolutionary sequence, which we define as the distance of the source in the host mass versus SFR plane from the 1σ scatter from the star-forming galaxies main sequence line.

From this we can see that the AGN fraction increases along the evolutionary sequence, which is expected as the host galaxy star formation reduces and the AGN becomes more prominent. Also as expected, the BH mass increases along the evolutionary sequence. Source 3 is the furthest above the star-forming main sequence and has the largest Eddington ratio. The upper limit to Eddington ratio seems to decrease along the evolutionary sequence, this could imply its running out of fuel at later stages.

X-ray observed AGN are more likely to be found in the green valley than in the star-forming region (e.g. Treister et al. 2009; Pović et al. 2012, 2013). This is corroborated by the most X-ray luminous of the AGN being found in the green valley. X-ray luminosity increases along the evolutionary sequence, which could correspond with decreasing R (ratio of outer torus radii to inner torus radii) and torus fraction, implying a thinning torus, which would mean that there is less dust and gas to absorb the X-ray emission.

### 4.3 Radio analysis

#### 4.3.1 Radio morphology

From the radio continuum images taken with ASKAP of the SMC and LMC, all 18 sources appear compact (unresolved at ASKAP resolutions) apart from three: Sources 6, 15, 16, which are shown in Figure 10. Sources 6 and 16’s extended nature could be caused by radio emission from nearby sources blending with the main source. Source 15’s radio lobes would imply we are observing the source close to edge-on. The CIGALE model predicts $i = 0.4^\circ$, and therefore close to face-on. However, the radio image in Figure 10 also shows a bright centre to the source. This could mean that the lobes are old relics, since then the source has rotated, and is now emitting a face-on radio jet.

#### 4.3.2 Spectral Indices

We define the spectral index $\alpha$ by $F_\nu \propto \nu^{\alpha}$, where $F_\nu$ is the integrated flux density at frequency $\nu$. A flatter spectral index close to zero indicates free–free emission, and a steep negative spectral index of approximately $-0.7$, indicates synchrotron emission. Table 9 shows the radio luminosity and radio MHz spectral indices, $\alpha$.

Figure 11 shows the distribution of spectral indices for our sample compared to the spectroscopically observed AGN behind the Magellanic Clouds. This shows that whilst there is a peak at $\alpha \sim -0.7$, coinciding with the expected value for synchrotron radiation, there is also an unexpected peak at more negative values.

#### 4.3.3 Radio properties across the green valley

We compare the radio properties of our sources with the distance along the evolutionary sequence, which we define as the distance of the source in the host mass versus SFR plane from the 1σ scatter from the star formation main sequence line (Figure 12).

From Figure 12 (top) we can see that the spectral index is steep at the start of the evolutionary sequence, is flattest at the beginning of the green-valley section and then steepens again. Figure 12 (bottom) shows that radio loudness, $R_{\mathrm{AGN}}$ (see Table 5), is lowest at the start of the evolutionary sequence, reaches a peak at the beginning of the green-valley section, and then reduces again.

Sources 3 and 8 (two sources on the far left of Figure 12) could be Compact Steep Spectrum (CSS) sources which are young sources that could go on to become large-scale Fanaroff–Riley II (FR II) objects (Fanti et al. 1995), such as Source 15. Furthermore, an observational signature of an AGN “switching-off” is also a steep spectrum ($\alpha \sim -1.5$). This is due to plasma ejected from the AGN losing energy causing high energy particles that radiate mostly at high radio frequencies to lose their energy fastest, making radio emission strongest at lower frequencies and causing a steep spectrum to be observed. This could imply that the AGN of the sources at the beginning of the evolutionary sequence have just switched on, explaining their steep radio spectrum. As the sources transition into the green valley the sources are at their radio loudest and have spectral indices $\sim -0.7$, implying steady synchrotron emission, after which the AGN, and subsequently the radio emission switches off, causing the radio loudness to decrease and the spectral index to steepen. The overall implication is that the AGN traces the transition from star-forming, across the green valley and into quiescence.

| Source Name | L ($\times 10^{23}$ W) | $\alpha$ |
|-------------|-----------------------|--------|
| SAGE0536/AGN | 0.5 ± 0.1             | –      |

Table 9. Radio luminosities and spectral indices for the t-SNE selected sample from ASKAP (888 MHz for LMC, 960 MHz for SMC).
Figure 9. (centre) The position of the t-SNE selected sample on a SFR versus stellar mass diagram. The blue and red dashed lines are an approximation of the boundary (at the 1σ level in scatter from the main trend lines of the star-forming (SF) and quiescent galaxies) of the star-forming main sequence and the quiescent sequence, respectively, taken from Chen et al. (2016). Those with blue error bars are sources with known black hole masses to calculate stellar mass from. Those with grey error bars are those with no known black hole mass, set at the average black hole mass of the sample. (top) How Eddington ratio changes with M* (left) How R changes with SFR. This shows that green-valley (GV) galaxies tend to have smaller tori than star-forming galaxies. (right) How X-ray luminosity changes with SFR. This shows that higher X-ray luminosities are seen in the green valley. (bottom) How the torus and polar dust emission fractions of the AGN change with M*, Accretion disk emission is the remaining fraction of AGN not plotted here.

4.4 AGN dust properties

4.4.1 Variability

All the sources show some variability. From those with a known Eddington ratio we can see that high Eddington ratio sources tend to have little variability, while those with decreasing Eddington ratios tend to include sources with larger variability (Figure 13). This relation holds true for black hole mass in place of Eddington ratio, so therefore smaller black holes (with smaller tori) vary the most whilst larger black holes (with larger tori) tend to vary less.

There is a general increase in variability with an increase in optical depth, implying the more emission from the accretion disk that is absorbed by the torus, the greater the variability. The Eddington ratio also decreases with increased optical depth and torus fraction. This implies Eddington ratio increases with less attenuation by the torus, as expected, but also that variability decreases with less attenuation by the torus, implying the torus is playing a part in the variability of the AGN that we observe. This could mean we are seeing variability in the attenuation of the emission from the accretion disk, instead of the variability of the accretion disk emission, which could mean high variability is caused by a “clumpy” torus moving around the accretion disk causing the amount of attenuation of the emission to increase and decrease.

High Eddington ratio sources vary the least. In general the highest Eddington ratios are at the start of the evolutionary sequence, whilst the lowest Eddington ratios are at the end of the green valley. This could imply that the sources at the beginning, where the AGN is just “switching on” and have the greatest amount of fuel and a high accretion rate, have the lowest variability, whilst the AGN that are starting to “switch off” and have the lowest amount of fuel and a lower accretion rate, have the highest variability. This could be due to the erosion of the dusty torus surrounding the AGN leading to a more porous torus and therefore increased variability. This would however be dependent on inclination angle of the AGN.
Figure 10. ASKAP 1320 MHz radio flux of Sources 6, 15 and 16 shown as contours on top of the VMC K_s band images. Source 6 has five linearly spaced contours from 0.18 – 1.1 mJy. Source 15 has eight linearly spaced contours from 1 – 70 mJy. Source 16 has five linearly spaced contours from 0.3 – 0.72 mJy. Source 6 could potentially be an FR II source, with an offset radio peak and a counter-lobe at the other side. Source 15 is an FR II source. Source 16 radio emission extends towards the West most likely due to the point source to the West of it also being a radio source.

Figure 11. Spectral indices of the sample compared to other spectroscopically observed AGN behind the Magellanic Clouds.

Figure 12. Variation of spectral indices, α (top), and radio loudness (bottom) of the sample as they transition from star-forming to green-valley galaxies.

Figure 13. The comparison of variability with Eddington ratio and optical depth, τ, of the t-SNE selected sample.

4.4.2 CIGALE model components

CIGALE provides the separate models that make up the overall best-fit model. These models can be seen in Figure 15. In the optical, the sources where the host galaxy dominates over the AGN disk are SAGE0536AGN and Source 7.

Polar dust contribution varies from source to source. Source 7 has the highest polar dust fraction at ~53%. This source also has one of the lowest AGN fractions of ~72%. However, the source with the lowest AGN fraction of ~70%, only has polar dust fraction of ~3%. Those with <1% polar fraction can all be found in the green valley. These could be those where no outflows are present to push out the polar dust, and the AGN is starting to turn off.

As expected, we see a negative correlation between accretion disk fraction and torus disk fraction (Figure 14), where SAGE0534AGN has the highest disk fraction and SAGE056AGN has the highest torus dust fraction, bracketing the sample. The opening angle also follows this trend, increasing with torus dust fraction (and decreasing with accretion disk fraction). However, Source 16,
of 0.85 estimate SAGE0536AGN (low-\(z\) source) as \(\text{Si}_{\nu,7\mu m} \sim 0.72\). This could imply the modelling of the silicate feature strength is not accurate or missing something.

The model predicts that all sources in this sample show silicate 9.7-\(\mu m\) emission. This could mean that the t-SNE selection separates those sources in emission from those in absorption. Confirming this requires follow-up mid-IR spectroscopy.

4.4.4 Comparison to other silicate emitting AGN
SAGE0534AGN and SAGE0536AGN are not alone in their emission of silicate features. Comparing the two with more common less extreme versions of silicate emitting AGN may lend a clue to how these came about, whether they be extreme versions of an already established class of AGN or exist in a class of their own. To compare, a sample of local (\(z < 0.1\)) type 1 AGN with silicate emission were taken from Martínez-Paredes et al. (2020). They are a sample of 67 local (\(z < 0.1\)) type 1 AGN. Another comparison was made with a sample from Dicken et al. (2014) which include 46 2Jy radio galaxies (0.05 < \(z < 0.7\)) and 17 3CR FRII radio galaxies (\(z < 0.1\)) nuclei (AGN) with Spitzer spectra dominated by non-stellar processes. The sources in this sample have silicate strength calculated using Equation 6.

The silicate strength of SAGE0534AGN, SAGE0536AGN and the silicate emitting AGN sample were compared with their far-IR colour (WISE 4 (23 \(\mu m\) – IRAS 60 \(\mu m\)). For the sources in these samples that had no IRAS 60-\(\mu m\) measurements, a limit on the flux was calculated from the IRAS images. For the t-SNE selected sample the IRAS 60-\(\mu m\) magnitudes were estimated from the CIGALE best fit models. This comparison is shown in figure 16. The AGN sample are all to the right from SAGE0536AGN, SAGE0534AGN and the t-SNE selected sample. The higher redshift galaxies tend to be further to the right, but this could be because high-\(z\) galaxies are most likely biased towards star-forming galaxies to make them bright enough. The limits on W4 – IRAS60 could suggest there are already interesting sources observed. SAGE0536AGN however, remains apart due to its high silicate strength.

SAGE0536AGN is the strongest 10-\(\mu m\) silicate emitter currently known. In terms of torus properties predicted by CIGALE, SAGE0536AGN has one of the highest values for \(R\) and \(\tau\), are most likely biased towards star-forming galaxies to make them bright enough. The limits on W4 – IRAS60 could suggest there are already interesting sources observed. SAGE0536AGN however, remains apart due to its high silicate strength.

5 CONCLUSIONS
In this work we used unsupervised machine learning, t-SNE, with Gaia EDR3, VMC, AllWISE and EMU ASKAP photometric data,
Figure 15. Separate components of the CIGALE models for the t-SNE sample at rest-wavelength.

Figure 16. Silicate strength versus WISE band 4 – IRAS 60-𝜇m (in magnitudes). The IRAS60 measurements for SAGE0536AGN, SAGE0534AGN and the t-SNE sample are all calculated from the CIGALE model best fit.

to find sources similar to SAGE0536AGN, the strongest 10-𝜇m silicate emitter known, and SAGE0534AGN, a similar source with weaker silicate emission. This provided 16 sources to add to the sample. We took optical spectra of 15 of these sources and found that all but one were extragalactic in nature. From these spectra we calculated black hole masses and Eddington ratios. We used CIGALE to model the SEDs and characterise these sources, as well as used GALFIT to model the morphology of the three nearest sources.

From this investigation we discovered most of the sources (12 out of 17) are in the green valley transitional phase, with the potential for some of these to be quiescent. We find that as sources move away from the star-forming phase and through the green valley phase the properties of the AGN change, such as the torus depletes, the Eddington ratio decreases, signalling the AGN is running out of fuel, and the X-ray luminosity increases as the material that would absorb it has depleted. Radio properties also change across this evolutionary sequence. The radio spectral slope starts off steep in the star-forming phase, before flattening to the expected value of $\alpha \sim -0.7$ at the beginning of the green valley, and then steepening again as the sources move further into the green valley. Radio loudness also follows this trend, starting off quiet in the star-forming...
phase, becoming loudest at the beginning of the green valley, before quieting again. This implies the “turning on” of the AGN to transition from star-forming to green valley, and then the AGN “turns off” again, before transition to quiescence.

All sources are variable and this variability decreases when there is less attenuation by the torus, implying the torus is playing a part in the variability.

SAGE0536AGN remains the most extreme 10-μm silicate emitter, which is not modelled well with CIGALE, which predicts weaker emission for SAGE0536AGN and stronger emission for SAGE0534AGN. CIGALE predicts all sources have silicate in emission. This needs to be verified by spectroscopic observations in the mid-IR, such as with the James Webb Space Telescope.

6 DATA AVAILABILITY

The data used to create the spectroscopy plots are available as online supplementary material. The inputs and outputs for CIGALE, Galfit and t-SNE are also available as online supplementary material. The spectroscopy data and the photometry data will be made available on the CDS\(^3\) website when the paper is published.

The VMC photometry is available from ESO in the regular VMC data releases (http://www.eso.org/rm/publicAccess#/dataReleases). The VMC image data on the SMC, Bridge and Stream used in this paper are available in the VISTA Science Archive (VSA), at http://horus.roe.ac.uk/vsa. The deep stack VMC images of the LMC will be released mid-2022, whereas the individual observations are publicly available at the ESO archive (http://archive.eso.org/cms.html).

ACKNOWLEDGEMENTS

We thank the anonymous referee for their feedback, which helped improve the paper. C.M.P. and J.E.M.C. acknowledge STFC studentship. J.O.A. acknowledges Nigerian Tertiary Education Trust Funded studentship. A.N. acknowledges support from Narodowe Centrum Nauki (UMO-2020/38/E/ST9/00077). This paper uses observations made at the South African Astronomical Observatory (SAAO) under programme Pennock-2019-05-74-inch-257, and with the Southern African Large Telescope (SALT) under programmes 2021-1-SCI-018 (PI: Jacco van Loon), 2021-1-SCI-029 (PI: Jacco van Loon), 2021-1-SCI-032 (PI: Jacco van Loon) and 2021-2-SCI-017 (PI: Joy Anih). This paper also made use of spectra contributed by Makoto Kishimoto, observed with the European Southern Observatory’s 3.6m telescope with EFOSC2 under programme 073.B-0501(A). This research made use of Astropy,\(^4\) a community-developed core Python package for Astronomy (Astropy Collaboration et al. 2013, 2018). We have made extensive use of the SIMBAD Database at CDS (Centre de Données astronomiques de Strasbourg), the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, CalTech, under contract with NASA, and of the VizieR catalog access tool, CDS, Strasbourg, France. This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement no. 682115). We thank the Cambridge Astronomy Survey Unit (CASU) and the Wide Field Astronomy Unit (WFAU) in Edinburgh for providing the necessary data products under the support of the Science and Technology Facility Council (STFC) in the UK.
