Abstract

The highly non-linear nature of deep neural networks causes them to be susceptible to adversarial examples and have unstable gradients which hinders interpretability. However, existing methods to solve these issues, such as adversarial training, are expensive and often sacrifice predictive accuracy.

In this work, we consider curvature, which is a mathematical quantity which encodes the degree of non-linearity. Using this, we demonstrate low-curvature neural networks (LCNNs) that obtain drastically lower curvature than standard models while exhibiting similar predictive performance, which leads to improved robustness and stable gradients, with only a marginally increased training time. To achieve this, we minimize a data-independent upper bound on the curvature of a neural network, which decomposes overall curvature in terms of curvatures and slopes of its constituent layers. To efficiently minimize this bound, we introduce two novel architectural components: first, a non-linearity called centered-softplus that is a stable variant of the softplus non-linearity, and second, a Lipschitz-constrained batch normalization layer.

Our experiments show that LCNNs have lower curvature, more stable gradients and increased off-the-shelf adversarial robustness when compared to their standard high-curvature counterparts, all without affecting predictive performance. Our approach is easy to use and can be readily incorporated into existing neural network models.

1 Introduction

The high degree of non-linearity present in deep neural networks, or equivalently their large curvature, is critical to achieving good performance in difficult tasks such as image classification or machine translation. Practically, having a large curvature is undesirable because they are susceptible to adversarial vulnerability and have unstable gradient maps that hinder interpretability. Further conceptually, Occam’s razor requires us to train models that are as linear (“simple”) as possible, and this involves penalizing any excess non-linearity. In this work, we focus on removing such excess curvature from neural network models without affecting predictive performance.

Central to this work is a precise notion of curvature, which is a mathematical quantity that encodes the deviation of a curve from ‘flatness’. In deep learning, the curvature of a function at a point is often quantified as the norm of the Hessian at that point. For example, Dinh et al. [1] consider the

Preprint. Under review.
Figure 1: Decision boundaries of (a) standard NN and (b) LCNN trained on the two moons dataset. LCNN recovers highly regular decision boundaries in contrast to the standard NN. (c) Comparison of softplus and centered-softplus non-linearities (defined in §3.3). These behave similarly for large $\beta$ values, and converge to linear maps for low $\beta$ values. However, softplus diverges while centered-softplus stays close to the origin.

Our overall contributions in this paper are:

1. In §3.1 we propose a novel measure of curvature, dubbed normalized curvature, that is invariant to scaling of the gradients.
2. In §3.2 we prove upper bounds on the normalized curvature of neural networks, which decomposes overall curvature in terms of curvatures and slopes of individual layers.
3. We introduce architectural innovations including a novel activation function called the centered-softplus (§3.3), and a novel Lipschitz constrained batch normalization layer (§3.4.2).
4. In §4 we prove bounds on the relative gradient robustness and adversarial robustness of models in terms of normalized curvature, showing that controlling normalized curvature directly controls these properties.
5. In §5 we show experiments demonstrating that our proposed innovations are successful in training low-curvature models without sacrificing training accuracy, and that such models have robust gradients, and are more robust to adversarial examples out-of-the-box.

2 Related Work

Adversarial Robustness of Neural Networks: The well-known phenomenon of adversarial vulnerabilities of neural networks [3, 4] shows that adding small amounts of imperceptible noise can cause deep neural networks to misclassify points with high confidence. The canonical method to defend against this vulnerability is adversarial training [5] which trains models to accurately classify adversarial examples generated via an attack such as projected gradient descent (PGD). However, this approach is computationally expensive and provides no formal guarantees on robustness. Cohen
et al. [6] proposed randomized smoothing, which provides a formal guarantee on robustness by generating a smooth classifier from any black-box classifier. Hein and Andriushchenko [7] identified the local Lipschitz constant as a critical quantity to prove formal robustness guarantees. Moosavi Dezfooli et al. [8] penalize the Frobenius norm of the Hessian, and show that they perform similarly to models trained via adversarial training. Qin et al. [9] introduce a local linearity regularizer, which also implicitly penalizes the Hessian. Similar to these works, we enforce low curvature to induce robustness, but we focus on out of the box robustness of LCNNs.

Unreliable Gradient Interpretations in Neural Networks: Gradient explanations in neural networks can be unreliable. Ghorbani et al. [10], Zhang et al. [11] showed that for any input, it is possible to find adversarial inputs such that the gradient explanations for these points are highly dissimilar to each other. Srinivas and Fleuret [12] showed that pre-softmax logit gradients however are independent of model behaviour, and as a result we focus on post-softmax loss gradients in this work. Ros and Doshi-Velez [13] showed empirically that robustness can be improved by gradient regularization, however Dombrowski et al. [14] showed that gradient instability is primarily due to large Hessian norms. This suggests that the gradient penalization in Ros and Doshi-Velez [13] performed unintentional Hessian regularization, which is consistent with our experimental results. To alleviate this, Dombrowski et al. [15] proposed to train low curvature models via softplus activations and weight decay, broadly similar to our strategy. However, while Dombrowski et al. [15] focused on penalizing the Frobenius norm of the Hessian, we penalize the the curvature – a scaled version of the Hessian spectral norm – which is strictly smaller than the Frobenius norm, and this results in a more sophisticated penalization strategy.

Lipschitz Layers in Neural Networks: There has been extensive work on methods to bound the Lipschitz constant of neural networks. Cisse et al. [16] introduced Parseval networks, which penalizes the deviation of linear layers from orthogonality, since an orthogonal linear operator evidently has a Lipschitz constant of one, this shrinks the Lipschitz constant of a layer towards one. Trockman and Kolter [17] use a reparameterization of the weight matrix, called the Cayley Transform, that is orthogonal by construction. Miyato et al. [18], Ryu et al. [19] proposed spectral normalization, where linear layers are re-parameterized by dividing by their spectral norm, ensuring that the overall spectral norm of the parameterized layer is one.

3 Training Low-Curvature Neural Networks

In this section, we introduce our approach for training low-curvature neural nets (LCNNs). Unless otherwise specified, we shall consider a neural network classifier $f$ that maps inputs $x \in \mathbb{R}^d$ to a scalar loss value $f(x) \in \mathbb{R}^+$. 

3.1 Measuring Relative Model Non-Linearity via Normalized Curvature

We begin our analysis by discussing a desirable definition of curvature $C_f(x) \in \mathbb{R}^+$. A typical property of a curvature measure is that $C_f(x) = 0 \; \forall x \in \mathbb{R}^d \iff f$ is linear, and hence $\max_{x \in \mathbb{R}^d} C_f(x)$ can be thought of as a measure of a model’s non-linearity. A common way to define curvature in machine learning [8] [14] [11] has been via Hessian norms. However, these measures are sensitive to gradient scaling, which is undesirable.

For example, if two functions $f, g$ are scaled ($f = k \times g$), or rotated versions of each other ($\nabla_x f = k \times \nabla_x g$), then we would like them to have similar curvatures in the interest of disentangling curvature (i.e., extent of non-linearity) from scaling. It is easy to see that Hessian norms $\|\nabla^2_x f(x)\|_2$ do not have this property, as scaling the function also scales the corresponding Hessian. We would like to be able to recover low-curvature models with steep gradients, precisely to be able to disentangle their properties from low-curvature models with small gradients, which Hessian norms do not allow us to do.

To avoid this problem, we propose a definition of curvature that is approximately normalized: $C_f(x) = \|\nabla^2_x f(x)\|_2 / (\|\nabla_x f(x)\|_2 + \varepsilon)$. Here $\|\nabla_x f(x)\|_2$ and $\|\nabla^2_x f(x)\|_2$ are the $l_2$ norm of the gradient and the spectral norm of the Hessian, respectively, where $\nabla_x f(x) \in \mathbb{R}^d, \nabla^2_x f(x) \in \mathbb{R}^{d \times d}$, and $\varepsilon > 0$ is a small constant to ensure numerical stability. This definition measures Hessian norm
relative to the gradient norm, and captures a notion of relative local linearity, which can be proved via Taylor’s theorem:

$$\frac{\|f(x + \epsilon) - f(x) - \nabla_x f(x)^\top \epsilon\|_2}{\|\nabla_x f(x)\|_2} \leq \frac{1}{2} \max_{x \in \mathbb{R}^d} \frac{1}{\|
abla f(x)\|_2} \frac{\|\epsilon\|_2}{\|\epsilon\|_2}.$$  

(1)

Here the numerator on the left captures the local linearity error, scaled by the gradient norm in the denominator, which can be shown using Taylor’s theorem to be upper bounded by the normalized curvature. We also observe that the normalized curvature is invariant to scaling both the function and its gradients, unlike the Hessian norm. Hence this is a valid measure of curvature, which we shall consider penalizing in the rest of the paper.

### 3.2 A Data-Free Upper Bound on Curvature

Directly penalizing the curvature is computationally expensive as it requires backpropagating from an estimate of the Hessian norm, which itself requires backpropagating gradient-vector products. This requires chaining the entire computational graph of the model at least three times. Moosavi Dezfooli et al. [8] reduce the complexity of this operation by computing a finite-difference approximation to the Hessian from gradients, but even this double-backpropagation is expensive.

To address this issue, we propose to minimize a data-free upper bound on the curvature. To illustrate the idea, we first show this upper bound for the simplified case of the composition of one-dimensional functions ($f : \mathbb{R} \to \mathbb{R}$).

**Lemma 1.** Given a 1-dimensional compositional function $f = f_L \circ f_{L-1} \circ \ldots \circ f_1$ with $f_i : \mathbb{R} \to \mathbb{R}$ for $i = 1, 2, \ldots, L$, the normalized curvature $C_f := |f''/f'|$, is bounded by

$$\left|\frac{f''}{f'}\right| \leq \sum_{i=1}^L \frac{f''}{f'} \prod_{j=1}^i |f'_j|$$

**Proof.** We first have $f' = \prod_{i=1}^L f'_i$. Differentiating this expression we have $f'' = \sum_{i=1}^L f''/f'_i \prod_{j=1}^i f'_j \prod_{k=1,k\neq i}^L f'_k$. Dividing by $f'$, taking absolute value of both sides, and using the triangle inequality, we have the intended result.

Extending the above expression to functions $\mathbb{R}^n \to \mathbb{R}$ is not straightforward, as the intermediate layer Hessians are order three tensors. We derive this using a result from Wang et al. [20] that connects the spectral norms of order-3 tensors to the spectral norm of their matrix “unfoldings”. The full derivation is presented in the appendix, and the (simplified) result is stated below.

**Theorem 1.** Given a function $f = f_L \circ f_{L-1} \circ \ldots \circ f_1$, the curvature $C_f$ can be written as the sum of curvatures of individual layers $C_{f_i}(x)$, i.e.,

$$C_f(x) \leq \sum_{i=1}^L C_{f_i}(x) \prod_{j=1}^i \|\nabla f_{i-j}(x)f_j(x)\|_2 \leq \sum_{i=1}^L \max_x C_{f_i}(x) \prod_{j=1}^i \max_x \|\nabla f_{i-j}(x)f_j(x)\|_2.$$  

(2)

The rightmost term is independent of $x$ and thus holds uniformly across all data points. This bound shows that controlling the curvature and Lipschitz constant of each layer of a neural network enables us to control the overall curvature of the model.

Practical neural networks typically consist of linear maps such as convolutions, fully connected layers, and batch normalization layers, and non-linear activation functions. Linear maps have zero curvature by definition, and non-linear layers often have bounded gradients ($= 1$), which simplifies computations. In the sections that follow, we shall see how to penalize the remaining terms, i.e., the curvature of the non-linear activations, and the Lipschitz constant of the linear layers.

### 3.3 Centered-Softplus: Activation Function with Trainable Curvature

Theorem[2] shows that the curvature of a neural network depends on the curvature of its constituent activation functions. We thus propose to use activation functions with minimal curvature.

---

*We ignore self-attention layers in this work.*
The kink at the origin of the ReLU function implies an undefined second derivative. On the other hand, a smooth activation such as the softplus function, \( s(x; \beta) = \log(1 + \exp(\beta x))/\beta \) is better suited to analyzing questions of curvature. Despite not being a common baseline choice, softplus does see regular use, especially where its smoothness facilitates analysis \[21\]. The curvature of the softplus function is

\[
C_{s(\cdot; \beta)}(x) = \beta \times \left( 1 - \frac{ds(x; \beta)}{dx} \right) \leq \beta
\]  

Thus using softplus with small \( \beta \) values ensures low curvature. However, we observe two critical drawbacks of softplus preventing its usage with small \( \beta \): (1) divergence for small \( \beta \rightarrow 0 \) which ensures that well-behaved low curvature maps cannot be recovered and, (2) instability upon composition i.e., \( s^n(x = 0; \beta) = s \circ s \circ \ldots \circ s(x = 0; \beta) = \frac{\log(n+1)}{\beta} \). Thus we have that \( s^n(x = 0; \beta) \rightarrow \infty \) as \( n \rightarrow \infty \), which shows that composing softplus functions exacerbates instability around the origin. This is critical for deep models with large number of layers \( n \), which is precisely the scenario of interest to us. To remedy this problem, we propose centered-softplus \( s_0(x; \beta) \), a simple modification to softplus by introducing a normalizing term as follows.

\[
s_0(x; \beta) = s(x; \beta) - \frac{\log 2}{\beta} = \frac{1}{\beta} \log \left( \frac{1 + \exp(\beta x)}{2} \right). \]  

This ensures that \( s(x = 0; \beta) = s^n(x = 0; \beta) = 0 \) for any positive integer \( n \), and hence also ensures stability upon composition. More importantly, we have \( s_0(x; \beta \rightarrow 0) = x/2 \) which is a scaled linear map, while still retaining \( s_0(x; \beta \rightarrow \infty) = \text{ReLU}(x) \). This ensures that we are able to learn both well-behaved linear maps, as well as highly non-linear ReLU-like maps if required.

We further propose to cast \( \beta \) is a learnable parameter and penalize its value, hence directly penalizing the curvature of that layer. Having accounted for the curvature of the non-linearities, the next section discusses controlling the gradients of the linear layers.

### 3.4 Lipschitz Linear Layers

Theorem 2 shows that penalizing the Lipschitz constants of the constituent linear layers in a model is necessary to penalize overall model curvature. There are broadly three classes of linear layers we consider: convolutions, fully connected layers, and batch normalization.

#### 3.4.1 Spectrally Normalized Convolutions and Fully Connected Layers

We propose to penalize the Lipschitz constant of convolutions and fully connected layer via existing spectral normalization-like techniques. For fully connected layers, we use vanilla spectral normalization Miyato et al. \[18\] which controls the spectral norm of a fully connected layer by reparameterizing – replace a weight matrix \( W \), by \( W/||W||_2 \) which has a spectral norm of unity. Ryu et al. \[19\] generalize this to convolutions by presenting a power iteration method that works directly on the linear mapping implicit in a convolution: maintaining 3D left and right singular “vectors” of the 4D tensor of convolutional filters and developing the corresponding update rules. They call this “real” spectral normalization to distinguish it from the approximation that \[18\] proposed for convolutions. Using spectral normalization on fully connected layers and “real” spectral normalization on convolutional layers ensures that the spectral norm of these layers is exactly equal to one, further simplifying the bound in Theorem 2.

#### 3.4.2 \( \gamma \)-Lipschitz Batch Normalization

In principle, at inference time batch normalization (BN) is multiplication by the diagonal matrix of inverse running standard deviation estimates.\(^*\) Thus we can spectrally normalize the BN layer by computing the reciprocal of the smallest running standard deviation value across dimensions

\(^*\)We ignore the learnable parameters of batch normalization here for simplicity.
\[ i, \text{ i.e., } \|\text{BN}\|_2 = \max_x \|\text{BN}(x)\|_2 = 1/\min_i \text{running-std}(i). \]

In practice, we found that models with such spectrally normalized BN layers tended to either diverge or fail to train in the first place, indicating that the scale introduced by BN is necessary for training. To remedy this, we introduce the \( \gamma \)-Lipschitz batch normalization, defined by

\[
1\text{-Lipschitz-BN}(x) \leftarrow \text{BN}(x)/\|\text{BN}\|_2 \\
\gamma\text{-Lipschitz-BN}(x) \leftarrow \min(\gamma, \|\text{BN}\|_2) \times 1\text{-Lipschitz-BN}(x).
\]

By clipping the scaling above at \( \gamma \) (equivalently, the running standard deviation below, at \( 1/\gamma \)), we can ensure that the Lipschitz constant of a batch normalization layer is at most equal to \( \gamma \in \mathbb{R}^+ \). We provide a PyTorch-style code snippet in the appendix. As with \( \beta \), described in §3.3, we cast \( \gamma \) as a learnable parameter in order to penalize it during training.

### 3.5 Penalizing Curvature

We have discussed three architectural innovations – centered-softplus activations with a trainable \( \beta \), spectrally normalized linear and convolution layers and a \( \gamma \)-Lipschitz batch normalization layer. We now discuss methods to penalize the overall curvature of a model built with these layers.

Since convolutional and fully connected layers have spectral norms equal to one by construction, they contribute nothing to curvature. Thus, we restrict attention to batch normalization and activation layers. The set of which will be subsequently referred to respectively \( \beta \text{SP} \) and \( \gamma \text{BN} \). For models with batch normalization, naively using the upper bound in Theorem 2 is problematic due to the product of Lipschitz constants of batch normalization layers, which can quickly grow exponentially due to the product term. To alleviate this, we propose to use a penalization \( R_f \) where \( \gamma_i \) terms are aggregated additively across batch normalization layers in the following manner:

\[
R_f = \lambda_\beta \times \sum_{i \in \beta \text{SP}} \log \beta_i + \lambda_\gamma \times \sum_{j \in \gamma \text{BN}} \log \gamma_j
\]

An additive aggregation ensures that the penalization is well-behaved during training and does not grow exponentially. Further, penalizing the \( \log \) of \( \beta, \gamma \) ensures a gentler regularization, which we found to be stable to train. Note that this achieves the same objective as the upper bound and ensures that the \( \beta \) and \( \gamma \) terms are both small. We shall henceforth use the term “LCNN” to refer to a model trained with the proposed architectural components (centered-softplus, spectral normalization, and \( \gamma \)-Lipschitz batch normalization) and associated regularization terms on \( \beta, \gamma \). We next discuss the robustness and interpretability benefits that we obtain with LCNNs.

### 4 Advantages of Low Curvature Models

In this section we discuss the advantages that low-curvature models offer, particularly as it pertains to robustness and interpretability. These statements apply not just to LCNNs, but low-curvature models in general obtained via any other mechanism.

#### 4.1 Low Curvature Models have Stable Gradients

Recent work \[10, 11\] has shown that gradient explanations are manipulable, and that we can easily find inputs whose explanations differ maximally from those at the original inputs, making them unreliable in practice for identifying important features. As we shall show, this amounts to models having a large curvature. In particular, we show that the relative gradient difference across points \( \|\epsilon\|_2 \) away in the \( \ell_2 \) sense is upper bounded by the normalized curvature \( C_f \), as given below.

**Proposition 1.** Consider a model \( f \) with \( \max_x C_f(x) \leq \delta \), and two inputs \( x \) and \( x + \epsilon (\in \mathbb{R}^d) \).

The relative distance between gradients at these points is bounded by
\[
\frac{\|\nabla_x f(x + \epsilon) - \nabla_x f(x)\|_2}{\|\nabla_x f(x)\|_2} \leq \|\epsilon\|_2 \delta_c \exp(\|\epsilon\|_2 \delta_c) \sim \|\epsilon\|_2 \mathcal{C}_f(x) \quad (\text{Quadratic Approximation})
\]

The proof expands \( f(x) \) in a Taylor expansion around \( x + \epsilon \) and bounds the magnitude of the second and higher order terms over the neighborhood of \( x \) – the full argument is given in the appendix. The upper bound is considerably simpler when we assume that the function locally quadratic, which corresponds to the rightmost term \( \|\epsilon\|_2 \mathcal{C}_f(x) \).

4.2 Low Curvature is Necessary for \( \ell_2 \) Robustness

Having a small gradient norm is known to be an important aspect of adversarial robustness [7]. However, small gradients alone are not sufficient, and low curvature is necessary, to achieve robustness. This is easy to see intuitively - a model may have low gradients at a point leading to robustness for small noise values, but if the curvature is large, then gradient norms at neighboring points can quickly increase, leading to misclassification for even slightly larger noise levels. This effect is an instance of gradient-masking [22], which provides an illusion of robustness by making models locally robust.

In the result below, we formalize this intuition and establish an upper bound on the distance between two nearby points, which we show depends on both the gradient norm (as was known previously) and well as the max curvature of the underlying model within an \( \epsilon \)-ball.

**Proposition 2.** Consider a model \( f \) with \( \max_x \mathcal{C}_f(x) \leq \delta_c \), then for two inputs \( x \) and \( x + \epsilon (\in \mathbb{R}^d) \), we have the following expression for robustness

\[
\|f(x + \epsilon) - f(x)\|_2 \leq \|\epsilon\|_2 \|\nabla_x f(x)\|_2 (1 + \|\epsilon\|_2 \delta_c \exp(\|\epsilon\|_2 \delta_c)) \\
\sim \|\epsilon\|_2 \|\nabla_x f(x)\|_2 (1 + \|\epsilon\|_2 \mathcal{C}_f(x)) \quad (\text{Quadratic Approximation})
\]

The proof uses similar techniques to those of proposition[1] and is also given in the appendix. This result shows that given two models with small gradients at data points, the larger robustness will be achieved by the model with the smaller curvature.

5 Experiments

In this section we perform experiments to (1) evaluate the effectiveness of our proposed method in training models with low curvature as originally intended, (2) evaluate whether low curvature models have robust gradients in practice, and (3) evaluate the effectiveness of low-curvature models for adversarial robustness. Our experiments are primarily conducted on a base ResNet-18 architecture ([23]) using the CIFAR10 and CIFAR100 datasets ([24]), and using the Pytorch ([25]) framework. Our methods entailed fairly modest computation – most involved computations can be completed in under three days on an NVIDIA GeForce GTX 1080 Ti, and all experimental results could be computed in less than 60 NVIDIA GeForce GTX 1080 Ti-days. We used a mixture of GPUs – primarily NVIDIA GeForce GTX 1080 Ti – on an internal compute cluster.

**Baselines and Our Methods** Our baseline model for comparison involves using a ResNet-18 model with softplus activation with a high \( \beta = 10^4 \) to mimic ReLU, and yet have well-defined curvatures. Another baseline is gradient norm regularization (which we henceforth call ‘GradReg’) [20], where the same baseline model is trained with an additional penalty on the gradient norm. We train two variants of our approach - a base LCNN, which involves penalizing the curvature, and another variant combining LCNN penalty and gradient norm regularization (LCNN + GradReg), which controls both the curvature and gradient norm. Our theory indicates that the LCNN + GradReg variant is likely to produce more robust models, which we verify experimentally. We also compare with CURE [8], softplus with weight decay [15] and adversarial training with \( \ell_2 \) PGD [5] with noise magnitude of 0.1 and 3 iterations of PGD. We provide experimental details in the appendix.

**Parameter Settings** All our models are trained for 200 epochs with an SGD + momentum optimizer, with a momentum of 0.9 and an initial learning rate of 0.1 which decays by a factor of 10 at 150 and 175 epochs, and a weight decay of \( 5 \times 10^{-4} \).
5.1 Evaluating the Efficacy of Curvature Penalization

In this section, we evaluate whether LCNNs indeed control model curvature as intended. Table 1 contains our results, from which we make the following observations: (1) most of our baselines except CURE and adversarial training do not meaningfully lose predictive performance (2) GradReg and adversarially trained models are best at reducing gradient norm while LCNN-based models are best at penalizing curvature. Overall, these experimental results show that LCNN-based models indeed control curvature as intended.

We also observe in Table 1 that GradReg [26] has an unexpected regularizing effect on the Hessian and curvature. We conjecture that this is partly due to the following decomposition of the loss Hessian, which can be written as 

\[
\nabla^2_x f(x) \sim \nabla_x f_i(x) \nabla^2_{f_j} \text{LSE}(x) \nabla_x f_i(x) + \nabla f_j \text{LSE}(x) \nabla^2_x f_i(x),
\]

where LSE(x) is the LogSumExp function, and \( f_i(x) \) is the pre-softmax logit output. We observe that the first term strongly depends on the gradients, which may explain the Hessian regularization effects of GradReg, while the second term depends on the Hessian of the bulk of the neural network, which is penalized by the LCNN penalties. This also explains why combining both penalizations (LCNN + GradReg) further reduces curvature.

In addition, the average per-epoch training times on a GTX 1080Ti are: standard models / softplus + weight decay (∼ 100 sec), LCNN (∼ 160 sec), GradReg (∼ 270 sec), LCNN+GradReg (∼ 350 sec), CURE / Adversarial Training (∼ 500 sec). Note that the increase in computation for LCNN is primarily due to the use of spectral normalization layers. The results show that LCNNs are indeed able to penalize curvature by only marginally (1.6×) increasing training time, and using LCNN+GradReg only increases times 1.3× over GradReg while providing curvature benefits.

Table 1: Model geometry of various ResNet-18 models trained with various regularizers on the CIFAR100 test dataset. Gradient norm regularized models [26] (‘GradReg’) are best at reducing gradient norms, while LCNN-based models are best at reducing curvature, leaving gradients unpenalized. We obtain the benefits of both by combining these penalties. Results are averaged across two runs.

| Model                  | \( E_x \| \nabla^2_x f(x) \|_2 \) | \( E_x \| \nabla^2_x f(x) \|_2 \) | \( E_x C_f(x) \) | Accuracy (%) |

5.2 Evaluating the Impact of Curvature on Gradient Robustness

In §4.1, we showed that low-curvature models must have robust gradients. Here we evaluate whether this is true in practice by measuring the relative gradient robustness for the models with various ranges of curvature values and noise levels. In particular, we measure robustness to random noise at fixed magnitudes ranging logarithmically from \(1 \times 10^{-3}\) to \(1 \times 10^{-1}\). We plot our results in Figure 2 where we find that our results match theory (i.e, the simplified quadratic approximation in §4.1) quite closely in terms of the overall trends, and that low curvature models have an order of magnitude improvement in robustness over standard ones. The close correspondence with theory also shows that deep neural networks can be well-approximated locally by a quadratic.

5.3 Robustness

Our theory in §4.2 shows that having low curvature is necessary along with having small gradient norms for robustness. In this section we evaluate this claim empirically, by evaluating adversarial examples via \( \ell_2 \) PGD [5] adversaries with various noise magnitudes. We use the Cleverhans library [28] to implement PGD. Our results are present in Table 2 where we find that LCNN+Grad models perform on par with adversarial training, without a resulting accuracy loss.
The current limitations of our approach are that we only consider convolutional and fully connected layers, and not self-attention or recurrent layers. We also do not investigate the learning-theoretic benefits (or harms) of low-curvature models, or characterize how they may improve generalization.

5.4 Train-Test Discrepancy in Model Geometry

During our experiments, we observed a consistent phenomenon where the gradient norms and Hessian norms for test data points were much larger than those for the train data points, which hints at a form of overfitting with regards to these quantities. We term this phenomenon as the train-test discrepancy in model geometry. Interestingly, we did not observe any such discrepancy using our proposed curvature measure, indicating that our proposed measure may be a more reliable measure of model geometry. We report our results in Table 3, where we measure the relative discrepancy, finding that the discrepancy for our proposed measure of curvature is multiple orders of magnitude smaller than the corresponding quantity for gradient and Hessian norms. We leave further investigation of this phenomenon – regarding why curvature is stable across train and test – as a topic for future work.

6 Discussion

In this paper, we presented a modular approach to remove excess curvature in neural network models. Importantly, we found that combining vanilla LCNNs with gradient norm regularization resulted in models with the smallest curvature, the most stable gradients as well as those that are the most adversarially robust.

Table 2: Results indicating off-the-shelf model accuracies (%) upon using $\ell_2$ PGD adversarial examples across various noise magnitudes. Adversarial training performs the best overall, however sacrifices clean accuracy. LCNN + GradReg models perform similarly but without significant loss of clean accuracy. Results are averaged across two runs.

| Model            | Acc. (%) | $\|\epsilon\|_2 = 0.05$ | $\|\epsilon\|_2 = 0.1$ | $\|\epsilon\|_2 = 0.15$ | $\|\epsilon\|_2 = 0.2$ |
|------------------|----------|--------------------------|--------------------------|--------------------------|--------------------------|
| Standard         | 77.42 ± 0.10 | 59.97 ± 0.11          | 37.55 ± 0.13             | 23.41 ± 0.08             | 16.11 ± 0.21             |
| LCNN             | 77.16 ± 0.07  | 61.17 ± 0.05           | 39.72 ± 0.17             | 25.60 ± 0.32             | 17.66 ± 0.18             |
| GradReg          | 77.20 ± 0.26  | 71.90 ± 0.11           | 61.06 ± 0.03             | 49.19 ± 0.12             | 38.09 ± 0.47             |

A Proof of Theorem 1

In this section, we provide the proof of the main theorem in the paper, which decomposes overall curvature into curvatures and slopes of constituent layers. We state Theorem 1 below for reference.

**Theorem 2.** Given a function \( f = f_L \circ f_{L-1} \circ \ldots \circ f_1 \) with \( f_i : \mathbb{R}^{n_i-1} \to \mathbb{R}^{n_i} \), the curvature \( C_f \) can be bounded as follows

\[
C_f(x) \leq \sum_{i=1}^{L} n_i \times C_{j_i}(x) \prod_{j=1}^{i} \| \nabla f_{j-1} f_j(x) \|_2 \leq \sum_{i=1}^{L} n_i \times \max_{x} C_{j_i}(x) \prod_{j=1}^{i} \max_{x} \| \nabla f_{j-1} f_j(x) \|_2.
\]

(6)

This statement is slightly different than the one given in the paper, differing by a term of the width of each nonlinear layer. Since we do not use or care about the units of curvature, only its minimization, and have elected to equally-weight each term of the sum, this is an inconsequential discrepancy.

A similar bound is constructed recursively in [29]. [15] gives a similar formula, albeit for the Frobenius norm. The Frobenius norm is both simpler, because the sum of squared entries is independent of the layout of the data, and also weaker, since it cannot deliver a bound which holds uniformly in the data. To our knowledge Equation 6 is the first explicit, easily-interpreted formula of its type.

We start with some preliminaries, with the actual proof being in subsection A.4.

A.1 Derivatives of compositional functions

For a function \( f : \mathbb{R}^d \to \mathbb{R}^r \), let \( \nabla f : \mathbb{R}^d \to \mathbb{R}^{d \times r} \) denote its gradient, and \( \nabla^2 f : \mathbb{R}^d \to \mathbb{R}^{d \times r \times d} \) denote its Hessian. We drop the subscripts on the differentiation operators for brevity. We drop the argument to functions when possible, and all norms will be spectral norms.

Given \( L \) functions \( f_i : \mathbb{R}^{n_i-1} \to \mathbb{R}^{n_i}, i = 1 \ldots, L \) let \( f_{k,k+j} = f_{k+j} \circ f_{k+j-1} \circ \ldots \circ f_k : \mathbb{R}^{n_{k-1}} \to \mathbb{R}^{n_{k+j}} \) for \( 1 \leq k \leq k+j \leq L \). This function composition will be our model of a deep neural network where \( f_k \) represents the action of the \( k \)th layer.

If each \( f_i \) is continuously differentiable, we have this formula for the gradient of \( f_{k,k+j} \)

\[
\nabla f_{k,k+j} = \prod_{i=1}^{j} \nabla f_{k+j-i+1} \in \mathbb{R}^{n_{k+j} \times n_k}.
\]

(7)

where we adopt the convention that \( f_{j,j}(x) = x \) in order to make the boundary conditions correct. The product begins at the end, with \( \nabla f_{k+j} \) and progresses forward through the indices – a straightforward consequence of the chain rule of differentiation. Supposing moreover that each \( f_i \) is twice-differentiable, we have this formula for the second derivative of \( f_{1,k} \):

\[
\nabla^2 f_{1,k} = \sum_{i=1}^{k} \nabla^2 f_{1,i} - \nabla^2 f_{1,i-1}
\]

(8)

where \( (\nabla^2 f_{1,i} - \nabla^2 f_{1,i-1}) = (\nabla^2 f_{i}) (\nabla f_{i-1}^T, \nabla f_{i+1,k}^T, \nabla f_{i,k}) \in \mathbb{R}^{n_{0} \times n_{k} \times n_{0}} \)

and we have used the **covariant multilinear matrix multiplication** notation: \( \nabla^2 f_i \) is an order-three tensor \( \in \mathbb{R}^{n_i \times n_i \times n_i} \), with the first and third modes multiplied by \( \nabla f_{1,i-1} \in \mathbb{R}^{n_i \times n_0} \) and the second mode multiplied by \( \nabla f_{1,k} \in \mathbb{R}^{n_i \times n_k} \).

A.2 Tensor calculus

In this section, we present a simplified version of the notation from [20]. A \( k \)-linear map is a function of \( k \) (possibly multidimensional) variables such that if any \( k-1 \) variables are held constant, the map is linear in the remaining variable. A \( k \)-linear function is can be represented by an order-\( k \) tensor \( \mathcal{A} \) given elementwise by \( \mathcal{A} = [a_{j_1 \ldots j_k}] \in \mathbb{R}^{d_1 \times \ldots \times d_k} \).
The covariant multilinear matrix multiplication of a tensor with matrices (order 2 tensors) \( M_1 = (m_{i_1j_1}^{(1)}) \in \mathbb{R}^{d_1 \times s_1}, \ldots, M_k = (m_{i_kj_k}^{(k)}) \in \mathbb{R}^{d_k \times s_k} \) is

\[
A(M_1, \ldots, M_k) = \begin{bmatrix}
d_1 & \cdots & d_k \\
\sum_{i_1=1}^{d_1} \cdots \sum_{i_k} a_{i_1 \ldots i_k} m_{i_1j_1}^{(1)} \cdots m_{i_kj_k}^{(k)}
\end{bmatrix} \in \mathbb{R}^{s_1 \times \ldots \times s_k}.
\]

This operation can be implemented via iterated einsums as:

```python
def covariant_multilinear_matmul(a: torch.Tensor, mlist: List[torch.Tensor]) -> torch.Tensor:
    order = a.ndim
    base_indices = string.ascii_letters
    indices = base_indices[:order]
    next_index = base_indices[order]

    val = a
    for idx in range(order):
        resp_str = indices[:idx] + next_index + indices[idx+1:]
        einsum_str = indices + f"{indices[idx]}{next_index}->{resp_str}" + mlist[idx]
        val = torch.einsum(einsum_str, val, mlist[idx])

    return val
```

For example, covariant multilinear matrix multiplication of an order two tensor is pre- and post-multiplication by its arguments: \( A_1^1 A_2 \). The generalization of the matrix spectral norm is \( ||A||_2 = \sup \{ A(x_1, \ldots, x_k) : ||x_i|| = 1, x_i \in \mathbb{R}^{d_i}, i = 1, 2, \ldots, k \} \). The computation of order-\( k \) operator norms is hard in theory, and also in practice (cf. [30]). In order to address this difficulty, we introduce an instance of the *unfold* operator.

For \( A \in \mathbb{R}^{d_1 \times d_2 \times d_3} \), \( \text{unfold}_{\{1,2,3\}}(A) \in \mathbb{R}^{d_1 d_2 \times d_3} \) is the matrix with the \( j \)th column being the flattened \( j \)th (in the final index) \( d_2 \times d_3 \) matrix. Unfolding is useful because it allows us to bound an order-3 operator norm in terms of order-2 operator norms – Wang et al. [20] shows that \( ||A|| \leq ||\text{unfold}_{\{1,2,3\}}(A)|| \). The upper bound, the operator norm of a matrix, can computed with standard largest singular-value routines. A similar unfolding-based bound was used in the deep-learning context by [31] to give improved estimates on the spectral norm of convolution operators.

To facilitate the analysis of unfolded tensors, we coin operations that *put* to the diagonal of tensors:

- \( \text{pdiag}_2 : \mathbb{R}^d \mapsto \mathbb{R}^{d \times d} \) defined by \( \text{pdiag}_2(x)_{ij} = \begin{cases} x_j & \text{if } i = j \\ 0 & \text{otherwise} \end{cases} \)
- \( \text{pdiag}_3 : \mathbb{R}^d \mapsto \mathbb{R}^{d \times d \times d} \) defined by \( \text{pdiag}_3(x)_{ijk} = \begin{cases} x_j & \text{if } i = j = k \\ 0 & \text{otherwise} \end{cases} \)

Further, let \( 1_n \in \mathbb{R}^n \) be a vector of ones, \( I_n = \text{pdiag}_2(1_n) \in \mathbb{R}^{n \times n} \) be the \( n \)-dimensional identity matrix, and \( I_n = \text{pdiag}_3(1_n) \in \mathbb{R}^{n \times n \times n} \). For two vectors \( a \in \mathbb{R}^n, b \in \mathbb{R}^n \), let \( ab \) denote the elementwise product. \( \otimes \) denotes the well-understood Kronecker product, so that, for example, \( I_n \otimes I_m \) is an \( m \times nm \) matrix consisting of \( n \) copies of the \( m \times m \) identity matrix stacked side by side. Where it is redundant, we drop the subscripts indicating dimension.

We use the following facts about tensors, their unfoldings, and their operator norms, in what follows.

1. \( A = \text{pdiag}_3(ab) \implies A(M_1, M_2, M_3) = I(M_2)M_1, M_2, \text{pdiag}_2(b)M_3) \)
2. \( \text{unfold}_{\{1,2,3\}}(I(M_1, M_2, M_3)) = (M_1 \otimes I_{s_2})^\top \text{unfold}_{\{1,2,3\}}(I(I_{d_1}, M_2, M_3)) \)
3. \( ||(1_{d_1}^\top \otimes I_{s_2}) \text{unfold}_{\{1,2,3\}}(I(I_{d_1}, M_2, M_3))|| \leq ||M_2^2 M_3||s_2 \)

Taken together Fact #2 and #3 imply that

\[ ^* \text{In PyTorch notation, } \text{unfold}_{\{1,2,3\}}(a) = \text{torch.flatten}(a, \text{end_dim}=1) \]
\[ \|\text{unfold}_{(1,2),(3)}(\mathcal{I}(M_1, M_2, M_3))\| \leq \|M_1\| \times \|M_2^T M_3\| \times s_2 \] (9)

which is our essential bound for the norm of an order-3 tensor in terms of order-2 tensors.

### A.3 Hessian increment bound

Let \( \sigma(x) = \exp(x)/(1 + \exp(x)) \) denote the (elementwise) logistic function \( \mathbb{R}^d \mapsto \mathbb{R}^d \). The derivatives of \( s(x; \beta) \) can be written as

\[
\nabla s(x; \beta) = \text{pdiag}2(\sigma(\beta x)) \in \mathbb{R}^{d \times d}
\]
(10)

\[ \nabla^2 s(x; \beta) = \text{pdiag}3(\sigma(\beta x)(1 - \sigma(\beta x))) \in \mathbb{R}^{d \times d \times d}. \]
(11)

Let the \( i \)th softplus layer have coefficient \( \beta_i \), then the increment from Equation 8 can be bounded as follows:

\[ \|\nabla^2 f_i (\nabla f_{1,i-1}, \nabla f_{i+1,k}, \nabla f_{1,i-1})\| \]
(12)

\[ = \|\beta_i \mathcal{I}_n (\text{pdiag}2(1 - \sigma(\beta x))\nabla f_{i,i-1}, \nabla f_{i+1,k}, \text{pdiag}2(\sigma(\beta x))\nabla f_{1,i-1})\| \]
(13)

\[ \leq \|\beta_i \text{unfold}_{(1,2),(3)}(\mathcal{I}_n (\text{pdiag}2(1 - \sigma(\beta x))\nabla f_{i,i-1}, \nabla f_{i+1,k}, \text{pdiag}2(\sigma(\beta x))\nabla f_{1,i-1})]\|
(14)

\[ \leq \|\beta_i (\text{pdiag}2(1 - \sigma(\beta x))\nabla f_{i,i-1})\| \times \|\nabla f_{i+1,k}\text{pdiag}2(\sigma(\beta x))\nabla f_{1,i-1}\| \times n_i \]
(15)

\[ \leq n_i \times \|\beta_i \text{pdiag}2(1 - \sigma(\beta x))\| \times \|\nabla f_{i,i-1}\| \times \|\nabla f_{i+1,k}\nabla f_{i}\nabla f_{1,i-1}\| \]
(16)

\[ \Rightarrow = n_i \times C_{f_i} \times \|\nabla f_{1,i-1}\| \times \|\nabla f\|. \]
(17)

Equation 13 follows by Fact #1 above, along with Equation 11. Equation 14 is the standard unfolding bound by [20]. Equation 15 is our main bound on order-3 tensors in terms of order-2 matrices, Equation 9 follows from the Cauchy-Schwarz inequality. The replacement in the last term of the product is Equation 10. Equation 17 rewrites Equation 16 using Equation 7.

\[ f_{i+1,k} \nabla f_i \nabla f_{1,i-1} = \nabla f_{1,k} \]

and the definition of the curvature of \( f_i \).

### A.4 Putting it together

Ignoring the \( \epsilon \) term,

\[ C_f(x) = \frac{\|\nabla^2 f(x)\|}{\|\nabla x f(x)\|} \]
(18)

\[ = \frac{1}{\|\nabla x f(x)\|} \sum_{i=1}^{L} \|\nabla^2 f_{1,i}(x) - \nabla^2 f_{1,i-1}(x)\| \]
(19)

\[ \leq \frac{1}{\|\nabla x f(x)\|} \sum_{i=1}^{L} \|\nabla^2 f_{1,i}(x) - \nabla^2 f_{1,i-1}(x)\| \]
(20)

\[ \leq \sum_{i=1}^{L} n_i \times C_{f_i}(x) \times \|\nabla f_{1,i-1}(x)\| \]
(21)

\[ \leq \sum_{i=1}^{L} n_i \times C_{f_i}(x) \times \prod_{i=1}^{j} \|\nabla f_i(x)\| \]
(22)

\[ \leq \sum_{i=1}^{L} n_i \times \max_x C_{f_i}(x) \times \prod_{i=1}^{j} \max_x \|\nabla f_i(x)\| \]
(23)

Equation 19 is Equation 8. Equation 20 is the triangle inequality. Equation 21 is Equation 17, along with cancelling the term of \( \|\nabla f\| \) top and bottom. Equation 22 are Equation 23 are obvious and a standard simplification in the literature on controlling the Lipschitz constant of neural networks. Because exactly computing the smallest Lipschitz constant of a general neural network is NP-complete, a widely-used baseline measure of Lipschitz-smoothness is rather the product of the Lipschitz constants of smaller components of the network, such as single layers (32).
B Loss curvature vs logit curvature

We have thusfar discussed how to assure a bound on curvature independent of the input $x$. However, a truly data-independent bound must also not depend on the class label $y$. In this short section we discuss the main consideration that accompanies this: the differences between loss and (pre-softmax) logit curvature. Let the function including the loss for a class $c$ be denoted by $f^{\text{loss}}_c$, and the logit corresponding to a class $c \in [1,C]$ be $f^{\text{logit}}_c$, and let $f^{1:C}_{\text{logit}}$ denote the vector valued function corresponding to all the logits. Then we have $f^{\text{loss}}_c = \text{lsm}^c \circ f^{1:C}_{\text{logit}}$, where $\text{lsm}^c(x) = -\log \frac{\exp(x_c)}{\sum_{i=1}^C \exp(x_i)} = -x_c + \log \sum_{i=1}^C \exp(x_i)$ is the negative log softmax function.

The derivatives of this function are:

$$\frac{d\text{lsm}^c(x)}{dx_c} = \frac{\exp(x_c)}{\sum_{i=1}^C \exp(x_i)} - 1$$

$$\frac{d^2\text{lsm}^c(x)}{dx_c^2} = \frac{\exp(x_c)}{\sum_{i=1}^C \exp(x_i)} \left(1 - \frac{\exp(x_c)}{\sum_{i=1}^C \exp(x_i)}\right)$$

whose norm is upper bounded by 1 and 0.25 respectively. This implies that bounding the logit curvature also ensures that the loss curvature is bounded, as the gradients and Hessians of the negative log softmax layer do not explode. In other words, $C_{f^{\text{loss}}} < C_{f^{\text{logit}}}$.

However penalizing an upper bound may not be the most efficient way to penalize the loss Hessian. Consider the following decomposition of the loss Hessian, which can be written as $\nabla_x^2 f(x) \sim \nabla_x f^{\text{logit}}(x) \nabla_f^\text{LSE}(x) \nabla_x f^{\text{logit}}(x)^\top + \nabla_f^\text{LSE}(x) \nabla_x^2 f^{\text{logit}}(x)$, where $\text{LSE}(x)$ is the LogSumExp function. Thus a more efficient way to penalize the loss Hessians is to both use our LCNN penalties, as well as penalize the gradient norm, which we also find to be true in our experiments.

C $\gamma$-Lipschitz Batchnorm

We present here a Pytorch-style pseudo-code for the $\gamma$-Lipschitz Batchnorm for clarity.

```python
self.bn = nn.BatchNorm2d(in_channels, affine=False)
gamma = nn.Parameter(torch.tensor(10.))
...
# perform spectral normalization for BN in closed form
bn_spectral_norm = torch.max(1 / (self.bn.running_var + 1e-5).sqrt())
one_lipschitz_bn = self.bn(x) / bn_spectral_norm
# multiply normalized BN with a learnable scale
return one_lipschitz_bn * torch.minimum(bn_spectral_norm, 1. + gamma)
```

D Proofs of LCNN Properties

Here we present proofs for the properties linking LCNNs to gradient smoothness and adversarial robustness. To this end, we first prove a lemma that is used in both these results, which states that the gradient norm can rise exponentially in the worst case. In the text below, $B_r(x)$ denotes the $r$-ball around $x$.

**Lemma 2.** The ratio of gradient norms at nearby points rises exponentially with distance between those points. For a function $f$ whose curvature is $\max_{x \in B_r(x)} C_f(x) = \delta_C$, points $x$ and $x + \epsilon$ that are $\|\epsilon\|_2 = r$ away, we have

$$\frac{\|\nabla f(x + \epsilon)\|_2}{\|\nabla f(x)\|_2} \leq \exp(r\delta_C)$$
Proof. Let \( g(x) = \log \|\nabla_x f(x)\|^2 \). Applying a first order Taylor series with Lagrange remainder formula, we have

\[
g(x + \epsilon) - g(x) = \nabla_x g(x + \xi) \top \epsilon
g(\|\nabla_x f(x + \epsilon)\|^2) \leq 2 \frac{\nabla_x f(x + \xi) \nabla_x^2 f(x + \xi) \top \epsilon}{\|\nabla_x f(x + \xi)\|^2}
\]

(Cauchy-Schwartz inequality)

\[
\leq 2 \frac{\|\nabla_x f(x + \xi)\|_2 \|\nabla_x^2 f(x + \xi)\|_2 \|\epsilon\|_2}{\|\nabla_x f(x + \xi)\|^2}
\]

\[
\leq 2r\delta_C
\]

Note that to apply the Cauchy-Schwartz inequality, we first upper bound the term on the right by its 2-norm, which for a scalar is simply its absolute value. Taking exponent on both sides of the final expression and taking square root, we have the intended result.

\[ \square \]

D.1 LCNNs have Robust Gradients

Proposition 3. Let \( \max_{x \in B_r(x)} C_f(x) \leq \delta_C \), then the relative distance between gradients at \( x \) and \( x + \epsilon \) is

\[
\frac{\|\nabla_x f(x + \epsilon) - \nabla_x f(x)\|_2}{\|\nabla_x f(x)\|_2} \leq r\delta_C \exp(r\delta_C) \sim rC_f(x) \ \text{(Quadratic Approximation)}
\]

Proof. We begin the proof by invoking the Taylor series approximation of \( \nabla_x f(x + \epsilon) \) at \( x \), and using the explicit Lagrange form of the Taylor error. This is equivalent to using a form of the multivariate mean-value theorem. Let \( \xi \in B_r(x) \), then there exists some \( \xi \) such that the following holds

\[
\nabla_x f(x + \epsilon) - \nabla_x f(x) = \nabla_x^2 f(x + \xi) \top \epsilon \ \text{(Taylor Series)}
\]

\[
\|\nabla_x f(x + \epsilon) - \nabla_x f(x)\|_2 \leq \|\nabla_x^2 f(x + \xi)\|_2 \|\epsilon\|_2 \ \text{(Cauchy-Schwartz inequality)}
\]

\[
\frac{\|\nabla_x f(x + \epsilon) - \nabla_x f(x)\|_2}{\|\nabla_x f(x)\|_2} \leq C_f(x + \xi_0) \|\nabla_x f(x + \xi)\|_2 \ \text{(Divide by gradnorm)}
\]

Plugging in the value of \( \|\nabla_x f(x + \xi_0)\|_2/\|\nabla_x f(x)\|_2 \) from Lemma 2, and further upper bounding \( C_f(x + \xi) \leq \delta_C \), we have the intended result.

To derive the simplified quadratic approximation, replace the first step in the Taylor series with \( \nabla_x f(x + \epsilon) - \nabla_x f(x) = \nabla_x^2 f(x + \xi) \top \epsilon \), i.e., use \( \xi = 0 \).

\[ \square \]

D.2 Curvature is Necessary for Robustness

Proposition 4. Let \( \max_{x \in B_r(x)} C_f(x) \leq \delta_C \), then for two points \( x \) and \( x + \epsilon \),

\[
\|f(x + \epsilon) - f(x)\|_2 \leq r\|\nabla_x f(x)\|_2 \left(1 + \frac{1}{2}r\delta_C \exp(r\delta_C)\right) \sim r\|\nabla_x f(x)\|_2 \left(1 + \frac{1}{2}rC_f(x)\right) \ \text{(Quadratic Approximation)}
\]
Proof. Let $\xi \in B_{\epsilon}(x)$, then there exists some $\xi$ such that the following holds

$$f(x + \epsilon) - f(x) = \nabla_x f(x)^T \epsilon + \frac{1}{2} \epsilon^T \nabla_x^2 f(x + \xi) \epsilon$$  \hspace{1cm} \text{(Taylor Series)}$$

$$\|f(x + \epsilon) - f(x)\|_2 \leq \|\nabla_x f(x)^T \epsilon\|_2 + \frac{1}{2} \epsilon^T \nabla_x^2 f(x + \xi) \epsilon \|_2$$  \hspace{1cm} \text{(\triangle inequality)}$$

$$\leq \|\nabla_x f(x)\|_2 \|\epsilon\|_2 + \frac{1}{2} \lambda_{\text{max}}(x + \xi) \|\epsilon\|_2^2$$  \hspace{1cm} \text{(Cauchy-Schwarz inequality)}$$

$$\leq \|\nabla_x f(x)\|_2 \|\epsilon\|_2 + \frac{1}{2} C_f(x + \xi) \|\epsilon\|_2^2 \|\nabla_x f(x + \xi)\|_2$$  \hspace{1cm} \text{(Defn of } C_f(x + \xi)\text{)}$$

Factoring out $\|\nabla_x f(x)\|_2 \|\epsilon\|_2$ in the RHS, and using Lemma 2 and further upper bounding $C_f(x + \xi) \leq \delta_C$ we have the intended result.

To derive the simplified quadratic approximation, replace the first step in the Taylor series with $f(x + \epsilon) - f(x) = \nabla_x f(x)^T \epsilon + \frac{1}{2} \epsilon^T \nabla_x^2 f(x) \epsilon$, i.e., use $\xi = 0$.

$\square$

E Experimental Settings

In this section we elaborate on the hyper-parameter settings used for our tuning our models. For the standard ResNet-18, we use standard hyper-parameter settings as indicated in the main paper, and we do not modify this for the other variants. For LCNNs, we chose regularizing constants as $\lambda_\beta = 10^{-4}$ and $\lambda_\gamma = 10^{-3}$. For GradReg, we use $\lambda_{\text{grad}} = 10^{-3}$, and for LCNNs + GradReg, we chose $\lambda_\beta = 10^{-4}$, $\lambda_\gamma = 10^{-5}$, $\lambda_{\text{grad}} = 10^{-3}$. We performed a coarse grid search and chose the largest regularizing constants that did not affect predictive performance.
