Abstract

The beam energy measurement system (BEMS) for the upgraded Beijing electron-positron collider BEPC-II is described. The system is based on measuring the energies of Compton back-scattered photons. The relative systematic uncertainty of the electron and positron beam energy determination is estimated as $2 \cdot 10^{-5}$. The relative uncertainty of the beam’s energy spread is about 6%.

Keywords: compton backscattering, beam energy calibration, collider BEPC-II, tau-charm factory

1. Introduction

The upgraded Beijing electron-positron collider (BEPC-II) is a $\tau$-charm factory with a center of mass energy range from 2.0 to 4.6 GeV and a design peak luminosity of $10^{33}$ cm$^{-2}$ s$^{-1}$\textsuperscript{[1]}. For experiments at BEPC-II, the BESIII (Beijing spectrometer) detector with high efficiency and resolution both for charged and neutral particles was constructed\textsuperscript{[2]}. BESIII started data taking in 2008. The BESIII research program covers charmonium physics, $D$-meson physics, spectroscopy of light hadrons and $\tau$-lepton physics\textsuperscript{[3]}. The $\tau$-lepton is a fundamental particle, and its mass is a Standard Model parameter, which requires that its mass be determined with high precision. The measurements of the $\psi$ and $D$ meson masses are also of interest.

The current value of the $\tau$ mass, $m_{\tau}$, is $1776.82 \pm 0.16$\textsuperscript{[4]}. In BEPC-II/BESIII, the mass will be measured using the threshold scan method. The accuracy of the measurement was studied in Ref.\textsuperscript{[3],[6]}. Two weeks of data...
taking will lead to a statistical uncertainty of less than 50 keV. The systematic uncertainty (without the accuracy of beam energy determination) is about 20 keV and includes uncertainties of the luminosity, detection efficiency, branching fraction, background, energy spread, and theoretical uncertainty. The most important source of uncertainty is the accuracy of the absolute beam energy determination.

In some cases, the energy scale of colliders can be calibrated with extremely high accuracy using the resonant depolarization technique \[7\]. But this approach is not applicable for \(e^+e^-\) factories, where the great advance in luminosity is made possible by fast bunch-to-bunch feedback systems that usually have a strong depolarization impact on the beam. There are two possible methods of the beam energy determination at BEPC-II. First is a calibration of the energy scale from scan of the \(J/\psi\) and \(\psi'\) resonances \[8\]. The expected accuracy in this case is about 100 keV.

Another possibility is the beam energy measurement using Compton back-scattering of monochromatic laser radiation on the \(e^\pm\) beams. This approach was developed and experimentally proved in Ref. \[9, 10, 11, 12\]. At the BESSY-I and BESSY-II storage rings, the relative accuracies of energy measurement of about \(10^{-4}\) and \(3 \times 10^{-5}\) for the beam energies of 800 and 1700 MeV, respectively, were achieved \[11\]. In collider experiments, this method was applied at VEPP-4M \[12\]. Based on the VEPP-4M experience, such a system was proposed and constructed for BEPC-II \[13, 14\]. In this paper, the system design and performance are reported.

2. The Compton Back-scattering approach

Let us consider the Compton scattering process in a case where the angle \(\alpha\) between initial particles is equal to \(\pi\) and their energies are \(\omega_0 \ll m_e \ll \varepsilon\) (Fig. 1). Here \(\omega_0\) and \(\varepsilon\) are the energies of the initial photon and electron, respectively. The back-scattered photons with \(\theta = 0\) have the maximal energy (Fig. 2), and the energy spectrum of the scattered photons has a sharp edge at the maximal energy (Fig. 3).

The general idea is based on the following:

- The maximal energy of the scattered photon \(\omega_{max}\) is related with the electron energy \(\varepsilon\) by the kinematics of Compton scattering \[13\]:

\[
\omega_{max} = \frac{\varepsilon^2}{\varepsilon + m_e^2/4\omega_0},
\]

(1)

If one measures \(\omega_{max}\), then the electron energy can be calculated:

\[
\varepsilon = \frac{\omega_{max}}{2} \left[ 1 + \sqrt{1 + \frac{m_e^2}{\omega_0 \omega_{max}}} \right].
\]

(2)
Figure 1: The Compton scattering process. $\varepsilon, \omega_0$, and $\omega$ are the particles energies, and $\alpha = \pi$.

Figure 2: The dependence of the scattered photon energy $\omega$ on the angle $\theta$ between the initial electron and the final photon in the Compton scattering process. The initial electron and photon energies are $\omega_0 = 0.12$ eV and $\varepsilon = 1770$ MeV, respectively, and $\alpha = \pi$.

Figure 3: Energy spectrum of scattered Compton photons. The initial electron and photon energies are $\omega_0 = 0.12$ eV and $\varepsilon = 1770$ MeV, respectively, and $\alpha = \pi$. 
• The ultra-high energy resolution (\(\sim 10^{-3}\)) of commercially available High Purity Germanium (HPGe) detectors allows the statistical accuracy in the beam energy measurement to be at the level of \(\delta\varepsilon/\varepsilon \approx 10^{-5}\).

• The systematical accuracy is mostly defined by absolute calibration of the detector energy scale. Accurate calibration can be performed in the photon energy range up to about 10 MeV by using \(\gamma\)-active radionuclides.

The measurement procedure is as follows. As a source of initial photons, the monochromatic laser radiation with \(\omega_0 \approx 0.12\) eV is used. The laser light is put in collision with the electron or positron beams, and the energy of the back-scattered photons is precisely measured using the HPGe detector. The maximal energy of the scattered photons is determined by fitting the abrupt edge in the energy spectrum by the erfc-like function (Fig. 4). The relation between the measured \(\omega_{\text{max}}\) and the beam energy \(\varepsilon\) is shown in Fig. 5. The detector energy scale is accurately calibrated by using well-known radiative sources of \(\gamma\)-radiation (Fig. 5).

3. The beam energy measurement system for BEPC-II.

The beam energy measurement system is located at the north beam crossing point of the BEPC-II storage rings (Fig. 6). This location allows measurement of the electron and positron beams energy by the same HPGe detector. The layout schematic of the system is shown in Fig. 7.

The system consists of the laser source, optical and laser-to-vacuum insertion systems to transport the laser beam into the interaction regions where the laser beam collides with either the electron or positron beam, and the HPGe detector to measure back-scattered photons. The laser and optical system elements are deployed in the corridor outside the collider hall.

The laser and electron (positron) beams interact in the straight sections of the collider’s rings beyond the R2IAMB (R1IAMB) dipole magnets. The total yield of scattered photons was estimated in Ref. [13] and is about 17000 gammas per second, per 1 mA of electron (positron) beam current, per 1 W of laser power.

3.1. Laser and optical system

The source of initial photons is the GEM Selected 50\textsuperscript{TM} \(\text{CO}_2\) laser from Coherent, Inc.. It is a continuous operation (CW), high power, and single-line laser. It provides 25 W of CW power at the wavelength \(\lambda_0 = 10.835231\) µm (\(\gamma\)-quantum energy \(\omega_0 = 0.114426901\) eV), which corresponds to the 10P42 transition in the carbon dioxide molecule \(\text{CO}_2\). \(\omega_0\) is known with relative accuracy better then 0.1 ppm. The relative width of the laser photon spectrum is \(\sigma_\omega/\omega_0 \approx 3\) ppm. This wavelength was adopted in order to avoid any interference between \(\gamma\)-radiation lines of radiative sources, used for HPGe detector calibration, and the Compton edges of all interesting energy points in the \(\tau\)-charm.
Figure 4: The measured edge of the scattered photons energy spectrum. The line is the fit result.

Figure 5: Relation between $\omega_{\text{max}}$ and $\varepsilon$ (solid line). Dots are the energies of $\gamma$-active radionuclide reference lines for the HPGe detector calibration. The initial photon energy is $\omega_0 = 0.12$ eV.
Figure 6: Location of the energy measurement system at the BEPC-II collider. The deployment place is indicated as “beam energy detector”.

Figure 7: Simplified schematic of the energy measurement system. The positron and electron beams are indicated. R1IAMB and R2IAMB are accelerator magnets, and the HPGe detector is represented by the dot at the center. The shielding wall of the beam tunnel is shown cross-hatched, and the laser is located outside the tunnel.
energy region (Fig. 8). The laser is installed on a special support which can be adjusted as necessary.

The optical system includes the following units which are situated along the collider wall (Fig. 7):

1. Two ZnSe lenses with focal lengths of \( f = 40 \) cm. The laser beam is focused at the BEPC-II vacuum chamber entrance flange, where the geometrical aperture is minimal: vertical size \( \times \) horizontal size is 14 mm \( \times \) 50 mm. The total distance from the laser output aperture to the entrance flange of the BEPC-II vacuum chamber is about 18 m. The lenses are placed at 300 and 382 cm from the laser and provide the laser beam transverse size at the flange from 0.20 to 0.25 cm.
2. A 45° mirror, which reflects the beam through an angle of 90° towards the movable prism.
3. A movable reflector prism which directs the laser beam towards the right or left mirror.
4. Two mirrors to reflect the right or left-traveling laser beam into the collider tunnel through holes in the concrete wall. The laser beam is incident on a viewport in a vacuum pipe extension of the beam pipe. The mirrors are installed on special supports that allow precise vertical and horizontal angular alignment by the use of stepping motors (one step equals \( 1.5 \times 10^{-6} \) rad).

3.2. Laser-to-vacuum insertion system

The insertion of the laser beam into the vacuum chamber is performed using the laser-to-vacuum insertion system. The system is the special stainless steel vacuum chamber with a GaAs entrance viewport \([16]\) and water cooled copper mirror (Fig. 9). In the vacuum chamber, the laser beam is reflected through an angle of 90° by the copper mirror. After back-scattering, the photons return to the mirror, pass through it, leave the vacuum chamber, and are detected by the HPGe detector. Note, the copper mirror protects the viewport against high power synchrotron radiation due to low reflectivity of high energy photons (less than 1%) from a metallic surface.

The copper mirror design is shown in Fig. 10. The mirror can be turned by bending the vacuum flexible bellows, so the angle between the mirror and the laser can be adjusted as necessary. Synchrotron radiation (SR) photons heat the mirror. In order to reduce the heating of the mirror, it is placed 1.8 m from the BEPC-II vacuum chamber flange. The SR power absorbed by the mirror is about 200 W. The extraction of heat is provided by a water cooling system. To prevent adsorption of residual gas molecules on the mirror surface, it is covered with a 0.5 \( \mu \)m thick gold layer.

The viewport based on the GaAs mono-crystal provides:

1. transmission spectrum from 0.9 up to 18 \( \mu \)m,
2. baking out of the vacuum system up to 250°C,
3. extra high high vacuum.
Figure 8: The relation between beam energy $\varepsilon$ and energy of back-scattered Compton photons $\omega_{\text{max}}$. The $\gamma$ lines of $^{16}\text{O}^*$ are also shown.

Figure 9: Simplified schematic of the laser-to-vacuum insertion assembly.

Figure 10: Copper mirror.
The viewport design is shown in Fig. 11. It includes a 304 L steel DN63 conflat flange and a GaAs crystal plate with diameter of 50.8 mm and thickness of 3 mm. In order to compensate mechanically for the difference of the GaAs and stainless steel thermal expansion coefficients, the GaAs plate is brazed with pure soft lead to a titanium ring, which in turn is brazed with AgCu alloy to the stainless steel ring. The stainless steel ring is welded to the flange. To avoid decomposition of the GaAs plate during brazing, it is covered with a 0.6 µm thick SiO₂ film using gas-phase deposition. The transmission spectra of the plate before and after covering are shown in Fig. 12. The transmission of the plate increases from 55 to 60 % at the CO₂ laser wavelength λ = 10.6µm and from 20 to 35% at λ = 1µm.

After installation at BEPC-II, the vacuum chambers were baked out at 250°C for 24 hours. A pressure of 2 × 10⁻¹⁰ Torr was obtained. The residual gas spectrum is shown in Fig. 13.

3.3. Adjustment of the optical elements.

The optical elements of the system were adjusted using SR. The copper mirrors of the vacuum chambers and the mirrors of the optical system were adjusted in such a way, that the SR light comes to the laser output window. Actually the GaAs is not transparent for visible light (Fig. 12) but transmits infrared radiation. In order to detect the infrared light, IR-sensitive video cameras were used.

3.4. HPGe detector

The purpose of a HPGe detector is to convert gamma rays into electrical impulses which can be used with suitable signal processing, to determine their energy and intensity. A HPGe detector is a large germanium diode of the p-i-n type operated in the reverse bias mode. At a suitable operating temperature (normally ≃100 K), the barrier created at the junction reduces the leakage current to acceptably low values. Thus an electric field can be applied that is sufficient to collect the charge carriers liberated by the ionizing radiation.

For the BEPC-II energy calibration system, we use the coaxial HPGe detector manufactured by ORTEC (model GEM25P4-70). It has diameter of 57.8 mm and height of 52.7 mm with 31.2% relative efficiency 1. The energy resolution for the 1.33 MeV line of ⁶⁰Co is 1.74 keV (FWHM). The detector is connected to the multi-channel analyzer ORTEC DSpec Pro (MCA), which transfers data using the USB port of the computer.

The HPGe spectrum has 2¹⁴ = 16384 channels. The bin error for each channel is defined as

\[ \Delta N = \sqrt{N + \left(\zeta N\right)^2}, \]  \hspace{1cm} (3)

1The efficiency of each detector is usually specified by a parameter called relative detection efficiency. The relative detection efficiency of coaxial germanium detectors is defined at 1.33 MeV relative to that of a standard 3-in.-diameter, 3-in.-long NaI(Tl) scintillator.
Figure 11: The GaAs viewport.

Figure 12: The transmission spectra of GaAs are shown for a) the 3 mm thick original plate; b) the plate covered by SiO2 film with thickness of 0.6 µm.

Figure 13: Residual gas spectrum.
where \( N \) is number of counts in the channel and \( \zeta \) corresponds to the MCA differential non-linearity, which is \( \zeta = 0.02 \) according to the MCA specifications.

Since the HPGe detector is located near the collider’s beam pipes, background due to beam loss is extremely high. In order to protect the HPGe detector from background, it is surrounded by 5 cm of lead on the sides, by 1.5 cm of iron below, and by 5 cm of lead above. The detector is also shielded by 10 cm of paraffin on all sides. Since the main background comes from the beam direction, an additional 11 cm of lead is installed in these directions. Another 10 cm of lead can be moved into the beam using movable stages to shield from the beam direction that is not being measured and moved out when the beam is being measured.

### 4. Data Acquisition System

The BEMS data acquisition system is shown in Fig. 14. The MCA digitizes the signal from the HPGe detector and produces the energy spectrum. It is connected to a Windows PC. All spectra processing, monitoring, and control over the devices involved in the BEMS is concentrated in another PC, under the control of Linux.

The data acquisition procedure is as follows. The HPGe detector measurements are read every few seconds, and the detector counting rate is calculated. If the requested acquisition time has elapsed, or if conditions of the spectrum acquisition changed sufficiently, the current spectrum is saved to a file and the next spectrum acquisition cycle is launched. Simultaneously, another process periodically requests information from the BEPC-II database and writes the BEPC-II parameters, such as beam currents, lifetimes, and luminosity, to the file.

After finishing the spectrum acquisition cycle, another program processes the spectrum; it calibrates the energy scale, finds the Compton edge, and calculates the beam energy. The beam energy is written into the BEPC-II database. Since the BEPC-II parameters and the detector counting rate are saved during the spectra acquisition, conditions of any acquired spectrum can be analyzed at any time.

During data taking, mirrors are adjusted automatically to provide maximal photon/electron (positron) interaction efficiency, using the feedback from the detector counting rate. The prism directing the laser beam to either the electron or positron beams is controlled by the same program, as are the movable stages that move the extra lead protection in and out of the beam. The processing of the beam energy measurement is fully automated by a script controlling the mirrors, the prism, and the movable shielding.

### 5. Data processing

The processing of the spectrum (Fig. 15) includes calibration of the energy scale, Compton edge fitting and the calculation of the beam energy.
The energy scale must be calibrated in the range from 2 to 8 MeV. This is the energy range of back-scattered photons at BEPCII with beam energies from 1000 to 2100 MeV (Fig. 5). The following sources were used in this work:

- $^{137}$Cs : $E_γ = 661.657 \pm 0.003$ keV
- $^{60}$Co : $E_γ = 1173.228 \pm 0.003$ keV
- $^{60}$Co : $E_γ = 1332.492 \pm 0.004$ keV
- $^{16}$O* : $E_γ = 6129.266 \pm 0.054$ keV

The goal of HPGe detector calibration is to obtain the coefficients needed for conversion of the HPGe detector’s ADC counts into corresponding energy depo-

The $^{238}$Pu $^{13}$C] gamma source is used. The nuclear reaction occurs in this source: $\alpha + ^{13}$C $\rightarrow n + ^{18}$O*. The excited oxygen emits $\gamma$-rays with energy of 6129.266 ± 0.054 keV. [17]
The energy spectrum detected by the HPGe detector is shown. Several peaks, corresponding to monochromatic $\gamma$-radiation radiative sources, as well as the abrupt edge of the Compton photons spectrum slightly below 6000 keV are clearly seen.

The calibration procedure is as follows:

1. Peak searching is performed using a ROOT algorithm based on Refs. [18, 19, 20];
2. The found peaks are identified using the atlas of the well known radiative lines;
3. The peaks which correspond to calibration lines are fitted by the sum of signal and background distributions, $f(x, x_0, \sigma, \xi) + p_1(x)$ (Fig. 16), where $p_1(x)$ is a first-order polynomial. The free parameters of the fit are $x_0, \sigma, \xi$, and the coefficients of the polynomial.
4. Using the fit results, the energy dependencies of the response function (Eqn. 4) parameters are determined. The $\sigma$ energy dependence (Fig. 17) is described by the formula:

$$\sigma_E = \sqrt{K_0 + FE_\gamma} , \quad (6)$$
where $E_\gamma$ is the photon energy, $K_0 = 0.772 \pm 0.020$ keV$^2$, and $F = 0.56 \pm 0.02$ eV. The energy dependence of the asymmetry parameter $\xi$ is approximated with an empirical function, $g(x) = p_0 + p_1 \exp(-p_2 x)$ (Fig. 18). In order to obtain the correction to the measured energy due to spectrometer scale non-linearity, the difference between positions of the calibration peaks $x_0$ and their known reference values are fitted by a second-order polynomial (Fig. 19).

The edge of the back-scattered photon spectrum (Fig. 20) is fitted by the function:

$$S_2(x, x_0, \sigma, \sigma_s, \xi) = \int_{x}^{+\infty} S_1(y, x_0, \sigma, \sigma_s, \xi) \, dy + p_1(x).$$

(7)

Here $p_1(x)$ takes into account the background contribution, and $S_1$ is a convolution of the step function $\theta(x_0 - x)$:

$$\theta(x_0 - x) = \begin{cases} 
0, & x < x_0 \\
1, & x > x_0,
\end{cases}$$

(8)

which describes the “pure” edge shape with the HPGe detector response function (Eqn. 8) and a Gaussian:

$$g(x, x_0, \sigma_s) = \frac{1}{\sqrt{2\pi}\sigma_s} \exp\left\{-\frac{(x - x_0)^2}{2\sigma_s^2}\right\},$$

(9)

which takes into account the energy spread of back-scattered photons due to energy distribution of the collider beam.

$$S_1(x, x_0, \sigma, \sigma_s, \xi) = \frac{N}{2\sqrt{2\pi}} \times$$

$$\times \left[ \frac{1}{\sigma} \exp\left(\frac{\xi^2}{2} + \frac{\sigma^2}{\sigma^2} + \frac{\xi x_0}{\sigma}\right) \cdot \text{erfc}\left(\frac{\xi(\sigma^2 + \sigma_s^2) + x}{\sqrt{2\sigma\sigma_s}}\right) + \frac{1}{\sigma} \right]$$

(10)
Figure 17: $\sigma_E$ vs the photon energy, fitted by Eqn. The fit results in $\chi^2/NDF = 1.3/2$.

Figure 18: Asymmetry parameter $\xi$ vs photon energy.

Figure 19: Energy dependence of the differences between the calibration peaks from their true values.
The 6.129 MeV peak is also seen.

\[ + \frac{1}{\sqrt{\sigma^2 + \sigma_s^2}} \exp \left( - \frac{x^2}{2(\sigma^2 + \sigma_s^2)} \right) \cdot \text{erfc} \left( - \frac{\xi(\sigma^2 + \sigma_s^2) + x\sigma}{\sqrt{2(\sigma^2 + \sigma_s^2)}\sigma_s} \right) \].

The edge position \( \omega_{\text{max}} \equiv x_0, \sigma_s \), and the coefficients of the first-order polynomial \( p_1(x) \) are the free parameters of the fit. Using the \( \omega_{\text{max}} \) value obtained from the fit, the average beam energy \( \varepsilon_{\text{nip}} \) (\( \text{n} \)ip denotes north interaction region) in the \( e^- \gamma \) interaction region is calculated according to formula (2). Taking into account the energy losses due to synchrotron radiation, the beam energy in the south interaction point (sip) is obtained as

\[ \varepsilon_{\text{sip}}(\text{MeV}) = \varepsilon_{\text{nip}}(\text{MeV}) + 4.75 \times 10^{-3} \ast (0.001 \ast \varepsilon_{\text{nip}}(\text{MeV}))^4. \] (11)

### 6. System performance

The system was put in operation and tested with beams of energy about 1840 MeV. The relative statistical accuracy of the beam energy determination of about \( 5 \ast 10^{-5} \) was achieved after approximately 1 hour of data taking. The systematical accuracy was studied by comparison of the well known mass of the \( \psi' \) resonance \( m_{\psi'} = 3686.09 \pm 0.04 \) MeV [4] with its value obtained using the BEMS.

In order to obtain the \( \psi' \) mass two scans of the resonance energy region were done with a total integrated luminosity of about 3.95 pb\(^{-1}\). The data were collected at 12 energy points over 36 hours. The \( \psi' \) mass was measured as follows.

1. The multihadronic \( e^+e^- \rightarrow \text{hadrons} \) events were selected.
2. The events of \( e^+e^- \rightarrow \gamma\gamma \) were used to determine the integrated luminosity \( L \):

\[ L = \frac{N_{\gamma\gamma}}{\sigma_{\gamma\gamma}(w)}. \] (12)
where \( N^{\gamma\gamma} \) and \( \sigma^{\gamma\gamma} \) are the selected number of events and cross section obtained using Monte Carlo simulation, and \( w \) is the center of mass energy.

3. The resonance mass was obtained from the fit of the number of \( e^+e^- \rightarrow \text{hadrons} \) events expected, \( M^{\text{mhad}} = \sigma^{\text{mhad}} L \), to the number of detected multihadronic events \( N^{\text{mhad}} \). Here \( \sigma^{\text{mhad}} \) is the expected cross section of \( e^+e^- \rightarrow \text{hadrons} \):

\[
\sigma^{\text{mhad}}(w) = \sigma_{bg} \cdot \left( \frac{3686 \text{ MeV}}{w} \right)^2 + \epsilon \cdot \sigma_{\text{res}}(w, m, \sigma_w), \tag{13}
\]

where \( m \) is the \( \psi' \) meson mass, \( \sigma_{bg} \) is the nonresonant background cross section, \( \epsilon \) is the detection efficiency, \( \sigma_{\text{res}} \) is the cross section of the \( \psi' \) resonance production \( \sigma_0(w, m) \) \(^{[21]} \) convoluted with the beam energy spread \( \sigma_w \):

\[
\sigma_{\text{res}}(w, m, \sigma_w) = \int_{-\infty}^{+\infty} \frac{\exp\left(-\frac{(w-w')^2}{2\sigma_w^2}\right)}{\sqrt{2\pi}\sigma_w} \sigma_0(w', m) \, dw' \tag{14}
\]

Charged tracks were selected requiring their point of closest approach to the beam axis be within 1 cm of the beam line, and their angle with respect to the beam axis, \( \theta \), to satisfy \(|\cos\theta| < 0.93\) \(^{[22]} \). Photon candidates must have at least 25 (50) MeV of energy in the barrel (end cap) electromagnetic calorimeter (EMC) and have \(|\cos\theta| < 0.82 \) (0.86 < \(|\cos\theta| < 0.92\).

The \( e^+e^- \rightarrow \gamma\gamma \) events were selected using the following criteria

1. \( N_q = 0 \) and \( N_{\gamma} > 1 \), where \( N_q \) is the number of charged tracks and \( N_{\gamma} \) is the number of photons;
2. \(|\cos\theta_i| < 0.8 \), where here and below \( i = 1, 2 \) denotes the photons with the highest energy deposition;
3. \(|\Delta\theta| = |\pi - (\theta_1 + \theta_2)| < 0.05\);
4. \(-0.06 < \Delta\phi < 0.02 \), \( \Delta\phi = \pi - |\phi_1 - \phi_2| \), where \( \phi \) is the azimuthal angle around the beam direction;
5. \( 0.8 < E_i/E_{\text{beam}} < 1.2 \), where \( E_i \) is the energy deposition in the EMC of the \( i \)th photon and \( E_{\text{beam}} \) is the beam energy.

In order to select multihadronic events the following criteria were applied.

1. \( N_q > 3 \);
2. \( S > 0.06 \), where \( S = \frac{3}{2}(\lambda_2 + \lambda_3) \) is the sphericity parameter. Here \( \lambda_1 \geq \lambda_2 \geq \lambda_3 \) are eigenvalues of sphericity tensor:

\[
S^{ij} = \frac{\sum_{n=1}^{N_q} p_i^np_j^2}{\sum_{n=1}^{N_q} p_n^2},
\]

where \( p_i \) the momentum of the \( i \)th track.
The number of selected multihadronic events $N_{mhad}$ were fitted by minimizing the likelihood function:

$$\chi^2 = \sum_{i=1}^{N} \left( \frac{N_{i}^{mhad} - \sigma_{mhad} L_i}{N_i^{mhad} (1 + \frac{N_{i}^{mhad}}{N_i^{ee,\gamma}})} \right)^2 + \sum_{i=1}^{N} \left( \frac{w_i - W_i}{\Delta W_i} \right)^2. \quad (15)$$

The free parameters of the fit were $\psi'$ mass $m$, $\sigma_{bg}$, $\epsilon$, $\sigma_w$. The center of mass energy $w_i$ at each energy point was fitted to the values $W_i$ obtained as follows:

$$W = 2\sqrt{\epsilon_{\text{sip}}^{\pm} \epsilon_{\text{sip}}^{\mp} \cos \alpha}, \quad (16)$$

where $\epsilon_{\text{sip}}^{\pm}$ and $\epsilon_{\text{sip}}^{\mp}$ are the energies of the electron and positron beams respectively in the south interaction region calculated according to formula (11), $\alpha = 22$ mrad is the crossing angle of the beams. The error $\Delta W$ of the $W$ determination is calculated from the errors of $\epsilon_{\text{sip}}^{\pm}$ and $\epsilon_{\text{sip}}^{\mp}$.

The results of the fits for the two scans are in agreement. The results of the fit to all data are presented in Table 1 and in Fig. 21.

| $\Delta m$ (keV) | 1 ± 56 |
| $\sigma_w$ (MeV) | 1.58 ± 0.03 |
| $\sigma_{bg}$ (nb) | 4.7 ± 0.1 |
| $\epsilon$ (%) | 32.7 ± 0.5 |
| $\chi^2/ndf$ | 13.5/8 |
| $P(\chi^2, ndf)$ (%) | 9.7 |

In order to check the adequacy of the selection criteria for multihadron events, even more strict cuts were applied for their selection:

- $N_q > 4$
- $p_t > 50$ MeV and $|\cos \theta| < 0.8$ for each charged track. Here $p_t$ is the transverse momentum.

The fit was performed with the new number of selected multihadronic events, and $\Delta m = -17 ± 58$ keV and $\sigma_w = 1.56 ± 0.03$ MeV were obtained.

The luminosity determination was also tested using events of $e^+e^- \rightarrow e^+e^-$, scattered at small angles to suppress the contribution from $\psi' \rightarrow e^+e^-$ decay. The mass difference and beam energy spread were found to be $\Delta m = 17 ± 50$ keV and $\sigma_w = 1.59 ± 0.03$ MeV.

The bias of the center of mass energy obtained using the BEMS from the true value can be estimated as $\Delta m = m - m_{\psi'}$:

$$\Delta m = 1 ± 56 ± 24 ± 40 \simeq 1 ± 72 \text{ keV}. \quad (17)$$
Figure 21: Fit of the $\psi'$.

Figure 22: The center-of-mass energy spreads obtained by means of the BEMS.
Here the first error is the statistical, the second is due to systematical uncertainties of the luminosity determination and multihadronic event selection, and the last one is the error of the PDG $m_{\psi'}$ value. If we take the deviation of the measured beam energy $\Delta E$ from the actual value as $\Delta \varepsilon = \Delta m / 2$, then

$$\Delta \varepsilon = 1 \pm 36 \text{ keV}$$

(18)

Taking into account this deviation, the relative accuracy of the beam energy determination can be estimated as $2 \cdot 10^{-5}$.

The center-of-mass energy spreads $\sigma_W$ obtained by using the BEMS at the 12 energies are shown in Fig. 22. The relative statistical accuracy of the $\sigma_W$ determination per measurement is about 10%. The average of all measurements is $\sigma_W = 1.65 \pm 0.04$. The energy spread obtained from the fit of $\psi'$ resonance is $\sigma_w = 1.58 \pm 0.03$. The difference between these two values $\sigma_W - \sigma_w = 0.07 \pm 0.05$ is about 1.4 standard deviations and consistent with zero. Using this difference, the relative systematical accuracy of the energy spread determination can be estimated as 6%.

7. Conclusion

The energy measurement system of the BEPC-II collider beams based on the Compton back-scattering method was designed, constructed, and put into operation. The systematical error of the beam energy determination is tested through measurement of the $\psi'$ mass and is estimated as $2 \cdot 10^{-5}$.
