Abstract
The anisotropies of the cosmic microwave background (CMB) are computed for the half-turn space $E_2$, which represents a compact flat model of the Universe, i.e. one with finite volume. This model is inhomogeneous in the sense that the statistical properties of the CMB depend on the position of the observer within the fundamental cell. It is shown that the half-turn space describes the observed CMB anisotropies on large scales better than the concordance model with infinite volume. For most observer positions, it matches the temperature correlation function slightly better than the well-studied 3-torus topology.

1. Introduction
One of the enigmas of the cosmic microwave background (CMB) is the low power in the temperature correlations at large angles, $\vartheta$. This behaviour is most clearly revealed by the temperature two-point correlation function $C(\vartheta)$, which is defined as

$$C(\vartheta) := \langle \delta T(\hat{n}) \delta T(\hat{n}') \rangle \quad \text{with} \quad \hat{n} \cdot \hat{n}' = \cos \vartheta, \quad (1)$$

where $\delta T(\hat{n})$ is the temperature fluctuation in the direction of the unit vector $\hat{n}$. The COBE team [1] have already discovered the surprisingly low power at large angles of $\vartheta \gtrsim 60^\circ$, which is at variance with the $\Lambda$CDM concordance model, as has been found in [2] and recently emphasized in [3–5]. The reality of this discordance is questioned in [6] such that it could arise as an artefact of the method of analysis. The arguments are further investigated in [7] with the conclusion that it is very likely that the low power at large angles is real. In the following we take the latter point of view. Then there arises the desire for an explanation of this suppression of power.

One explanation could be that the Universe possesses a non-trivial topology, i.e. that the spatial space is multi-connected. For an introduction in cosmic topology, see [8–12].
In that case the multi-connected space would lead to a natural lower cut-off in the wave numbers describing the perturbations leading to the temperature anisotropy in the CMB. This mechanism works provided that the volume of the fundamental cell is not larger than the volume within the surface of the last scattering. On the other hand volumes too small are also excluded since they lead to a too strong suppression of the correlations also at smaller angular scales. The predicted CMB anisotropy thus depends on the size of the fundamental cell.

Multi-connected space forms are possible in all three spaces of constant curvature, i.e. in hyperbolic, flat and spherical spaces. Since the favoured $\Lambda$CDM concordance model describes our universe as a flat space, we also restrict ourselves in the following to the flat case. In the Euclidean space $\mathbb{E}^3$ there exist 18 topologically different space forms, but only 10 possess a finite volume. From these, four are non-orientable [8, 13]. The remaining six flat models are of great promise in explaining the low power in the CMB anisotropy at large scales. Only one from these six multi-connected spaces possesses the special property of global homogeneity, which means that the statistical properties of the CMB are independent of the position of the observer. This well-studied case is the 3-torus, also called hypertorus, where the three pairs of opposing faces are each identified. Because of the homogeneity it suffices to compute, e.g. the temperature correlation function $C(\theta)$ defined in equation (1) for one observer in the 3-torus. The ensemble average of $C(\theta)$ and its cosmic variance for this observer is identical to that of all other observers. This facilitates the numerical analysis and the comparison with the observational data.

This contrasts to the five remaining inhomogeneous flat space forms that are orientable and possess a finite volume. These are denoted as $E_2$ to $E_6$ in [8, 13]. This paper puts the focus on the space form $E_2$, also called the half-turn space, and presents a systematic observer-dependent analysis of the statistical properties of the CMB. In the pioneering works [14, 15] the statistical properties are investigated for two positions of the observer, which already reveal the suppression of the large-scale power. The investigation of the half-turn space is extended in [13] where the angular power spectrum $\delta T^2_l$ is shown for six different positions of the observer for a single sky realization. But again, no systematic analysis is carried out which is the aim of this paper.

2. The half-turn space and its eigenmodes

The Euclidean space forms are obtained as the quotient $\mathbb{E}^3/\Gamma$ of the Euclidean space $\mathbb{E}^3$ by a discrete and fixed point free symmetry group $\Gamma$. The simplest model is the 3-torus, in which case the group $\Gamma$ of symmetries is generated by three orthogonal translations which shift the points by the lengths $L_x$, $L_y$ and $L_z$. This model has the special property of homogeneity. The simplest model without this property, but which has finite volume and is orientable, is the half-turn space. One generator of the 3-torus, say the one in the $z$-direction, is replaced by a translation accompanied by a rotation by an angle of $180^\circ$. The half-turn space is then generated by the three transformations

\[
\begin{align*}
\vec{x} \rightarrow \vec{x}' &= \vec{x} + L_x \vec{e}_x, \\
\vec{x} \rightarrow \vec{x}' &= \vec{x} + L_y \vec{e}_y, \\
\vec{x} \rightarrow \vec{x}' &= \vec{x}_R + L_z \vec{e}_z,
\end{align*}
\]

where $\vec{x}_R = (-x L_x, -y L_y, z L_z)$ takes the rotation of $180^\circ$ in the $xy$-plane into account. The dimensionless coordinates $x, y, z \in [-0.5, 0.5]$ allow the description of points within the fundamental cell without reference to the topological length scales $L_x$, $L_y$ and $L_z$. The difference between the 3-torus and the half-turn space is illustrated in figure 1 where the $z$-transformation identifies the bottom and the top faces. In the case of the 3-torus (left) it is
The sketch illustrates the difference between the 3-torus topology (left) and the half-turn space (right). The identifications of the vertical faces are the same for both models. Only the transformation from the bottom face to the top face involves a rotation in the case of the half-turn space, which is absent for the 3-torus.

The fundamental cell of the half-turn space is shown for the observer positions $\vec{x}_o = (0, 0, 0)$ (left) and $\vec{x}_o = (\frac{1}{4} L_x, \frac{1}{4} L_y, 0)$ (right). Both cells have the same volume.

Figure 2. The fundamental cell of the half-turn space is shown for the observer positions $\vec{x}_o = (0, 0, 0)$ (left) and $\vec{x}_o = (\frac{1}{4} L_x, \frac{1}{4} L_y, 0)$ (right). Both cells have the same volume.

a simple shift, whereas for the half-turn space the additional rotation leads to a further twist as illustrated by the triangle. This modification leads to an inhomogeneous space form. For a definition of homogeneous space forms, see [16], p 16, and [17], p 135. All space forms that are not homogeneous are called inhomogeneous.

The inhomogeneity can be visualized by the fundamental cell. Let us define the fundamental cell with respect to an observer position $\vec{x}_o$ as the set of points $\vec{x}$ that cannot be transformed closer to $\vec{x}_o$ by applying any of the transformations, $g \in \Gamma$. For a homogeneous space form like the 3-torus, the fundamental cell is independent of the observer position $\vec{x}_o$ but not for an inhomogeneous one as is illustrated in figure 2. For the observer position $\vec{x}_o = (0, 0, 0)$, a cubic fundamental cell is obtained, whereas for the shifted position $\vec{x}_o = (\frac{1}{4} L_x, \frac{1}{4} L_y, 0)$ a much more complex fundamental cell is seen by the observer. Note that the symmetry group $\Gamma$ is the same in both cases. This behaviour leads to different statistical properties of the CMB.

The eigenfunctions of the Laplacian of the Euclidean space are plane waves or linear combinations thereof. In the case of a multi-connected space form every eigenfunction must be invariant under the action of the generators of the manifold. This restricts the admissible wave numbers $\vec{k}$ occurring in the eigenfunctions, which can be expressed by
\[ \vec{k} = 2\pi (n_x/L_x, n_y/L_y, n_z/2L_z) \quad \text{and} \quad \vec{k}' = 2\pi (-n_x/L_x, -n_y/L_y, n_z/2L_z). \]

The eigenfunctions of the half-turn space depend on the values of the integers \( n_x \geq 0, n_y \) and \( n_z \). For \( n_x = n_y = 0, n_z \in 2\mathbb{Z} \) the eigenfunctions are given by

\[ \Psi_\vec{k} (\vec{x}) = \exp(i \vec{k} \cdot \vec{x}), \quad (3) \]

and for \( n_x \in \mathbb{N}, n_y, n_z \in \mathbb{Z} \) or \( n_x = 0, n_y \in \mathbb{N}, n_z \in \mathbb{Z} \) by

\[ \Psi_\vec{k} (\vec{x}) = \frac{1}{\sqrt{2}} \left[ \exp(i \vec{k} \cdot \vec{x}) + (-1)^{n_x} \exp(i \vec{k}' \cdot \vec{x}) \right]. \quad (4) \]

To normalize the eigenfunctions with respect to the fundamental cell, they have to be multiplied by \( 1/\sqrt{L_x L_y L_z} \). We drop this overall factor in the following since the CMB anisotropy has to be normalized with respect to the data. The computation of the CMB anisotropy requires the expansion of the eigenfunctions with respect to the spherical basis

\[ \Psi_\vec{k} (r, \hat{n}, \vec{x}_o) = \sum_{l,m} \xi_{lm}^\vec{k} (\vec{x}_o) R_{kl} (r) Y_{lm} (\hat{n}), \quad (5) \]

where \( R_{kl} (r) = 4\pi \delta_{j(lkr)} \) is the radial function, i.e. the spherical Bessel function, \( Y_{lm} (\hat{n}) \) is the spherical harmonics, \( r = |\vec{x} - \vec{x}_o|, \hat{n} = (\vec{x} - \vec{x}_o)/r, \vec{x}_o \) is the position of the observer, and \( k = |\vec{k}| = |\vec{k}'| \). The expansion coefficients \( \xi_{lm}^\vec{k} (\vec{x}_o) \) for equation (3) are given by

\[ \xi_{lm}^\vec{k} (\vec{x}_o) = \frac{i}{\sqrt{2}} Y_{lm}^* (\hat{k}) \exp(i \vec{k} \cdot \vec{x}_o), \quad (6) \]

and for equation (4)

\[ \xi_{lm}^\vec{k} (\vec{x}_o) = \frac{i}{\sqrt{2}} \left[ Y_{lm}^* (\hat{k}) \exp(i \vec{k} \cdot \vec{x}_o) + (-1)^{nc} Y_{lm}^* (\vec{k}') \exp(i \vec{k}' \cdot \vec{x}_o) \right] \]

\[ = \frac{i}{\sqrt{2}} Y_{lm}^* (\hat{k}) \exp[i \vec{k} \cdot \vec{x}_o] + (-1)^{n_c} Y_{lm}^* (\vec{k}') \exp[i \vec{k}' \cdot \vec{x}_o], \quad (7) \]

where \( Y_{lm}^* (\vec{k}') = (-1)^{n_c} Y_{lm}^* (\vec{k}), \vec{k} = \vec{k}/k \), and \( \vec{k}' = \vec{k}'/k \).

Expanding the temperature fluctuations of the CMB according to the spherical harmonics, i.e.

\[ \delta T (\hat{n}) = \sum_{l,m} a_{lm} Y_{lm} (\hat{n}), \quad (8) \]

the corresponding coefficients \( a_{lm} \) of the half-turn space are determined by

\[ a_{lm} = \sum_k T_l^c \Phi_{\vec{k}} \xi_{lm}^\vec{k} (\vec{x}_o), \quad (9) \]

where the sum runs over the allowed values of \( \vec{k} \) as discussed above. Here \( \Phi_{\vec{k}} (\vec{x}_o) \) contains the information about the manifold. \( T_l^c (k) \) is the transfer function containing the full Boltzmann physics, e.g. the ordinary and the integrated Sachs–Wolfe effect, the Doppler contribution, the Silk damping and the reionization are taken into account. The initial conditions are specified by \( \Phi_{\vec{k}} \), where it is assumed that they are Gaussian random fluctuations at the early universe. For the half-turn space, \( \Phi_{\vec{k}} \) has to fulfil the condition

\[ \Phi_{\vec{k}} \sim (-1)^{n_c} = \Phi_{-\vec{k}}, \quad (10) \]

where \( \Phi_{\vec{k}} \in \mathbb{R} \) if \( n_z = 0 \) and \( \Phi_{\vec{k}} \in \mathbb{C} \) otherwise. The assumption of initial Gaussian random fluctuations determines the correlation of \( \Phi_{\vec{k}} \) to be

\[ \left\langle \Phi_{\vec{k}} \Phi_{\vec{k}'} \right\rangle = P (k) \delta_{\vec{k},\vec{k}'} \quad (11) \]
The primordial spectrum $P(k)$ is assumed to be $P(k) \sim k^{n_s-4}$, where $n_s$ is the spectral index. With correlation (11) the ensemble average $\langle \cdots \rangle$ of the multipole moments $C_l$ can be calculated from equation (9) for a given position $\vec{x}_o$ of the observer. This leads to the multipole moments $C_l$ of the half-turn space

$$C_l := \frac{1}{2l+1} \sum_{m=-l}^l \langle |a_{lm}|^2 \rangle$$

$$= \sum_k \frac{T_l^2(k)}{2l+1} \sum_{m=-l}^l Y_{lm}(\vec{k})^2 \left[ 1 + (-1)^n_x n_y \right] \left[ 1 + (-1)^n_z \right] \cos((\vec{k} - \vec{k}') \cdot \vec{x}_o)$$

$$= \frac{1}{4\pi} \sum_k T_l^2(k) P(k) \left[ 1 + (-1)^n_x n_y \right] \left[ 1 + (-1)^n_z \right] \cos((\vec{k} - \vec{k}') \cdot \vec{x}_o) P_l(\hat{k} \cdot \hat{k}').$$

(12) (13) (14)

The multipole moment of the half-turn space (14) depends on the position $\vec{x}_o$ of the observer within the fundamental cell. Taking the mean value of the multipole moment (14) over all observer positions leads to the simple expression

$$\bar{C}_l^{\vec{x}_o} = \frac{1}{4\pi} \sum_k T_l^2(k) P(k) r(k),$$

(15)

where $r(k)$ is the multiplicity of the eigenvalue $E_k = k^2$. The multiplicity is the number of triplets $(n_x, n_y, n_z)$, which satisfy $k = 2\pi \sqrt{n_x^2 + n_y^2 + n_z^2}$ and fulfil the restrictions stated in equations (3) and (4).

The ensemble average over the sky realizations of the temperature correlation function $C(\vartheta)$ is computed by

$$C(\vartheta) = \sum_l \frac{2l + 1}{4\pi} C_l P_l(\cos \vartheta).$$

(16)

The above formulae allow the computation of the CMB anisotropies when the cosmological parameters are specified. For these, we take the parameters of the ΛCDM concordance model, which are based on the WMAP five year data [18]. The parameters are obtained from the LAMBDA website (lambda.gsfc.nasa.gov), see the WMAP cosmological parameters of the model ‘lcdm+sz+lens’ using the data ‘wmap5+bao+snall+lyapost’. The values are $\Omega_{\text{bar}} = 0.0474$, $\Omega_{\text{cdm}} = 0.243$, $\Omega_\Lambda = 0.709$ and $h = 0.697$ for the present-day reduced Hubble constant. The spectral index is $n_s = 0.969$ and the depth to reionization is $\tau = 0.094$. These parameters specify a flat universe with an angular power spectrum $\delta T^2_l = l(l+1)C_l/(2\pi)$ having its first acoustic peak at $l \simeq 220$. The $\delta T^2_l$ spectrum is normalized to the WMAP best fit angular power spectrum at $l = 220$ having $\delta T^2_{220} = 5785.6 \mu K^2$.

3. The cubic half-turn space

As described in the introduction and in the previous section the ensemble average of the CMB statistics depends not only on the position of the observer but also on the sizes of the three topological lengths $L_x$, $L_y$ and $L_z$, which identify the opposing pairs of faces of the half-turn space. In order to simplify the already complicated analysis in the first step we devote this section to the cubic half-turn space where all three side lengths are equal, i.e.
Figure 3. The $S(60^\circ)$ statistic, defined in equation (17), is shown for the cubic half-turn space as a function of the topological length scale $L$ in units of the Hubble length $L_H$. The solid curve displays the average over all positions of the observer. The dotted and the dashed curves give the maximal and the minimal value, respectively, of $S(60^\circ)$ in order to reveal the range of variation.

$L_x = L_y = L_z \equiv L$. This allows us to discuss the position dependence of the half-turn space with respect to a single topological parameter.

To quantify the power at large angular scales by a scalar measure, the $S(60^\circ)$ statistic

$$S(60^\circ) := \int_{-1}^{\cos(60^\circ)} d \cos \vartheta \ |C(\vartheta)|^2$$

(17)

has been introduced [2], which measures the power in the correlation function $C(\vartheta)$ on scales larger than $60^\circ$. The value of $60^\circ$ is arbitrary and adapted to the observed fact that $C(\vartheta)$ almost vanishes for angles larger than this one. Note that due to the measure $d \cos \vartheta$, the $S(60^\circ)$ statistic is insensitive to the behaviour of the correlation function $C(\vartheta)$ at $\vartheta = 180^\circ$. It is sensitive for variations of $C(\vartheta)$ in the range $60^\circ \lesssim \vartheta \lesssim 120^\circ$.

It is important to distinguish between two different averages. On one hand there is the ensemble average for a single position $\vec{x}_o$ of the observer, which takes the ensemble of CMB sky realizations into account. On the other hand one can average this position-dependent ensemble average over all positions, which the observer can occupy in the fundamental cell. The position average of the ensemble averages of $S(60^\circ)$ is plotted in figure 3 as a solid curve as a function of the side length $L$. A variation between 2000 and 40 000 $\mu$K$^4$, depending on the side length $L$, is revealed. The low values of power are obtained for $L$ close to the side lengths 2 and 4 in units of the Hubble length $L_H = c/H_0$. In addition, figure 3 shows the maximal (dotted curve) and the minimal (dashed curve) values of $S(60^\circ)$ that occur among the different positions. An asymmetric distribution can be inferred from the figure because the difference between the mean and the maximal value is larger than the difference between the mean and the minimal value.

Since a low value of the $S(60^\circ)$ statistic is observed in the CMB data, the minima at the side lengths $L = 1.9$ and $L = 4$ in figure 3 are interesting, where values around 3500 and 8000 $\mu$K$^4$ occur, respectively. These low values have to be compared with the observed ones. We compute the correlation function $C_{\text{obs}}(\vartheta)$ from the ILC seven year map [19], which gives $S_{\text{ILC}}(60^\circ) = 8033 \mu$K$^4$. By applying the KQ75 seven year mask [19] to the ILC seven year map, a correlation function $C_{\text{obs}}(\vartheta)$ is obtained which leads to only $S_{\text{ILC,KQ75}}(60^\circ) = 1153 \mu$K$^4$. Note that the infinite volume concordance model has large
values which can be read off from figure 3 in the limit of large values of $L$, i.e. at $L = 9$. It is obvious that with respect to the power on large angular scales, the finite volume models lead to a better description of the data.

For the two side lengths $L = 1.9$ and $L = 4$, figure 4 displays the dependence of the ensemble average of the $S(60')$ statistic on the position $(x_o, y_o)$ of the observer in the $xy$-plane. Since there is no dependence on the $z$-coordinate, this figure already reveals the full range of variation in the fundamental cell. The coordinates are, as explained in the previous section, given in units of the side length $L$. Due to the symmetry expressed by equation (14) only the 16th part of the $x_o y_o$-plane is shown. One can read off from figure 4 the domains where the ensemble average of the $S(60')$ statistic drops to a minimum. A comparison of both panels shows that the minima occur at different positions of the observer in these two models. As discussed below the points $(x_o, y_o) = (0, 0)$ and $(0.25, 0.25)$ are special points since for these positions the correlation function $C(\vartheta)$ obtains maximal and minimal values, respectively, at $\vartheta = 180'$. These positions correspond to the local maxima in figure 4.

Since the $S(60')$ statistic integrates the correlation function $C(\vartheta)$ no information about the angular dependence $\vartheta$ is preserved. Thus figure 5 displays for six different topological scales $L$ the correlation function $C(\vartheta)$. The solid curve shows the position average of the ensemble average of $C(\vartheta)$, whereas the dotted and dashed curves show the correlation functions for the positions belonging to the extremal values of $S(60')$.

Above we discussed the dependence on the position of the observer in the case of the $S(60')$ statistic for two models, see figure 4. There we already point out that the correlation function $C(\vartheta)$ obtains, at $\vartheta = 180'$, extremal values for two special positions which in turn lead to a local maximum with respect to the $S(60')$ statistic. The maximal value of $C(180')$ always occurs at the point $(x_o, y_o) = (0, 0)$, whereas at $(x_o, y_o) = (0.25, 0.25)$ it drops to a minimum. Figure 6 demonstrates this observational fact for the two models with side length $L = 1.9$ (left) and 4.0 (right). The fact that these observer positions are special is revealed by equation (14) which simplifies for the above two observer positions. When the argument of the cosine is written explicitly as

$$\cos((\vec{k} - \vec{k'})x_o) = \cos(\pi(4n_x x_o + 4n_y y_o)),$$

![Figure 4](image_url)
The temperature correlation $C(\theta)$ is shown for the cubic half-turn space for the six topological lengths $L = 1.3, 1.9, 2.9, 4.0, 6.0$ and $9.0$. The average over all positions of the observer is plotted as a solid curve. The dashed curve belongs to the position with the smallest value of $S(60^\circ)$ and the dotted one to the largest value of $S(60^\circ)$.

one obtains 1 for $(x_0, y_0) = (0, 0)$ and $(-1)^{n_x+n_y}$ for $(x_0, y_0) = (0.25, 0.25)$. These are the extreme situations which can occur with respect to the cancellation of neighbouring terms in the sum. Equation (14) reduces for $(x_0, y_0) = (0, 0)$ to

$$C_l = \sum_{\vec{k}} \frac{T_l^2(k) P(k)}{4\pi} [1 + (-1)^{n_x + n_y} (1 - \delta_{0,n_x} \delta_{0,n_y}) P_l(\hat{k} \cdot \hat{k}')],$$  

(18)

and for $(x_0, y_0) = (0.25, 0.25)$ to

$$C_l = \sum_{\vec{k}} \frac{T_l^2(k) P(k)}{4\pi} [1 + (-1)^{n_x+n_y+n_z} (1 - \delta_{0,n_x} \delta_{0,n_y} \delta_{0,n_z}) P_l(\hat{k} \cdot \hat{k}')].$$  

(19)

The sum over $\vec{k}$ runs over the integers $n_x, n_y,$ and $n_z$. The complicated structure of the transfer function $T_l(k)$ and the presence of the Legendre function $P_l(\hat{k} \cdot \hat{k}')$ prevent the derivation of...
analytical expressions which would show how these values of $C_l$ lead to extremal values for $C(180^\circ)$. Note that equation (16) for the computation of $C(\vec{\theta})$ reduces for $\theta = 180^\circ$ to

$$C(180^\circ) = \sum_l (-1)^l \frac{2l + 1}{4\pi} C_l.$$  \hspace{1cm} (20)

It turns out that the argument of the Legendre function

$$\hat{k} \cdot \hat{k}' = \frac{-n_x^2 - n_y^2 + (n_z/2)^2}{n_x^2 + n_y^2 + (n_z/2)^2}$$

is for most summands close to $\hat{k} \cdot \hat{k}' \approx -1$ since the terms with either $n_x \gg n_z$ or $n_y \gg n_z$ or both dominate those terms with $n_z \gg \max(n_x, n_y)$. Thus for most terms one approximately gets $P_l(\hat{k} \cdot \hat{k}') = (-1)^l$. Furthermore, the absence of $n_x$ and $n_y$ in the sign factor $(-1)^{n_x}$ in equation (18) causes the coherent addition of all terms with the same $n_z$ but different $n_x$ and $n_y$. The reverse situation is realized in equation (19). The numeric reveals that equation (18) leads to extreme fluctuations in $C_l$ alternating in $l$, where even values of $l$ yield large $C_l$’s and odd $l$’s yield small $C_l$’s. The factor $(-1)^l$ in equation (20) then leads to a maximal value of $C(180^\circ)$. Although the fluctuations of $C_l$ in equation (19) are less pronounced than in equation (18), the crucial difference is that now odd values of $l$ belong to the large values of $C_l$ (for not too large values of $l$) which in turn leads to a small value of $C(180^\circ)$. This discussion highlights that inhomogeneous spaces have much more freedom than homogeneous spaces with respect to their CMB statistics.

4. General half-turn spaces

In the previous section only half-turn spaces are considered where all three topological lengths $L_x$, $L_y$, and $L_z$ are identical. This restriction to cubic half-turn spaces is now dropped. The analysis in the previous section has shown that cubic models with a topological length $L \approx 4$ yield especially low values for the $S(60^\circ)$ statistic. This corresponds to models with a volume $V = L^3$, where this volume is specified in units of the Hubble volume $L_H^3$. The Hubble length $L_H = c/H_0$ is close to $L_H \approx 4.28$ Gpc for $h \approx 0.7$, leading to a physical volume of
Figure 7. The $S(60^\circ)$ statistic, defined in equation (17), is shown for general half-turn spaces with volume $V = 64$ as a function of the distortion parameter $\alpha$. The parameter $\beta$ is fixed as $\beta = 1$, i.e. $L_z = 4$. The solid curve displays the average over all positions of the observer. The dotted and dashed curves give the maximal and the minimal value, respectively, of $S(60^\circ)$.

$V_{\text{phys}} \simeq 5000 \text{Gpc}^3$. This is the same volume as that of the cubic torus, i.e. a homogeneous space form, which gives a good description [3] of the WMAP data. In order to obtain a volume which does not depend on the Hubble constant $H_0$, one can consider the ratio $V_{\text{phys}}/V_{\text{als}}$, where $V_{\text{als}}$ is the volume within the surface of the last scattering. For the cubic half-turn space, as well as for the cubic torus, one obtains $V_{\text{phys}}/V_{\text{als}} \simeq 0.42$. It is worthwhile to note that in the case of the three spherical space forms studied in [20], similar volumes are also found which provide a good match with the WMAP data. For the dodecahedral space, the binary octahedral space and the binary tetrahedral space, one finds $V_{\text{phys}}/V_{\text{als}} \simeq 0.47, 0.40$ and $0.37$, respectively [20]. Thus it is natural to compare half-turn spaces where the volume $V = L^3$ is held fixed by using the parameterization

$$L_x = \alpha L, \quad L_y = \beta L, \quad L_z = \frac{L}{\alpha\beta}. \quad (21)$$

This provides, for $L = 4$, a parametric plane spanned by $\alpha$ and $\beta$ which is still too large for a systematic numerical search. We confine here to two lines in the $\alpha\beta$-plane. The first line is obtained by setting $\beta = 1$, and the second line is the ‘diagonal’ in the $\alpha\beta$-plane by setting $\alpha = \beta$.

Figures 7 and 8 show the $S(60^\circ)$ statistic for these two parametric curves. The $S(60^\circ)$ statistic is based on the correlation function $C(\theta)$ computed from equation (16), which takes the ensemble average of sky realizations into account. The solid curves display the average over all positions of the observer. In order to reveal the range of variation with respect to the observer position, these figures also show the maximal and the minimal values of the $S(60^\circ)$ statistic that occur among the various positions. One observes that for small values of $\alpha$, the range of variation diminishes. This can be understood as follows. The inhomogeneity is due to the transformation in the $z$-direction which involves rotation by $\pi$. A necessary requirement for the observability of inhomogeneity is that the diameter $D_{\text{als}}$ of the surface of the last scattering is smaller than the topological length scale $L_z = L/(\alpha\beta)$. The $z$-transformation is observable for $\alpha\beta \geq L/D_{\text{als}}$. The set of cosmological parameters of the concordance model used in this paper leads to a diameter $D_{\text{als}} = 6.44$. The transition takes place for the $\beta = 1$ case shown in figure 7 at $\alpha \simeq 0.62$, and for the other case, $\beta = \alpha$, shown in figure 8 at $\alpha \simeq 0.79$. It is striking to see that the variability with respect to the observer position sets
Figure 8. The $S(60^\circ)$ statistic is shown for general half-turn spaces with volume $V = 64$ as a function of the distortion parameter $\alpha$. The parameter $\beta$ is specified as $\beta = \alpha$. The solid curve displays the average over all positions of the observer. The dotted and dashed curves give the maximal and the minimal value, respectively, of $S(60^\circ)$.

Table 1. For five values of $\alpha$, the values of the $S(60^\circ)$ statistic are given in units ($\mu K^4$), which are shown as the three curves in figure 7 ($L = 4$ and $\beta = 1$), i.e. the mean value as well as the two extrema.

| $\alpha$ | $\bar{S}(60^\circ)$ | $\min_{\mathbf{x}_o}(S(60^\circ))$ | $\max_{\mathbf{x}_o}(S(60^\circ))$ |
|---------|----------------------|----------------------------------|----------------------------------|
| 0.5     | 51 494               | 51 371                           | 51 628                           |
| 0.7     | 23 428               | 23 358                           | 24 377                           |
| 1.0     | 7 769                | 7 282                            | 11 150                           |
| 1.4     | 16 188               | 10 185                           | 30 576                           |
| 2.0     | 29 566               | 8 971                            | 88 285                           |

in at exactly these values of $\alpha$. For smaller values of $\alpha$, the topology mimics that of the slab space which is, however, homogeneous [21]. In addition, for $\alpha > 1$ there are always positions for which the $S(60^\circ)$ statistic has nearly as small values as for the cubic case $\alpha = 1$, although there are positions for which values almost as large as 90 000 $\mu K^4$ occur (at $\alpha = 2$).

We now discuss the $\beta = 1$ case in more detail. Figure 9 shows the dependence of the $S(60^\circ)$ statistic on the observer position $(x_o, y_o)$ for four selected values of $\alpha$. The cubic case $\alpha = 1$ is already shown in figure 4. The first panel shows the case with very little variability belonging to $\alpha = 0.5$ which is below the critical value $\alpha \simeq 0.62$. Here, the $S(60^\circ)$ statistic varies only marginally between 51 371 and 51 628 $\mu K^4$, see table 1. This variability increases with increasing value of $\alpha$ as is revealed by the next panels and by table 1. For $\alpha \geq 0.7$, the maximal values again occur at the special points $(x_o, y_o) = (0, 0)$ or $(x_o, y_o) = (0.25, 0.25)$. In the case of the more interesting position belonging to the minimum of the $S(60^\circ)$ statistic, there are no such distinguished positions. For values of $\alpha$ larger than 1, the strongest variation takes place with respect to the coordinate $y_o$ as revealed by the more or less horizontal lines. The symmetric case $\alpha = 1$ possesses diagonal lines in the $x_o y_o$-plane as shown in figure 4.

For the four cases presented in figure 9, figure 10 displays the ensemble average of the correlation function $C(\theta)$. The solid curve is the average over all positions of the observer, and the dashed and dotted curves belong to the positions at which the smallest and largest
Figure 9. The $S(60^\circ)$ statistic is plotted in units ($\mu K^4$) in dependence on the position $(x_o, y_o)$ of the observer. The generic half-turn spaces with the distortion parameters $\alpha = 0.5$, $\alpha = 0.7$, $\alpha = 1.4$ and $\alpha = 2.0$ are shown. The parameter $\beta$ is fixed as $\beta = 1$. The coordinates $(x_o, y_o)$ of these observers are given in units of the side lengths $L_x$ and $L_y$.

values of $S(60^\circ)$ occur. Again one observes the trend of increasing variability of $C(\vartheta)$ with increasing values of $\alpha$. This trend is also revealed by the increasing width of the standard deviation, which is shown as a dark grey band. The full width of variation is given by the light grey band, which gives the maximal and minimal values of the correlation function $C(\vartheta)$ that occur among the different positions and show the same trend.

5. Comparison with observations

The discussion in the previous section puts the focus on the $S(60^\circ)$ statistic. This quantity has the advantage that it is independent of any measurements and describes the properties of the considered model. In this section we compare the CMB properties of the half-turn space with the correlation function $C_{\text{obs}}(\vartheta)$ obtained from the WMAP seven year data. We compute two correlation functions $C_{\text{obs}}(\vartheta)$. The first one is obtained from the ILC seven year map, whereas the second one uses the same map restricted to the pixels outside the KQ75 seven year mask [19]. Due to the recent discussions [4–7] on the relevance of these two correlation
Figure 10. The ensemble average of the temperature correlation function $C(\vartheta)$ for the general half-turn space for $\alpha = 0.5, 0.7, 1.4$ and $2.0$ is shown. The parameter $\beta$ is fixed as $\beta = 1$. The average over all positions of the observer is plotted as a solid curve and its standard deviation as a dark grey band. The distribution of the correlation function $C(\vartheta)$ depending on the position of the observer is given as a light grey band. The dashed curve belongs to the position with the smallest value of $S(60^\circ)$ and the dotted one to the largest value of $S(60^\circ)$.

functions, we use both in the following analysis. In order to compare the correlation function $C_{\text{model}}(\vartheta)$ with the observed correlation function $C_{\text{obs}}(\vartheta)$ the integrated weighted temperature correlation difference [3]

$$I := \int_{-1}^{1} d \cos \vartheta \left( \frac{C_{\text{model}}(\vartheta) - C_{\text{obs}}(\vartheta))^2}{\text{Var}(C_{\text{model}}(\vartheta))} \right)$$

(22)

is introduced which tests all angular scales $\vartheta \in [0^\circ, 180^\circ]$. The variance is computed using

$$\text{Var}(C(\vartheta)) \approx \sum_l \frac{2l + 1}{8\pi^2} |C_l P_l(\cos \vartheta)|^2.$$  

(23)

The results are shown in figures 11–13 for the three half-turn space sequences that are studied in the previous sections. The cubic half-turn space is parameterized by $L$, and figure 11 reveals that models with $L$ close to $L = 4$ describe the data better than the infinite volume concordance model whose behaviour is approximately seen at $L = 9 > D_{\text{als}}$. It is worthwhile to note that the minimum close to $L = 4$ is present in the comparison with the full ILC data set, as well as with the reduced data set using the KQ75 seven year mask. With the mask the minimum lies slightly below $L = 4$ and without slightly above. This again justifies the restriction to models with a volume $V = L^3 = 64$, as discussed in the previous section.

The minimum around $L = 2$ in the $S(60^\circ)$ statistic, see figure 3, is now a local minimum with a value even above the $L = 9$ value. This is the reason why we do not discuss this volume.
Figure 11. The integrated weighted temperature correlation difference $I(L)$ is shown for the cubic half-turn space depending on the length $L$. The results are shown for $C^{\text{obs}}(\theta)$ obtained from the ILC seven year map with and without applying the KQ75 seven year map. The bands show the range of variation with respect to the observer positions. The dotted curves represent the corresponding results for the cubic torus model, which is a homogeneous space form having no such range of variation.

Figure 12. The same quantities as in figure 11 are shown but now for the general half-turn space with $L = 4$ and $\beta = 1$. Thus, $I(\alpha)$ is plotted as a function of the distortion parameter $\alpha$.

$\forall$ in detail in this paper. But we would like to note that a further extension [22] of the KQ75 seven year mask leads to a minimum at $L \simeq 2$ comparable to that at $L \simeq 4$ as shown in [23]. Only future CMB data can decide whether this second minimum is a genuine alternative to that at $L \simeq 4$.

Figure 11 also shows the results for the homogeneous cubic torus model for the two correlation functions $C^{\text{obs}}(\theta)$. Although the values of $I(L)$ of the 3-torus are contained within the range of variation of the half-turn space, it is striking to see that the minimum of the average over the observer positions of the half-turn space is lower than that of the torus model. Furthermore, the half-turn space provides observer positions which possess an even better match with the observations as revealed by the even lower values of $I(L)$. Thus, the half-turn
space describes the CMB data not only better than the concordance model, but even slightly better than the torus topology.

In figures 12 and 13 the integrated weighted temperature correlation difference $I(\alpha)$ is shown as a function of the parameter $\alpha$ where the volume is fixed as $V = 64$. As in the case of the $S(60')$ statistic, the range of variation with respect to the observer position increases up to $\alpha = 1$; thereafter the behaviour is more involved and increases only for the full ILC data set. A preference for an almost cubic half-turn space occurs when $I(\alpha)$ is computed by restricting the ILC data by the KQ75 mask. Using the full ILC map leads to such an increase of the range of variation that there are observer positions for $\alpha > 1$ as good as in the cubic case. However, the average over the observer positions points to a preference for a cubic half-turn space. The preference for symmetrical space forms is also found in other topologies [24].

6. Summary

In this paper we study a model of our Universe where the spatial space has a finite volume. Although the cosmological parameters are those of the concordance model, the finite spatial size leads to a suppression of the anisotropy in the CMB on large scales, which is indeed observed in the data. Most topological models that are studied in the literature have the property that they are homogeneous with respect to the statistical properties of the CMB, i.e. the statistical expectations are the same for each observer position within the fundamental cell when the ensemble average over the sky realizations is carried out. This is different in the case of inhomogeneous space forms, where the comparison with the observational data is much more involved since the variation of the observer position has to be taken into account.

The model system considered in this paper is the so-called half-turn space form. This inhomogeneous space tessellates the Euclidean space in a similar way as the homogeneous 3-torus topology, except that the identification of one pair of faces includes an additional rotation with an angle of 180°. This rotation leads to the inhomogeneity. The large-scale angular power is conveniently described by the temperature two-point correlation function $C(\theta)$, equation (1), from which the $S(60')$ statistic, the scalar quantity defined in equation (17), can be obtained. The latter is a measure of the power in the CMB anisotropies at scales above $\theta \geq 60'$ and has the advantage that it facilitates the comparison of the various observer
positions. Figure 3 shows that cubic half-turn spaces with a topological length close to \( L = 4 \) present a good choice with respect to the desired small power on large angular scales. The second minimum at \( L = 2 \) is probably not favoured by the current observations (see, however, [23]) such that the following discussion puts the focus on spaces with \( L = 4 \). This leads to a volume ratio \( V_{\text{phys}}/V_{\text{dik}} \) around 0.4 which is also favoured by several topological spaces with positive curvature. Figures 7 and 8 address the question whether non-cubic half-turn spaces provide models with even lower large-scale power. Here, two sequences of asymmetric half-turn spaces are shown which are parameterized by \( \alpha \). As can be seen in both figures, the average over all observer positions gets its minimum close to the cubic half-turn space with \( \alpha = 1 \). However, in both cases there are observer positions which also possess, for \( \alpha \gtrsim 1 \), a large-scale power almost as low as in the cubic case. The dependence of the \( S(60') \) statistic on the observer position is visualized in figures 4 and 9, which reveal the regions within the fundamental cell that possess the desired small anisotropy. This emphasizes the variety of inhomogeneous space forms.

A comparison with the WMAP seven year data [19] is carried out using the integrated weighted temperature correlation difference \( I \) defined in equation (22). The correlation function is computed from the full ILC seven year map and from this map again but subjected to the KQ75 seven year mask. For both correlation functions figure 11 shows the result for the cubic half-turn space. The minimum in \( I(L) \) around \( L = 4 \) is clearly revealed, and it demonstrates not only that low power on large angular scales, as expressed by the \( S(60') \) statistic, favours this size for the fundamental cell, but also the direct comparison of the corresponding correlation functions, as in equation (22). Figure 11 also presents the result for the cubic torus model which is a homogeneous space form. It shows that most observer positions of the half-turn space provide a slightly better description of the CMB data than the 3-torus topology. Figures 12 and 13 display the results for the two sequences of asymmetric half-turn spaces parameterized by \( \alpha \). These figures reveal that the special case of the cubic half-turn space yields the best description, although there are observer positions for \( \alpha \gtrsim 1 \) that describe the observed correlation function almost equally well. This is consistent with the result obtained from the \( S(60') \) statistic.

The analysis of this paper shows that the simplest inhomogeneous flat topology describes the large-scale angular anisotropy of the CMB better than the \( \Lambda \)CDM concordance model. Although the agreement is slightly better than those of the flat 3-torus model, the concrete identification of the topology requires a more direct measure of the topological signal as given by, e.g. the spatial correlation function [25, 26] or the covariance matrix [3, 27–29]. But this is left to a future work.

Acknowledgments

We would like to thank the Deutsche Forschungsgemeinschaft for financial support (AU 169/1-1). HEALPix (http://healpix.jpl.nasa.gov/) [30] and the WMAP data from the LAMBDA website (http://lambda.gsfc.nasa.gov/) were used in this work. The computations were carried out on the Baden-Württemberg grid (bwGRiD).
