Abstract

Following recent developments in the automatic evaluation of machine translation and document summarization, we present a similar approach, implemented in a measure called \textsc{PouriPre}, for automatically evaluating answers to definition questions. Until now, the only way to assess the correctness of answers to such questions involves manual determination of whether an information nugget appears in a system’s response. The lack of automatic methods for scoring system output is an impediment to progress in the field, which we address with this work. Experiments with the TREC 2003 and TREC 2004 QA tracks indicate that rankings produced by our metric correlate highly with official rankings, and that \textsc{PouriPre} outperforms direct application of existing metrics.

1 Introduction

Recent interest in question answering has shifted away from factoid questions such as “What city is the home to the Rock and Roll Hall of Fame?”, which can typically be answered by a short noun phrase, to more complex and difficult questions. One interesting class of information needs concerns so-called definition questions such as “Who is Vlad the Impaler?”, whose answers would include “nuggets” of information about the 16th century warrior prince’s life, accomplishments, and legacy. Actually a misnomer, definition questions can be better paraphrased as “Tell me interesting things about X.”, where X can be a person, an organization, a common noun, etc. Taken another way, definition questions might be viewed as simultaneously asking a whole series of factoid questions about the same entity (e.g., “When was he born?”, “What was his occupation?”, “Where did he live?”, etc.), except that these questions are not known in advance; see Prager et al. (2004) for an implementation based on this view of definition questions.

Much progress in natural language processing and information retrieval has been driven by the creation of reusable test collections. A test collection consists of a corpus, a series of well-defined tasks, and a set of judgments indicating the “correct answers”. To complete the picture, there must exist meaningful metrics to evaluate progress, and ideally, a machine should be able to compute these values automatically. Although “answers” to definition questions are known, there is no way to automatically and objectively determine if they are present in a given system’s response (we will discuss why in Section 2). The experimental cycle is thus tortuously long; to accurately assess the performance of new techniques, one must essentially wait for expensive, large-scale evaluations that employ human assessors to judge the runs (e.g., the TREC QA track). This situation mirrors the state of machine translation and document summarization research a few years ago. Since then, however, automatic scoring metrics such as \textsc{Bleu} and \textsc{Rouge} have been introduced as stopgap measures to facilitate experimentation.

Following these recent developments in evalua-
Table 1: The “answer key” to the question “What is the Cassini space probe?”

|   |   |
|---|---|
| 1 | vital | 32 kilograms plutonium powered |
| 2 | vital | seven year journey |
| 3 | vital | Titan 4-B Rocket |
| 4 | vital | send Huygens to probe atmosphere of Titan, Saturn’s largest moon |
| 5 | okay | parachute instruments to planet’s surface |
| 6 | okay | oceans of ethane or other hydrocarbons, frozen methane or water |
| 7 | vital | carries 12 packages scientific instruments and a probe |
| 8 | okay | NASA primary responsible for Cassini orbiter |
| 9 | vital | explore remote planet and its rings and moons, Saturn |
| 10 | okay | European Space Agency ESA responsible for Huygens probe |
| 11 | okay | controversy, protest, launch failure, re-entry, lethal risk, humans, plutonium |
| 12 | okay | Radioisotope Thermoelectric Generators, RTG |
| 13 | vital | Cassini, NASA’S Biggest and most complex interplanetary probe |
| 14 | okay | find information on solar system formation |
| 15 | okay | Cassini Joint Project between NASA, ESA, and ASI (Italian Space Agency) |
| 16 | vital | four year study mission |

2 Evaluating Definition Questions

To date, NIST has conducted two formal evaluations of definition questions, at TREC 2003 and TREC 2004.\(^1\) In this section, we describe the setup of the task and the evaluation methodology.

Answers to definition questions are comprised of an unordered set of [document-id, answer string] pairs, where the strings are presumed to provide some relevant information about the entity being “defined”, usually called the target. Although no explicit limit is placed on the length of the answer string, the final scoring metric penalizes verbosity (discussed below).

To evaluate system responses, NIST pools answer strings from all systems, removes their association with the runs that produced them, and presents them to a human assessor. Using these responses and research performed during the original development of the question, the assessor creates an “answer key”—a list of “information nuggets” about the target. An information nugget is defined as a fact for which the assessor could make a binary decision as to whether a response contained that nugget (Voorhees, 2003). The assessor also manually classifies each nugget as

\(^1\)TREC 2004 questions were arranged around “topics”; definition questions were implicit in the “other” questions.
The Cassini space probe, due to be launched from Cape Canaveral in Florida of the United States tomorrow, has a 32 kilogram plutonium fuel payload to power its seven year journey to Venus and Saturn.

**Nuggets assigned:** 1, 2

Early in the Saturn visit, Cassini is to send a probe named Huygens into the smog-shrouded atmosphere of Titan, the planet’s largest moon, and parachute instruments to its hidden surface to see if it holds oceans of ethane or other hydrocarbons over frozen layers of methane or water.

**Nuggets assigned:** 4, 5, 6

Figure 1: Examples of judging actual system responses.

| Let |
|-----|
| \( r \) | # of **vital** nuggets returned in a response |
| \( a \) | # of **okay** nuggets returned in a response |
| \( R \) | # of **vital** nuggets in the answer key |
| \( l \) | # of non-whitespace characters in the entire answer string |

Then

\[
{\text{recall }} (\mathcal{R}) = \frac{r}{R} \\
{\text{allowance }} (\alpha) = 100 \times \left( \frac{r + a}{l} \right) \\
{\text{precision }} (\mathcal{P}) = \begin{cases} 
1 & \text{if } l < \alpha \\
1 - \frac{l - \alpha}{l} & \text{otherwise}
\end{cases}
\]

Finally, the

\[
F(\beta) = \frac{(\beta^2 + 1) \times \mathcal{P} \times \mathcal{R}}{\beta^2 \times \mathcal{P} + \mathcal{R}}
\]

\( \beta = 5 \) in TREC 2003, \( \beta = 3 \) in TREC 2004.

Figure 2: Official definition of F-measure.

in a system response, given that they were usually extracted text fragments from documents (Voorhees, 2003). Thus, a penalty for verbosity serves as a surrogate for precision.

3 Previous Work

The idea of employing \( n \)-gram co-occurrence statistics to score the output of a computer system against one or more desired reference outputs was first successfully implemented in the BLEU metric for machine translation (Papineni et al., 2002). Since then, the basic method for scoring translation quality has been improved upon by others, e.g., (Babych and Hartley, 2004; Lin and Och, 2004). The basic idea has been extended to evaluating document summarization with ROUGE (Lin and Hovy, 2003).
Recently, Soricut and Brill (2004) employed n-gram co-occurrences to evaluate question answering in a FAQ domain; unfortunately, the task differs from definition question answering, making their results not directly applicable. Xu et al. (2004) applied ROUGE to automatically evaluate answers to definition questions, viewing the task as a variation of document summarization. Because TREC answer nuggets were terse phrases, the authors found it necessary to rephrase them—two humans were asked to manually create “reference answers” based on the assessors’ nuggets and IR results, which was a labor-intensive process. Furthermore, Xu et al. did not perform a large-scale assessment of the reliability of ROUGE for evaluating definition answers.

4 Criteria for Success

Before proceeding to our description of POURPRE, it is important to first define the basis for assessing the quality of an automatic evaluation algorithm. Correlation between official scores and automatically-generated scores, as measured by the coefficient of determination $R^2$, seems like an obvious metric for quantifying the performance of a scoring algorithm. Indeed, this measure has been employed in the evaluation of BLEU, ROUGE, and other related metrics.

However, we believe that there are better measures of performance. In comparative evaluations, we ultimately want to determine if one technique is “better” than another. Thus, the system rankings produced by a particular scoring method are often more important than the actual scores themselves. Following the information retrieval literature, we employ Kendall’s $\tau$ to capture this insight. Kendall’s $\tau$ computes the “distance” between two rankings as the minimum number of pairwise adjacent swaps necessary to convert one ranking into the other. This value is normalized by the number of items being ranked such that two identical rankings produce a correlation of 1.0; the correlation between a ranking and its perfect inverse is $-1.0$; and the expected correlation of two rankings chosen at random is 0.0. Typically, a value of greater than 0.8 is considered “good”, although 0.9 represents a threshold researchers generally aim for. In this study, we primarily focus on Kendall’s $\tau$, but also report $R^2$ values where appropriate.

5 POURPRE

Previously, it has been assumed that matching nuggets from the assessors’ answer key with systems’ responses must be performed manually because it involves semantics (Voorhees, 2003). We would like to challenge this assumption and hypothesize that term co-occurrence statistics can serve as a surrogate for this semantic matching process. Experience with the ROUGE metric has demonstrated the effectiveness of matching unigrams, an idea we employ in our POURPRE metric. We hypothesize that matching bigrams, trigrams, or any other longer n-grams will not be beneficial, because they primarily account for the fluency of a response, more relevant in a machine translation task. Since answers to definition questions are usually document extracts, fluency is less important a concern.

The idea behind POURPRE is relatively straightforward: match nuggets by summing the unigram co-occurrences between terms from each nugget and terms from the system response. We decided to start with the simplest possible approach: count the word overlap and divide by the total number of terms in the answer nugget. The only additional wrinkle is to ensure that all words appear within the same answer string. Since nuggets represent coherent concepts, they are unlikely to be spread across different answer strings (which are usually different extracts of source documents). As a simple example, let’s say we’re trying to determine if the nugget “A B C D” is contained in the following system response:

1. A
2. B C D
3. D
4. A D

The match score assigned to this nugget would be 3/4, from answer string 2; no other answer string would get credit for this nugget. This provision reduces the impact of coincidental term matches.

Once we determine the match score for every nugget, the final F-score is calculated in the usual way, except that the automatically-derived match scores are substituted where appropriate. For example, nugget recall now becomes the sum of the match scores for all vital nuggets divided by the total number of vital nuggets. In the official F-score calcula-
As a baseline, we revisited experiments by Xu et al. (2004) in using ROUGE to evaluate definition questions. What if we simply concatenated all the answer nuggets together and used the result as the “reference summary” (instead of using humans to create custom reference answers)?

### 6 Evaluation of POURPRE

We evaluated all definition question runs submitted to the TREC 2003 and TREC 2004 question answering tracks with different variants of our POURPRE metric, and then compared the results with the official F-scores generated by human assessors. The Kendall’s τ correlations between rankings produced by POURPRE and the official rankings are shown in Table 2. The coefficients of determination (R²) between the two sets of scores are shown in Table 3. We report four separate variants along two different parameters: scoring by term counts only vs. scoring by term idf, and microaveraging vs. macroaveraging. Interestingly, scoring based on macroaveraged term

---

2In TREC 2003, the value of β was arbitrarily set to five, which was later determined to favor recall too heavily. As a result, it was readjusted to three in TREC 2004. In our experiments with TREC 2003, we report figures for both values.
counts outperformed any of the *idf* variants.

A scatter graph plotting official F-scores against *POURPRE* scores (macro, count) for TREC 2003 ($\beta = 5$) is shown in Figure 3. Corresponding graphs for other variants appear similar, and are not shown here. The effect of stemming on the Kendall’s $\tau$ correlation between *POURPRE* (macro, count) and official scores is shown in Table 4. Results from the same stemming experiment on the other *POURPRE* variants are similarly inconclusive.

For TREC 2003 ($\beta = 5$), we performed an analysis of rank swaps between official and *POURPRE* scores. A rank swap is said to have occurred if the relative ranking of two runs is different under different conditions—they are significant because rank swaps might prevent researchers from confidently drawing conclusions about the relative effectiveness of different techniques. We observed 81 rank swaps (out of a total of 1431 pairwise comparisons for 54 runs). A histogram of these rank swaps, binned by the difference in official score, is shown in Figure 4. As can be seen, 48 rank swaps (59.3%) occurred when the difference in official score is less than 0.02; there were no rank swaps observed for runs in which the official scores differed by more than 0.061. Since measurement error is an inescapable fact of evaluation, we need not be concerned with rank swaps that can be attributed to this factor. For TREC 2003, Voorhees (2003) calculated this value to be approximately 0.1; that is, in order to conclude with 95% confidence that one run is better than another, an absolute F-score difference greater than 0.1 must be observed. As can be seen, all the rank swaps observed can be attributed to error inherent in the evaluation process.

From these results, we can see that evaluation of definition questions is relatively coarse-grained. However, TREC 2003 was the first formal evaluation of definition questions; as methodologies are refined, the margin of error should go down. Although a similar error analysis for TREC 2004 has not been performed, we expect a similar result.

Given the simplicity of our *POURPRE* metric, the correlation between our automatically-derived scores and the official scores is remarkable. Starting from a set of questions and a list of relevant nuggets, *POURPRE* can accurately assess the performance of a definition question answering system without any human intervention.

### 6.1 Comparison Against ROUGE

We choose ROUGE over BLEU as a baseline for comparison because, conceptually, the task of answering definition questions is closer to summarization than it is to machine translation, in that both are recall-oriented. Since the majority of question an-

| Run          | unstemmed | stemmed |
|--------------|-----------|----------|
| TREC 2004 ($\beta = 3$) | 0.833     | 0.825    |
| TREC 2003 ($\beta = 3$)  | 0.886     | 0.897    |
| TREC 2003 ($\beta = 5$)  | 0.878     | 0.895    |

Table 4: The effect of stemming on Kendall’s $\tau$; all runs with (macro, count) variant of *POURPRE*. 

Figure 3: Scatter graph of official scores plotted against the *POURPRE* scores (macro, count) for TREC 2003 ($\beta = 5$).

Figure 4: Histogram of rank swaps for TREC 2003 ($\beta = 5$), binned by difference in official score.
swearing systems employ extractive techniques, flu-
ency (i.e., precision) is not usually an issue.

How does POURPRE stack up against using ROUGE\(^3\) to directly evaluate definition questions? The Kendall’s \(\tau\) correlations between rankings produced by ROUGE (with and without stopword removal) and the official rankings are shown in Table 2; \(R^2\) values are shown in Table 3. In all cases, ROUGE does not perform as well.

We believe that POURPRE better correlates with official scores because it takes into account special characteristics of the task: the distinction between vital and okay nuggets, the length penalty, etc. Other than a higher correlation, POURPRE offers an advantage over ROUGE in that it provides a better diagnostic than a coarse-grained score, i.e., it can reveal why an answer received a particular score. This allows researchers to conduct failure analyses to identify opportunities for improvement.

7 The Effect of Variability in Judgments

As with many other information retrieval tasks, legitimate differences in opinion about relevance are an inescapable fact of evaluating definition questions—systems are designed to satisfy real-world information needs, and users inevitably disagree on which nuggets are important or relevant. These disagreements manifest as scoring variations in an evaluation setting. The important issue, however, is the degree to which variations in judgments affect conclusions that can be drawn in a comparative evaluation, i.e., can we still confidently conclude that one system is “better” than another? For the \textit{ad hoc} document retrieval task, research has shown that system rankings are stable with respect to disagreements about document relevance (Voorhees, 2000). In this section, we explore the effect of judgment variability on the stability and reliability of TREC definition question answering evaluations.

The vital/okay distinction on nuggets is one major source of differences in opinion, as has been pointed out previously (Hildebrandt et al., 2004). In the Cassini space probe example, we disagree with the assessors’ assignment in many cases. More importantly, however, there does not appear to be any op-

\(^3\)We used ROUGE-1.4.2 with \(n\) set to 1, i.e. unigram matching, and maximum matching score rating.
| Run                  | everything vital | vitalokay flipped | random judgments |
|---------------------|------------------|-------------------|-----------------|
| TREC 2004 (β = 3)   | 0.919            | 0.859             | 0.841 ± 0.0195  |
| TREC 2003 (β = 3)   | 0.927            | 0.802             | 0.822 ± 0.0215  |
| TREC 2003 (β = 5)   | 0.920            | 0.796             | 0.808 ± 0.0219  |

Table 5: Correlation (Kendall’s τ) between scores under different variations of judgments and the official scores. The 95% confidence interval is presented for the random judgments case.

TREC 2004 (RUN-12 and RUN-8) over the one thousand random trials is shown in Figure 5. In 511 trials, RUN-12 was ranked as the highest-scoring run; however, in 463 trials, RUN-8 was ranked as the highest-scoring run. Factoring in differences of opinion about the vital/okay distinction, one could not conclude with certainty which was the “best” run in the evaluation.

It appears that differences between POURPRE and the official scores are about the same as (or in some cases, smaller than) differences between the official scores and scores based on variant answer keys (with the exception of “everything vital”). This means that further refinement of the metric to increase correlation with human-generated scores may not be particularly meaningful; it might essentially amount to overtraining on the whims of a particular human assessor. We believe that sources of judgment variability and techniques for managing it represent important areas for future study.

8 Conclusion

We hope that POURPRE can accomplish for definition question answering what BLEU has done for machine translation, and ROUGE for document summarization; allow laboratory experiments to be conducted with rapid turnaround. A much shorter experimental cycle will allow researchers to explore different techniques and receive immediate feedback on their effectiveness. Hopefully, this will translate into rapid progress in the state of the art.⁴
