(Received 7 January 2011; published 19 January 2012)

A laser pulse traveling through a plasma can excite large amplitude plasma waves that can be used to accelerate relativistic electron beams in a very short distance—a technique called laser wakefield acceleration. Many wakefield acceleration experiments rely on the process of wave breaking, or self-injection, to inject electrons into the wave, while other injection techniques rely on operation without self-injection. We present an experimental study into the parameters, including the pulse energy, focal spot quality, and pulse power, that determine whether or not a wakefield accelerator will self-inject. By taking into account the processes of self-focusing and pulse compression we are able to extend a previously described theoretical model, where the minimum bubble size \( k_p r_b \) required for trapping is not constant but varies slowly with density and find excellent agreement with this model.

Laser wakefield acceleration, where an intense laser pulse drives a plasma wave with a relativistic phase velocity, is a promising technique for the development of compact, or “tabletop,” particle accelerators and radiation sources. Plasma waves driven in moderate density plasmas can support electric fields over a thousand times stronger than those in conventional accelerators. Laser driven plasma waves have demonstrated electron acceleration to \( \approx 1 \) GeV in distances \( \approx 1 \) cm [1–3]. These compact particle accelerators have significant potential as bright x-ray sources [4–6] offering peak brightness comparable to 3rd generation synchrotron sources in x-ray flashes on the order of just 10 fs.

At the heart of the laser wakefield acceleration concept is the fact that electron plasma waves with relativistic phase velocities are driven to very large amplitudes, where they become highly nonlinear. If the plasma wave is driven beyond a threshold amplitude, the wave breaks. When the wave is driven far beyond the wave breaking threshold, the wave structure is destroyed and large amounts of charge can be accelerated to high energy but with a broad energy spread [7]. With appropriately shaped laser pulses this normally catastrophic process of wave breaking can be tamed to produce high quality beams of electrons. This is because close to the wave breaking threshold the nature of wave breaking changes—some electrons from the background plasma can become trapped in the wave without destroying the wave structure, a process called self-injection.

The highly nonlinear broken wave regime [8] is used in many experiments to produce quasimonochromatic electron beams [9–11]. In such experiments a threshold plasma density is commonly observed, below which no electron beams are produced. Because of the inverse scaling of the electron beam energy with plasma density, the highest energy beams achievable with a given laser system are achieved just above the threshold, and it is well known that many of the beam parameters including the spectrum and stability are also optimized just above the threshold density [12,13]. It is also well known that to achieve self-injection at lower densities higher power lasers are required—although the exact scaling of the threshold with laser power is not well known. A number of techniques to improve the electron beam parameters including stability and total charge have recently been demonstrated by using alternative injection schemes [14–18]. Crucially these schemes all rely on operating the laser wakefield accelerator (LWFA) below the self-injection threshold. A number of recent purely theoretical papers have addressed the dynamics of wave breaking or self-injection [19–22]. Clearly a good understanding of the self-injection threshold is important for the development of laser wakefield accelerators. We report here on a series of experiments which identify the key laser and plasma parameters needed to predict the density threshold and we develop a model capable of predicting the self-injection threshold density for a given set of experimental parameters.

In LWFA experiments the laser pulse self-focuses due to the transverse nonlinear refractive index gradient of the plasma [23,24] and the spot size decreases towards a matched spot size. This matched spot size occurs when the ponderomotive force of the laser balances the space charge force of the plasma bubble formed. In situations
where there is no loss of energy during self-focusing, nor any change in the pulse duration, the final matched spot size, and hence the final intensity, is simply a function of \( \alpha P / P_c \); \( P \) is the laser power; \( \alpha \) is the fraction of laser energy within the full width at half maximum intensity of the focal spot—important because energy in the wings of the spot are not self-focused by the plasma wave and so do not contribute; \( P_c \) is the laser power where relativistic self-focusing dominates over diffraction, \( P_c = (8 \pi \epsilon_0 m c^3 / e^2)(n_c / n_e) = 17 n_c / n_e \) GW (where \( n_e \) is the background plasma electron density and \( n_c \) is the critical density for propagation of the laser in the plasma). We might therefore expect that the self-injection threshold would occur at a fixed value of \( \alpha P / P_c \) [25]. However, it is also known that the longitudinal nonlinear refractive index gradient also has a significant effect on the pulse properties [26,27] and we expect this to have an affect on the self-injection threshold.

The experiment was carried out using the multi-TW laser at the Lund Laser Centre. The laser delivered pulse energies of up to 0.7 J in pulses as short as 40 fs, corresponding to a peak power of 18 TW. An f/9 off-axis parabolic mirror was used to focus the pulse. A deformable mirror was used to optimize the focal spot, producing a spot size of 16 ± 1 \( \mu m \) FWHM. For a Gaussian focal spot the theoretical maximum fraction of energy within the FWHM is \( \alpha = 1/2 \), the best focus that we obtained had \( \alpha = 0.48 \). The focal plane was positioned onto the front edge of a supersonic helium gas jet with an approximately flat top profile of length 1.8 ± 0.1 mm.

To investigate the self-injection threshold, we studied the effect of the plasma density \( n_e \), the total laser energy \( E \), the focal spot quality \( \alpha \), and the pulse duration \( \tau \) on the amount of charge in the electron beam. We chose to use the total charge in the electron beam as the diagnostic of self-injection as it provides a clear unambiguous signal of an electron beam.

The charge was measured using an electron beam profile monitor, consisting of a Lanex screen placed on the back surface of a wedge (which was used to collect the transmitted laser light). The wedge was 1 cm thick and made of glass and therefore prevented electrons below approximately 4 MeV reaching the Lanex. The Lanex screen was imaged onto a 12 bit CCD camera. To reduce the amount of background light from the interaction, a narrow band interference filter matched to the peak emission of the Lanex screen was placed in front of the camera. In addition, the camera was triggered several microseconds after interaction but within the lifetime of the Lanex fluorescence. The Lanex screen was calibrated using the absolute efficiency data, absolute response of the CCD camera, and the details of the imaging system [28]. A beam profile monitor was used in preference to an electron spectrometer due to the fact that it has a higher sensitivity (i.e. the signal produced by a low charge beam dispersed inside a spectrometer will drop below the background level, whereas the same low charge beam will produce a bright image on the profile monitor). Also close to the threshold we do not expect the electrons to have particularly high energy (i.e. injection could be occurring but the electron beam energy could be outside the range of the electron spectrometer).

The gas jet could produce electron densities up to \( n_e = 5 \times 10^{19} \text{ cm}^{-3} \). The laser pulse energy was varied by altering the energy pumping the final laser amplifier. We used the deformable mirror to reduce \( \alpha \) by adding varying amounts of spherical aberration. Spherical aberration has the effect of decreasing \( \alpha \) without introducing asymmetry to the focal spot and without significantly affecting its size. Degrading the focal spot symmetrically was desirable as asymmetric pulses can drive asymmetric wakes which can have a strong effect on the dynamics of self-injection [29]. The pulse duration was altered by changing the separation of the gratings in the compressor. Changing the grating separation introduced both a chirp to the pulse spectrum and a skew to the pulse envelope. To take this into account, we investigated both positive and negative chirps.

Figure 1 shows the effect of varying the laser pulse energy within the focal spot on the self-injection threshold. Keeping the total laser energy constant and degrading the focal spot (i.e. lowering \( \alpha \)) moves the threshold to higher plasma densities. We also observe an increase in the threshold density when we keep \( \alpha \) constant and reduce the laser pulse energy. In fact, we find that the two effects are equivalent, i.e., that the threshold shifts according to the product \( \alpha E \). This demonstrates that it is only the energy within the FWHM of the focal spot that contributes to driving the plasma wave. This emphasizes the importance
of laser focal spot quality in LWFA experiments [30], which are often performed with $\alpha = 0.3$ [2,25]. Improving the focal spot could therefore result in a significant increase in the electron beam energy achievable from a given laser system.

The observed variation of the threshold with $\alpha E$ is as expected for one based on $\alpha P/P_c$ but this can only be confirmed by the behavior of the threshold when we vary the laser pulse duration, keeping $\alpha E$ constant. When we do this we see markedly different behavior.

We kept the plasma density constant, at a value just above the threshold density for the optimally compressed pulse. At this density ($n_e = 1.6 \times 10^{19} \text{ cm}^{-3}$), with full laser energy ($\alpha E = 0.32 \text{ J}$) and the fully compressed pulse ($\tau = 42 \text{ fs}$) we observed a bright electron beam. When we reduced either the plasma density or the pulse energy by a small factor ($20\%-25\%$) this beam disappeared, i.e., we dropped below the threshold. Even after increasing the pulse duration by a factor of 2, electrons are clearly still injected, as shown in Fig. 2. This is true regardless of the chirp of the laser pulse, however we do see an enhancement of the total charge using positively chirped (red at the front) pulses as reported previously [31]. These pulses have a fast rising edge indicating that the precise shape of the pulse may play a role in the total charge injected. The direction of chirp of the pulse may also affect the rate at which pulse compression occurs [32]. For both directions of chirp the fact that the threshold behavior is so significantly different to that observed when varying $\alpha E$ suggests that pulse compression is indeed playing an important role in determining whether or not the accelerator reaches wave breaking.

In Fig. 3 we plot the total charge observed on the profile monitor screen for the various data sets. Figure 3(a) shows the total charge, plotted against the pulse power normalized to the critical power for self-focusing, for the data sets where we varied the plasma density and the energy within the focal spot (either by varying the spot quality $\alpha$ or total pulse energy $E$). The charge rises rapidly with increasing $\alpha P/P_c$ until eventually reaching a plateau at around $\alpha P/P_c = 4$. There is an increase in the total charge of a factor of 10 between $\alpha P/P_c = 2$ and $\alpha P/P_c = 4$ for both sets of data. The fact that both data sets lie on the same curve confirms the fact that it is the energy within the focal spot which determines the wakefield behavior. This supports the hypothesis that energy in the wings of the focal spot is not coupled into the accelerator: energy in the wings of the spot is effectively wasted.

Figure 3(b) shows the charge plotted against $\alpha P/P_c$ for a data set where we kept the plasma density and $\alpha E$ constant but varied the pulse duration (by introducing either positive or negative chirp). The markedly different behavior is once again apparent: rather than the rapid increase of charge between $\alpha P/P_c = 2$ and $\alpha P/P_c = 4$ the charge is approximately constant for each data set.

Figure 3(c) plots all of the data sets (varying $\alpha$, $E$, and $\tau$) against a scaled pulse energy $\alpha En_e/n_e$ rather than the...
scaled pulse power. The fact that the pulse duration data set now fits closely with the $\alpha E$ data sets confirms that pulse compression is playing an important role in determining whether or not the wakefield accelerator reaches self-injection.

A recent paper that examined the trajectory of electrons inside the plasma bubble [21] predicts that self-trapping will occur when the radius of the plasma bubble ($r_b$) is larger than a certain value given by

$$k_p r_b > 2\sqrt{2\ln(2\gamma_p^2) - 1},$$

where $\gamma_p = \sqrt{\frac{n_e}{3n_e}}$ [33] is the Lorentz factor associated with the phase velocity of the bubble. When this condition is met, an electron starting at rest a distance $r_b$ from the laser axis and following an elliptical trajectory in the bubble fields (thus defining the edge of the bubble) will be accelerated by the bubble fields up to $\gamma_p m_e c^2$ by the time it reaches the back of the bubble. A key feature of this model is that the normalized bubble size required for self-injection $k_p r_b$ is not constant with density. As Eq. (1) depends only on the plasma density and bubble size, we can determine the minimum pulse properties required to reach the threshold by noting that the radius of the bubble is related to the pulse energy and duration through [34]

$$k_p r_b = 2\sqrt{2\ln\left(\frac{\alpha E}{\tau P_c}\right)^{1/6}}.$$  \hspace{1cm} (2)

Combining Eqs. (1) and (2) yields an expression for the minimum pulse energy required to reach self-injection:

$$\alpha E > \frac{\sqrt{\alpha E m_e^2 c^5}}{e^2} \left[\ln\left(\frac{2n_e}{3n_e}\right) - 1\right]^3 \frac{n_e}{n_c} \tau(l),$$

where $\tau(l)$ is the pulse duration after a propagation length $l$. A simple model for the rate of pulse compression was put forward in Ref. [27] based on the fact that the front of the pulse travels at the group velocity of the laser in the plasma and the back of the pulse travels in vacuum, this produces $\tau(l) = \tau_0 - (n_f)/2cn_e$. The interaction length will be limited by either the length of the plasma target or the pump depletion length $l_{pd} \approx c\tau_0 n_e/n_c$ [34]. For the depletion limited case Eq. (3) reduces to

$$\frac{\alpha P}{P_c} > \frac{1}{16} \left[\ln\left(\frac{2n_e}{3n_e}\right) - 1\right]^3.$$ \hspace{1cm} (4)

The threshold density for self-injection for a given experiment can be calculated from (3) and (4). This model requires knowledge of the initial pulse energy, pulse duration, and the length of the plasma to predict the threshold. As Eqs. (3) and (4) are transcendental, the density threshold for a given laser system must be found numerically.

A previous study showed that, at low density, the threshold is approximately $\alpha P/P_c > 3$ [25], this can be rearranged into a similar form to Eq. (3):

$$\alpha E > 3\frac{\pi e_0 m_e^2 c^5}{e^2} \frac{n_e}{n_c} \tau_0.$$ \hspace{1cm} (5)

We can then use Eq. (5) to predict the density threshold for specific experimental conditions. To use this model only the initial pulse power is required to calculate the threshold density. Combining $\alpha P/P_c > 3$ and Eq. (2) reveals that this threshold model is also equivalent to stating that the minimum bubble size for self-trapping is constant with density ($k_p r_b > 3.4$) in contrast to Eq. (1).

In Fig. 4 we plot the variation of the observed threshold density with laser energy ($\alpha E$). We have defined the experimentally observed threshold density as lying in the region between the highest density where we observe no electron beam and the lowest density where we clearly observe a beam. We also show the theoretical threshold density based on Eqs. (3) and (4), and the predicted threshold based on Eq. (5). Its agreement with the experimental data indicates that our model accurately predicts the self-injection threshold, confirming that the threshold is reached because the laser pulse undergoes intensity amplification due to a combination of pulse compression and self-focusing.

Our measurements of the threshold density for self-injection have been made with only moderate laser pulse energies $\sim 1$ J. Many laser wakefield experiments are now being performed with pulse energies $\sim 10$ J and the validity of this model at these higher laser energies can be verified by applying it to previously published data. We restrict ourselves to data obtained from experiments with gas jets as guiding structures can affect the trapping threshold by changing the way pulse evolution occurs [30] or by introducing additional effects such as ionization injection [35]. To calculate the density threshold for a particular set of experimental parameters, the following information is required: the laser energy $E$, the focal spot quality $\alpha$, the initial pulse duration $\tau$, and the maximum plasma length $l$. Equations (3) and (4) or Eq. (5) can then be used to calculate the expected density threshold for the two models. Kneip et al. [2], using a 10 J, 45 fs, 800 nm laser pulse

[FIG. 4. Observed density threshold as a function of laser energy ($\alpha E$) for our experiment. The solid curve represents our threshold model. The dashed curve represents a threshold based on $\alpha P/P_c > 3$.]
with \( \alpha = 0.3 \), observed a threshold density of \( n_e = 2 - 3 \times 10^{18} \text{ cm}^{-3} \) in an 8.5 mm long plasma; our model predicts that the threshold density for self-injection should occur at \( n_e = 3 \times 10^{18} \text{ cm}^{-3} \). Froula et al. [25], using a 60 fs, 800 nm laser with \( \alpha E = 6 \) J, observed a threshold density of \( n_e = 3 \times 10^{18} \text{ cm}^{-3} \) in an 8.0 mm plasma; our model also predicts \( n_e = 3 \times 10^{18} \text{ cm}^{-3} \). Schmid et al. [36], using an 8 fs, 840 nm laser with \( \alpha E = 15 \) mJ, observed electron beams at a density of \( n_e = 2 \times 10^{19} \text{ cm}^{-3} \) in a plasma 300 \( \mu \text{m} \) long; our model predicts a threshold of \( n_e = 2.2 \times 10^{19} \text{ cm}^{-3} \). Faure et al. [11], using a 33 fs, 820 nm laser, reported a dramatic decrease in the number of accelerated electrons at \( n_e = 6 \times 10^{18} \text{ cm}^{-3} \) in a 3 mm gas jet with \( \alpha E = 0.5 \) J. Our model predicts a threshold density of \( n_e = 7 \times 10^{18} \text{ cm}^{-3} \).

These additional data points, together with those from this experiment, are presented in Fig. 5. Because of the fact that our model does not depend on a single experimental parameter, we plot the experimentally observed density threshold \( n_i \) for each experiment on the x-axis and against the calculated threshold \( n_{\text{model}} \) obtained using either Eqs. (3) and (4) or Eq. (5). Figure 5 shows that our model is in good agreement with experiments over nearly 3 orders of magnitude in laser energy, whereas the threshold based on Eq. (5) matches the observed threshold over only a very limited range of pulse energies: it overestimates the threshold density for low energy laser systems and, on the other hand, would significantly underestimate the threshold for very high energy laser systems.

We note that simulations by Yi et al. [22] show that, at very low density and an initial laser spot size less than the matched spot size, diffraction of the laser pulse leads to a lengthening of the bubble which plays a role in determining self-injection. In that work they see self-injection with a 200 J, 150 fs laser pulse at a density of \( n_e = 10^{17} \text{ cm}^{-3} \). Our model predicts that the threshold would be \( n_e = 4 \times 10^{17} \text{ cm}^{-3} \)—actually in reasonable agreement with [22], however our model relies on pulse compression occurring over ~ 10 cm whereas Yi et al. show that in their simulations injection occurs after just 5 mm. This indicates that our model is only valid for initial laser spot sizes greater than or equal to the matched spot size (as is the case for the experiments shown in Fig. 5).

We now use our model to predict the self-injection threshold density for lasers currently under construction. For example, our model predicts that a 10 PW laser (300 J in 30 fs, \( \lambda = 0.9 \mu \text{m} \), such as the Vulcan 10 PW laser at the Rutherford Appleton Lab, or the ELI Beamlines facility in the Czech Republic) could produce electron injection at as low as \( n_e = 2 \times 10^{17} \text{ cm}^{-3} \) (assuming \( \alpha = 0.5 \)) in a 6 cm long plasma. For a 1 PW laser (40 J in 40 fs, \( \lambda = 0.8 \mu \text{m} \), such as the Berkeley Lab Laser Accelerator, BELLA), our model predicts that self-injection will occur at a density of \( n_e = 9 \times 10^{17} \text{ cm}^{-3} \) in 2.4 cm.

The lower the threshold density of a wakefield accelerator, the higher the maximum beam energy. However, for self-injecting accelerators there must be acceleration after injection, requiring operation at densities slightly above this threshold so that injection occurs earlier in the interaction.

In summary, we have measured the effect of various laser parameters on the self-injection threshold in laser wakefield accelerators. The simple model we use relies on the fact that pulse compression and self-focusing occur and that only the energy within the FWHM of the focal spot contributes towards driving the plasma wave. We find that in cases where the interaction is limited by pump depletion, the threshold can be expressed as a ratio of \( P/P_c \), but this ratio is not the same for all laser systems: for higher power lasers the threshold occurs at a higher value of \( P/P_c \) than for lower power lasers. When the plasma length is shorter than the pump depletion length, we find that the length of the plasma is an important parameter in determining the injection threshold.
