Abstract
Background: Whole-ventricular radiotherapy (WV-RT) followed by a boost to the tumor bed (WV-RT/TB) is recommended for intracranial germ cell tumors (IGCT). As the critical brain areas are mainly in the target volume vicinity, it is unclear if protons indeed substantially spare neurofunctional organs at risk (NOAR). Therefore, a dosimetric comparison study of WV-RT/TB was conducted to assess whether proton or photon radiotherapy achieves better NOAR sparing.

Methods: Eleven children with GCT received 24 Gy(RBE) WV-RT and a boost up to 40 Gy(RBE) in 25 fractions of 1.6 Gy(RBE) with pencil beam scanning proton therapy (PBS-PT). Intensity-modulated radiotherapy (IMRT) and volumetric-modulated arc therapy (VMAT) plans were generated for these patients. NOAR were delineated and treatment plans were compared for target volume coverage (TVC), homogeneity index (HI), inhomogeneity coefficient (IC) and (N)OAR sparing.

Results: TVC was comparable for all three modalities. Compared to IMRT and VMAT, PBS-PT showed statistically significant optimized IC, as well as dose reduction, among others, in mean and integral dose to the: normal brain (−35.2%, −32.7%; −35.2%, −33.0%, respectively), cerebellum (−53.7%, −33.1%; −53.6%, −32.7%) and right temporal lobe (−14.5%, −31.9%; −14.7%, −29.9%). The Willis’ circle was better protected with PBS-PT than IMRT (−7.1%; −7.8%). The left hippocampus sparing was higher with IMRT. Compared to VMAT, the dose to the hippocampi, amygdalae and temporal lobes was significantly decreased in the IMRT plans.

Conclusions: Dosimetric comparison of WV-RT/TB in IGCT suggests PBS-PT’s advantage over photons in conformality and NOAR sparing, whereas IMRT’s superiority over VMAT, thus potentially minimizing long-term sequelae.

1. Introduction

Intracranial germ cell tumors (IGCT) represent a histologically heterogeneous pediatric group of primary predominantly midline tumors of the CNS, most commonly seen in the pineal and the suprasellar region [1,2], classically divided into two main groups: germinomas – the most common –, and non-germinomatous GCT, which carry a less favorable prognosis [3,4]. Germinomas are highly sensitive to both chemotherapy and radiotherapy (RT), and curable by RT alone [1,2,4], either photons or protons [5]. They
present an excellent prognosis with overall survival of 93.7% five years after RT alone, 100% and 80.6% at 10- and 20-years, respectively [1,6,7]. Macdonald showed early clinical outcomes of IGCT patients treated with protons where local control, progression-free survival, and overall survival rates were, respectively, 100%, 95%, and 100%, at a median follow-up of 28 months [8]. Whole ventricular system irradiation followed by a boost to the tumor bed (WW-RT/TB) is considered a well-established treatment for localized germinomas [MacDonald, 2003 #259] [8].

There has been an effort for treatment de-escalation, due to: first, good response rates to neoadjuvant chemotherapy in non-disseminated disease [9], with low leptomeningeal recurrence [1]; second, noteworthy toxicity in long-term survivors [7]. However, evaluating cerebral toxicity is extremely difficult as we only begin to understand the intricate interplay between the different substructures in physiological conditions, let alone in pathological conditions [10]. Nonetheless, studies of Merchant et al. [11] demonstrated that radiation dose-volume parameters remain the most clinically significant determinants of intelligence quotient (IQ) outcomes and that further reduction in radiation dose to specific volumes of the brain should be pursued [12]. Relative to photons, hadron therapy could achieve even better protection of healthy tissues by improved beam trajectory [8], having the potential to prevent the genesis of radiogenic impairment [13], thus being expected to reduce late effects without decreasing local control and survival [5].

However, taking into account that most of the neurofunctional organs at risk (NOAR) are partly enclosed or in the direct vicinity of the target, we hypothesized that there would not be a dosimetric advantage of pencil beam scanning proton therapy (PBS-PT) over a state of the art photon treatment technique. To the best of our knowledge, no dosimetric comparison based on WW-RT/TB has yet been made between PBS-PT and photon RT for non-metastatic IGCT with focus on NOAR sparing. Therefore, we performed a planning study with the aim of determining the dosimetric difference between intensity-modulated radiotherapy (IMRT) and volumetric-modulated arc therapy (VMAT) on a cohort of IGCT patients treated with PBS-PT WW-RT/TB, using dose-volume indices of target volume coverage (TVC) and (N)OAR. Hereby, we compared the sparing potential of NOAR, currently used as a surrogate for neurocognition, cerebrovascular and neuroendocrine function, as well as other important structures, such as optic apparatus and cochleae, delineated on a routine basis for the planning of brain tumors RT.

2. Materials and methods

2.1. Patient selection

Between 2005 and 2017, 11 patients (8 males; 6–16 years, median 11) with a histologically proven diagnosis of localized IGCT were treated, after multi-agent chemotherapy, with PBS-PT at the Centre for Proton Therapy at the Paul-Scherrer Institute (PSI). They consisted of 2 bifocal germinomas, 4 pineal, 2 suprasellar, while 3 IGCT presented an atypical location with infiltrative spread within the ventricular system. Written, informed consent to the PBS-PT was obtained from the children legal guardians. Institutional review board approval was obtained before record and plan review. Complete anonymity of names and medical record numbers was maintained.

2.2. Target volume and organ at risk delineation

First, all the 11 treatment planning-CTs and pre-irradiation MRI studies were anonymized and imported into a research database of Velocity (version 3.2.1, Varian Medical Systems, Inc., Palo Alto, USA). The MRls were anatomically registered to the CT to facilitate volume definition. Then, for each patient, all volumes of interest (VOI) were delineated or adapted by a single radiation oncologist and reviewed by a neuro-radiation oncologist, as well as one neuroradiologist. For the purpose of this study, a 3 mm isometric margin, created on the same treatment planning software (TPS), was used for both planning treatment volumes (PTV). Delineation guidelines of the target volumes [14] and (N)OAR [15], as well as their dose constraints are detailed in the supplementary file A.

2.3. Treatment planning

The planning-CT data was sent in DICOM format, and all data transfers were made using file transfer protocol over Internet connections. The same VOI, dose prescription, and constraints were used to ensure comparability among the plans. The WW/TB were prescribed 24 Gy (PTV_Low), followed by a boost of 16 Gy to the TB (PTV_High), achieving a total dose of 40 Gy in 1.6 Gy per fraction. The plans were normalized to get 100% of the prescribed dose (D_100) as the mean dose to each PTV. All treatment plans were optimized to maximize TVC whilst sparing OAR. Besides the hippocampi and temporal lobes, no further fixed constraint was set for the NOAR than the as low as reasonably achievable (ALARA) concept [10], due to its location towards the target and lack of consensus constraints.

After trying and comparing different beam arrangements, all patients were treated with PBS-PT with three non-coplanar proton fields for both treatment series, with different gantry angulations and table rotation. Similar field arrangements have been used for the first phase and an adapted one for the boost (example in Fig. 1): one posterior field (G180deg, couch 0), two superior oblique fields (G00deg, couch 315–325 and G270deg, couch 35–45), in IEC61217 coordinate convention. All PBS-PT cases were planned with single field uniform dose, using the PSIPlan TPS (version 2.9.1-exp). The generic relative biologic effectiveness (RBE) factor for protons of 1.1 (relative to 60Co) was utilized, and proton dose was expressed in terms of Gy(RBE) (i.e., Gy(RBE) = proton physical Gy × 1.1) [16]. The ion source was a dedicated 250 MeV cyclotron. Protons were actively delivered using a PBS paradigm, as previously described [17]. Individual weights of the Bragg peak were computed using a dose based optimization scheme [18] to obtain an optimal TPC. Proton dose calculation was performed using a 3D dose-calculation algorithm developed at PSI [19].

Comparison planning with IMRT and VMAT was performed on the original anonymized planning CT datasets and its respective study VOI. For the IMRT planning, after comparing with other beam arrangements, seven fields were used for the primary and five for the boost phase. The dose distribution of the photon plans was calculated with the Anisotropic Analytical Algorithm version 13.6.23, and optimized with the Dose Volume Optimizer version 11.0.31, on the Eclipse External Beam Planning (same version as described in 2.2).

2.4. Comparative evaluation of treatment plans

The proton plans were imported to Eclipse for comparison with the photon plans, where they were quantitatively assessed using dose-volume histograms (DVH) for all VOI. Dose parameters were extracted to evaluate proper TVC, assure compliance with the OAR dose constraints and determine differences between all RT modalities. TVC was assessed by the evaluation of the volume receiving a minimum of 90%, 95%, and 100% of the prescribed doses (V90%, V95%, V100%, respectively) [13,20]. Dose distribution in the PTV was evaluated with the homogeneity index (HI) and inhomogeneity coefficient (IC). The integral dose (ID) (Supplementary file) allows the
evaluation of the lower dose spread compared to conventional measurements [21].

2.5. Statistics

Statistical analysis was performed on IBM® SPSS® Statistics software, version 24 (Armonk, NY). Descriptive statistics were used to calculate the differences in treatment parameters of proton and photon therapy. The Friedman test with the Bonferroni posttest was applied for analysis of statistically significant differences between several dosimetric parameters of the targets and (N) OAR of the proton and photon plans, with corresponding two-sided 95% confidence intervals to correct for multiple comparisons. A p-value inferior to 0.017 (Bonferroni correction) was considered statistically significant.

3. Results and discussion

3.1. Target volume coverage

Despite the normalization of each PTV (see 2.3), after extracting the DVH values automatically with an Eclipse protocol template, a technical deviation $\leq 0.25\%$ could be seen (Table 1) if performed on another TPS than where it was planned. Therefore, the PBS-PT results should be critically appraised with the same amount of uncertainty. For this reason, only higher deviations ($>0.25\%$), statistically significant ($p < 0.017$), will be mentioned.

TVC was comparable for all three modalities (Fig. 2). However, PBS-PT achieved a better $V_{100\%}$ (22.5%) in PTV_High, compared to VMAT.

Comparing to IMRT and VMAT, both PTV showed with PBS-PT a higher minimum dose ($D_{min}$) to the PTV (PTV_Low: 26.4%, 18.2%; PTV_High: 15.9%, 7.8%). Both IC were significantly lower for protons (PTV_Low: $-50.0\%$, $-33.3\%$; PTV_High: $-44.8\%$, $-30.4\%$), indicating a lower variability of the target dose distribution in PBS-PT than in the photon modalities.

The dose distribution homogeneity on the primary phase was optimized in the VMAT plans, as the PTV_Low HI was significantly lower than the other RT techniques, while PBS-PT was better than IMRT on the boost phase (Table 1).

3.2. Neurofunctional organ at risk sparing

For the OARs, 100% was considered to be 40 Gy (Table 1). All hard constraints were met, independently of the technique used.

3.2.1. NOAR of neurocognitive function

The hippocampal and amygdalae $D_{mean}$ and ID seem better spared with IMRT than VMAT, while on the left hippocampus the IMRT dose sparing seems higher than with the remaining techniques ($-6.2\%$ $D_{mean}$, $-6.1\%$ ID than PBS-PT; $-10.8\%$ $D_{mean}$ and ID each, comparing with VMAT). However, taking into account the hippocampal proximity to the target, its soft constraint of $D_{40\%}$ $\leq 7.3$ Gy could never be reached – its lowest absolute dose was 24.2 Gy on one PBS-PT plan.

There is growing evidence from structural and functional imaging studies that the cerebellum plays an evident role in neurocognition. Radiation to the posterior fossa has shown to have a negative effect on neurocognitive outcomes in long-term pediatric brain survivors [12]. Gan et al. described that the patient with the lowest neuropsychological scores received 36 Gy $D_{max}$ on the cerebellum and low radiation doses on the whole brain and hippocampi [22]. In our cohort, only one case (PBS-PT) achieved a $D_{max} < 36$ Gy, otherwise, the PBS-PT average was 39.6 Gy (range,
### Table 1
Comparison of target volume coverage and normal tissue sparing between PBS-PT, IMRT and VMAT.

| VOI            | Parameter | PBS-PT | IMRT | VMAT | PBS-PT vs. IMRT (%) | PBS-PT vs. VMAT (%) | IMRT vs. VMAT (%) |

35.5–41.6 Gy). However, the statistically significant difference to IMRT and VMAT could be seen on Dmean (−53.7%, −33.1%) and ID (−53.6%, −32.7%), favoring the proton over the photon plans. Between IMRT and VMAT, the latter seems dosimetrically beneficial (44.5% Dmean; 45.1% ID) regarding cerebellum dose exposure (Fig. 3).

Compared to IMRT and VMAT, PBS-PT showed the following statistically significant reduction in:

- temporal lobe – Dmax (−14.5%, −31.9%), ID (−14.7%, −29.9%), V20Gy (−24.2%, −41.1%) on the right side. Moreover, the left temporal lobe dose sparing was higher with protons (PBS-PT Dmean, ID better than IMRT; PBS-PT V20Gy better than VMAT). Compared to VMAT, IMRT seems advantageous in both lobes.

- subventricular zone (SVZ) – maximum dose (Dmax) (−2.0%, −2.6%) on the right side. Furthermore, VMAT had the least dose sparing in comparison to the other two modalities (PBS-PT Dmean and ID better spared on both sides, while IMRT Dmean and ID on the left side).

Fig. 3: Cumulative DVH (mean dose, n = 11) with range for (N)OAR with a significant dose difference for PBS-PT compared to photons.

Table 1 (continued)

| VOI          | Parameter    | PBS-PT      | IMRT        | VMAT        | PBS-PT vs. IMRT (%) | PBS-PT vs. VMAT (%) | IMRT vs. VMAT (%) |
|--------------|--------------|-------------|-------------|-------------|---------------------|---------------------|-------------------|
| TMJ right    | Dmax (%)     | 10.7 ± 11.8 | 18.0 ± 8.7  | 12.7 ± 4.6  | −40.6               | −15.7               | 41.7              |
|              | Dmean (%)    | 1.3 ± 1.8   | 9.7 ± 4.2   | 8.6 ± 2.6   | −86.1               | −83.8               | 16.2              |
|              | Mean ID (Gy.ml) | 1.1 ± 1.6   | 7.9 ± 4.5   | 6.8 ± 3.3   | −86.0               | −83.8               | 16.2              |

Values are given as mean relative dose with standard deviations in percentage (%):

- Primary phase (PTV_Low, CTV_Low, GTV_Low) 24 Gy
- Boost phase (PTV_High, CTV_High, GTV_High) 16 Gy
- Organs at risk All other VOI 40 Gy

Abbreviations: VOI, volume of interest; PTV, planning target volume; Dmax, maximum dose of VOI; Dmean, average dose of VOI; Dmin, minimum dose of VOI; ID, integral dose (Dmean × volume); V90%, percentage of PTV receiving a minimum of 90% of the prescribed dose; V95%, percentage of PTV receiving a minimum of 95% of the prescribed dose; V100%, percentage of PTV receiving a minimum of 100% of the prescribed dose; HI, homogeneity index [(D5% − D95%)/prescribed dose × 100]; IC, inhomogeneity coefficient ((Dmax − Dmin)/Dmean); CTV, clinical target volume; GTV, gross tumour volume; SVZ, subventricular zone; TMJ, temporomandibular joint.

* Indicates statistically significant differences (p < 0.017) in the Friedman test with the Bonferroni posttest.
in the temporal lobes and limbic cortex [25]. The proposed dose constraint for the hippocampi is currently $D_{\text{max}} \leq 7.3$ Gy to avoid memory loss [10]. Prospective data demonstrate not only a significant association between increasing dose to the hippocampus and temporal lobes and decline in neurocognitive skills following cranial irradiation [26], but also with the dose and volume of the irradiated healthy brain and the IQ [27]. Age was also an important determinant of impact on IQ, with younger children being more sensitive to neurocognitive effects of RT [11,28]. Especially in this population, a decrease in IQ, processing speed, and fine motor skills have been reported after chemoradiation, with memory impairment associated with a $D_{\text{max}} > 30$ Gy to the temporal lobe [29]. When normal tissue volumes such as the supratentorial brain or temporal lobes receive less of the low and intermediate doses [28], it resulted in clinically significant higher IQ scores for patients with intracranial tumors [30].

3.2.2. NOAR of cerebrovascular function

PBS-PT allowed for a statistically significant difference of $-7.1\%$ $D_{\text{mean}}$ and $-7.8\%$ ID of the Willis’ circle, when compared to IMRT. El-Fayech et al. reported that at 45 years of age, the cumulative stroke incidence was 11.3% in patients who had received $D_{\text{max}} \geq 10$ Gy to the Willis’ circle as children, compared with 1% expected from general population data [31]. In our cohort, the $D_{\text{mean}}$ applied to the Willis’ circle was 25.3 Gy (range, 10.3–39.7 Gy) for PBS-PT, 27.5 Gy (range, 14.1–39.7 Gy) for IMRT and 27.0 Gy (range, 2.5–39.4 Gy) for VMAT. Nevertheless, the ALARA concept seems to play an important role on the potential of decreasing the likelihood of vascular sequelae: an association of 5% stroke hazard increase per 1 Gy ($D_{\text{mean}}$) mainly to the Willis’ circle was estimated in a longitudinal data set of >10,000 cancer survivors [32], thus showing a dose-dependent effect (almost 30-fold higher risk of stroke after cranial RT than the general population) [31].

3.2.3. NOAR of neuroendocrine function

Regarding the hypothalamic-pituitary axis, only the VMAT $D_{\text{mean}}$ and ID of the left hypothalamus were significantly lower ($-0.6\%$ and $-0.9\%$, respectively) comparing with PBS-PT and $D_{\text{max}}$ ($-1.2\%$), comparing with IMRT.

Even low dose on the hypothalamic-pituitary axis influences the occurrence of endocrinopathy [19]. Pai et al. reported that $D_{\text{mean}} < 20$ Gy(RBE) to the hypothalamus was associated with endocrinopathy, even though this association was only found for a $D_{\text{mean}} > 50$ Gy(RBE) for the pituitary gland [33]. Chemaitilly et al. identified an association between luteinizing hormone/follicle-stimulating hormone deficiencies already with 22 Gy $D_{\text{mean}}$ to the pituitary gland and hypothalami on a lifetime cohort study of adult survivors of childhood cancers [34]. In our cohort, the lowest pituitary $D_{\text{mean}}$ was achieved with IMRT, with 21.4 Gy (range, 6.2–40.1 Gy), while PBS-T 21.8 Gy (range, 2.6–41.4 Gy) and VMAT 21.6 Gy (range, 1.7–40.0 Gy). Moreover, 30 Gy $D_{\text{mean}}$ to the pituitary gland might cause growth hormone deficiency in $\leq 30\%$ of patients, with 30–50 Gy affecting 50–100% [35].

3.2.4. Other NOAR function

3.2.4.1. Vision. The lacrimal glands, lenses and optic globes could be better spared with PBS-PT, comparing with photons (in $D_{\text{mean}}$ $D_{\text{max}}$, ID); yet better with IMRT, when compared to VMAT. The risk for keratoconjunctivitis sicca could be avoided, as in all modalities $D_{\text{mean}}$ of each lacrimal gland was $\leq 25$ Gy [10]. The potential for cataract is low, as $D_{\text{mean, 0.03cc}}$ of each lens was $\leq 10$ Gy [10], even $<6$ Gy [15], according to the recommended constraints. The risk for neuropathic complication is extremely low, considering the low optic nerve dose presented in every RT modality. The lowest optic nerve $D_{\text{max}}$ was achieved with IMRT. However, a statistically significant difference was reached in favor of IMRT (in $D_{\text{mean}}$ and ID) only by comparing it with VMAT.

3.2.4.2. Audition. To avoid tinnitus, the $D_{\text{mean}}$ of the cochleae should be $\leq 32$ Gy [10], which was possible with all three techniques. The lowest cochlear $D_{\text{mean}}$ was achieved with PBS-PT. However, a statistically significant difference was reached (in $D_{\text{max}}$, $D_{\text{mean}}$, ID) only by comparing IMRT with VMAT, in favor of the latter.

3.2.5. Other potential late toxicity

3.2.5.1. Radionecrosis. The $D_{\text{mean}}$ applied to the brainstem was 29.9 Gy (range, 24.9–34.3 Gy) for PBS-PT, 33.0 Gy (range, 28.7–36.3 Gy) for IMRT and 30.9 Gy (range, 28.7–36.6 Gy) for VMAT. According to Uy et al., exceeding the 30 Gy $D_{\text{mean}}$ might increase the incidence of severe brainstem necrosis in 3% [36]. Considering our pediatric cohort, a lower threshold should be taken into account. The lowest brainstem dose exposure was achieved with PBS-PT in all its dose-metrics. However, a statistically significant difference was reached only when compared to IMRT ($-9.2\%$ $D_{\text{mean}}$ and ID).

With the applied dose to the temporal lobes (3.2.1., Table 1), the risk for necrosis is very low.

3.2.5.2. Myelopathy. Even though the spinal cord $D_{\text{max}}$ of this cohort has not exceeded 30.2 Gy (IMRT) – therefore, not expecting the risk of myelopathy –, the highest spinal cord sparing was achieved with VMAT. Compared with PBS-PT and IMRT, VMAT presented reduced $D_{\text{mean}}$ ($-47.2\%$, $-39.3\%$) and ID ($-45.1\%$, $-43.1\%$).

3.2.5.3. Alopecia. No permanent alopecia is expected, as $D_{\text{0.03cc}}$ of the skin was $\leq 25$ Gy [10].

3.2.5.4. Risk for secondary malignancy. Healthy brain tissue, as a potential risk area for secondary malignancy, could be spared mainly with protons: $D_{\text{mean}}$ 12.0 Gy (range, 8–20.5 Gy) for PBS-PT, 18.5 Gy (range, 12.9–28.2 Gy) for IMRT and 17.9 Gy (range, 14.11–25.0 Gy) for VMAT. Despite no clinical proof of a sequela difference regarding this dose level to the pediatric brain, it is known that even relatively low doses of radiation, once perceived as being “safe”, may increase the probability of the development of secondary cancers [37]. Therefore, the ALARA concept should be followed. Moreover, an ID reduction, as seen in the proton plans, is expected to result in a lower rate of secondary tumor induction after treatment [38]. Compared to IMRT and VMAT, PBS-PT showed the following statistically significant differences:

- normal brain (brain without PTV) – $D_{\text{max}}$ ($-2.5\%$, $-1.6\%$), $D_{\text{mean}}$ ($-35.2\%$, $-32.7\%$) and ID ($-35.2\%$, $-33.0\%$, respectively);
- supratentorial brain – $D_{\text{mean}}$ ($-23.8\%$, $-20.7\%$) and ID ($-21.9\%$, $-20.1\%$);
- parotid glands – $D_{\text{max}}$ (left: $-96.7\%$, $-93.8\%$; right: $-98.2\%$, $-96.6\%$), $D_{\text{mean}}$ ($-100.0\%$, $-100.0\%$) and ID ($-100.0\%$, $-100.0\%$).

The dose to the parotid glands is way below the recommended 20 Gy in every modality, meaning that the expected xerostomia will be below 20% [39]. The PBS-PT dose is otherwise close to 0.0 Gy in every dose-metric, similar to the lenses and temporomandibular joints. In comparison, these healthy tissues would be susceptible to develop a secondary malignancy if this long-term survivor cohort would have been treated with photons.

3.3. Comparative evaluation of treatment plans

RT planning with steep dose gradient is required to better spare the NOAR. Effective immobilization and accurate radiation delivery methods are therefore crucial to provide the higher degree of
set-up reproducibility required. This varies with the immobilization type used and compliance of the patient. For PBS-PT plans, a 4 mm CTV-PTV margin for a bite-block immobilization system was applied at PSI. At Inselspital, a 3 mm margin for a frameless thermoplastic mask would have been used instead. On the one hand, the lowest margin could be advantageous in comparison to the 4 mm margin by reducing the NOAR volume irradiated, mainly from the thalamus (Supplementary file Fig. A.1, light blue VOI). On the other hand, within this 1 mm difference, the number of NOAR included in the PTV_Low is the same. Furthermore, the 3 mm expansion on one TPS showed similar volume to the 4 mm expansion on the other TPS, thus being cursory to perform an analysis comparing both.

IMRT with dose painting has been shown in dosimetric comparisons to provide the most conformal photon treatment for WV-RT [40,41]. However, some studies raised concern about its possibility of creating a greater ID delivered mainly to the healthy brain [42]. Another sparing approach with photons is VMAT, with reduced treatment delivery time compared to conventional static field IMRT [43], which can be advantageous in a pediatric population. For future multiple-arc treatments, dynamic trajectory VMAT [27,44] might be a good study objective to provide further improvements in OAR sparing in IGCT, especially when PT is not available.

PT is an acknowledgeable technique for normal tissue sparing in pediatric cranial RT, with its predicted consistently lower doses to critical normal tissues and ID to the body [38] compared with photons [30]. Regarding WV-RT, MacDonald published one demonstrative case of WV-RT/TB in localized IGCT (WV = 23.4 Gy, boost 30.6 Gy, pediatric cranial RT, with its predicted consistently lower doses to available.

Improvements in OAR sparing in IGCT, especially when PT is not available.

4. Conclusion

Taking into account the ALARA concept, PBS-PT can be a reasonable alternative to photons for IGCT, as it seems to reduce dose exposure to the surrounding NOAR while keeping good target coverage and better conformity. Otherwise, IMRT seems dosimetrically superior to WV-RT regarding the NOAR sparing in WV-RT/PTB. Overall, technical attempts to potentially reduce the dose- and volume-related side effects of treatment in long-term survivors should be pursued, ideally on prospectively assessing outcome.

Declarations of interest

None.

Authorship

All authors listed on the manuscript contributed to the experimental design, its implementation, or analysis and interpretation of the data. All authors were involved in the writing of the manuscript at draft and any revision stages, and have read and approved the final version.
