Rejection Sampling for Tempered Lévy Processes

Michael Grabchak* University of North Carolina Charlotte
June 5, 2018

Abstract
We extend the idea of tempering stable Lévy processes to tempering more general classes of Lévy processes. We show that the original process can be decomposed into the sum of the tempered process and an independent point process of large jumps. We then use this to set up a rejection sampling algorithm for sampling from the tempered process. A small scale simulation study is given to help understand the performance of this algorithm.

Keywords: tempered Lévy processes; tempered stable distributions; rejection sampling
MSC2010: 60G51; 60E07

1 Introduction
Tempered stable distributions are a class of models obtained by modifying the tails of stable distributions to make them lighter. This leads to models that are more realistic for a variety of applications, where real-world frictions prevent extremely heavy tails from occurring. Perhaps the earliest models of this type are Tweedie distributions, which were introduced in Tweedie (1984), see also Küchler and Tappe (2013) for a recent review. A more general approach is given in Rosiński (2007). This was further generalized in several directions in Rosiński and Sinclair (2010), Bianchi et al. (2011), and Grabchak (2012). A survey with many references, which discuss a variety of applications, including those to actuarial science, biostatistics, computer science, mathematical finance, and physics can be found in Grabchak (2016).

Associated with every tempered stable distribution, is a tempered stable Lévy process, which behaves like a stable Lévy process in a small time frame, but it has fewer large jumps.

The purpose of this paper is two-fold. First, we extend the idea of tempering a stable Lévy process to tempering any Lévy process, and give results about the relationship between the original process and the tempered one.

*Email address: mgrabcha@uncc.edu
In particular, we show that the original process can be decomposed into the sum of the tempered process and an independent point process of large jumps. Our second purpose is to use this decomposition to set up a rejection sampling algorithm for simulating from the tempered process.

The problem of simulation has not been resolved even for tempered stable distributions. For these, rejection sampling techniques are currently known only for Tweedie distributions. For other tempered stable distributions, the only known exact simulation technique is the inversion method, which is computationally inefficient because it requires numerically calculating the quantile function, which can only be done by numerically inverting the cumulative distribution function (cdf). However, calculating the cdf is, itself, expensive, since, for most tempered stable distributions, it can only be evaluated by numerically applying an inverse Fourier transform to the characteristic function. Other simulation techniques are only approximate, and are based either on truncating a shot-noise representation (Imai and Kawai 2011), or on approximations by a compound Poisson Process (Baeumer and Kovacs, 2012) or a Brownian motion (Cohen and Rosiński, 2007).

The basic idea of our rejection sampling approach is to start by sampling an increment of the original process. This increment is then rejected if it is too large, otherwise it is accepted. The procedure is in keeping with the motivation for defining tempered processes as having marginal distributions that are similar to those of the original process, but with lighter tails. In deciding if the observation is too large, we require the ability to evaluate the probability density functions of the marginal distributions of both the original and the tempered process. While this may be computationally challenging, in many situations it is more efficient than implementing the inversion method, see the simulation results in Section 7 below.

The rest of the paper is organized as follows. In Section 2, we recall basic facts about infinitely divisible distributions and their associated Lévy processes. In Section 3, we formally introduce tempered Lévy processes and give our main theoretical results. Then, in Section 4, we show how to use these results to set up a rejection sampling algorithm. In Section 5, we recall some basic facts about tempered stable distributions and give conditions under which our results hold. Then, in Section 6, we give detailed conditions for an important subclass of tempered stable distributions, which has additional structure and is commonly used. Finally, in Section 7, we give a small scale simulation study to illustrate how our method works in practice.

Before proceeding, we introduce some notation. Let \( \mathbb{N} = \{1, 2, \ldots\} \) be the set of natural numbers. Let \( \mathbb{R}^d \) be the space of \( d \)-dimensional column vectors of real numbers equipped with the usual inner product \( \langle \cdot, \cdot \rangle \) and the usual norm \( |\cdot| \). Let \( \mathbb{S}^{d-1} = \{x \in \mathbb{R}^d : |x| = 1\} \) denote the unit sphere in \( \mathbb{R}^d \). Let \( \mathcal{B}(\mathbb{R}^d) \) and \( \mathcal{B}(\mathbb{S}^{d-1}) \) denote the Borel sets in \( \mathbb{R}^d \) and \( \mathbb{S}^{d-1} \), respectively. For a Borel measure \( M \) on \( \mathbb{R}^d \) and \( t \geq 0 \), we write \( tM \) to denote
the Borel measure on $\mathbb{R}^d$ given by $(tM)(B) = tM(B)$ for every $B \in \mathfrak{B}(\mathbb{R}^d)$. If $a, b \in \mathbb{R}$, we write $a \vee b$ and $a \wedge b$ to denote, respectively, the maximum and the minimum of $a$ and $b$. If $\mu$ is a probability measure on $\mathbb{R}^d$, we write $X \sim \mu$ to denote that $X$ is an $\mathbb{R}^d$-valued random variable with distribution $\mu$. Finally, we write $U(0, 1)$ to denote the uniform distribution on $(0, 1)$ and $N(b, A)$ to denote the multivariate normal distribution with mean vector $b$ and covariance matrix $A$.

2 Infinitely Divisible Distributions and Lévy Processes

Recall that an infinitely divisible distribution $\mu$ on $\mathbb{R}^d$ is a probability measure with a characteristic function of the form $\phi_\mu(z) = \exp\{C_\mu(z)\}$, where, for $z \in \mathbb{R}^d$, 

$$C_\mu(z) = -\frac{1}{2}\langle z, Az \rangle + i\langle b, z \rangle + \int_{\mathbb{R}^d} \left( e^{i\langle z, x \rangle} - 1 - i\langle z, x \rangle h(x) \right) L(dx).$$

Here, $A$ is a symmetric nonnegative-definite $d \times d$-dimensional matrix called the Gaussian part, $b \in \mathbb{R}^d$ is called the shift, and $L$ is a Borel measure, called the Lévy measure, which satisfies 

$$L(\{0\}) = 0 \text{ and } \int_{\mathbb{R}^d} (|x|^2 \wedge 1) L(dx) < \infty. \quad (1)$$

The function $h : \mathbb{R}^d \mapsto \mathbb{R}$, which we call the $h$-function, can be any Borel function satisfying 

$$\int_{\mathbb{R}^d} \left| e^{i\langle z, x \rangle} - 1 - i\langle z, x \rangle h(x) \right| L(dx) < \infty \quad (2)$$

for all $z \in \mathbb{R}^d$. For a fixed $h$-function, the parameters $A$, $L$, and $b$ uniquely determine the distribution $\mu$, and we write 

$$\mu = ID(A, L, b)_h.$$ 

The choice of $h$ does not affect parameters $A$ and $L$, but different choices of $h$ result in different values for $b$, see Section 8 in [Sato (1999)].

Associated with every infinitely divisible distribution $\mu = ID(A, L, b)_h$ is a Lévy process, $\{X_t : t \geq 0\}$, which is stochastically continuous with independent and stationary increments, and the characteristic function of $X_t$ is $(\phi_\mu(z))^t$. We denote the distribution of $X_t$ by $\mu^t$. It follows that, for each $t \geq 0$, $X_t \sim \mu^t = ID(tA, tL, tb)_h$. For more on infinitely divisible distributions and their associated Lévy processes see [Sato (1999)].
3 Main Results

Let $\mu = ID(A, L, b)_h$ be any infinitely divisible distribution, and define the Borel measure $\tilde{L}$ by

$$\tilde{L}(dx) = g(x)L(dx),$$

where $g : \mathbb{R}^d \mapsto [0, \infty)$ is a Borel function. Throughout, we make the following assumptions:

A1. $0 \leq g(x) \leq 1$ for all $x \in \mathbb{R}^d$, and

A2.

$$\int_{\mathbb{R}^d} (\lvert xh(x) \rvert \vee 1) (1 - g(x)) L(dx) < \infty.$$

Assumption A1 guarantees that $\tilde{L}$ satisfies (1) and (2). Thus $\tilde{L}$ is a valid Lévy measure, and we can use the same $h$-function with $\tilde{L}$ as with $L$. Let $\tilde{\mu} = ID(A, \tilde{L}, \tilde{b})_h$, where

$$\tilde{b} = b - \int_{\mathbb{R}^d} xh(x) (1 - g(x)) L(dx).$$

We call $\tilde{\mu}$ the tempering of $\mu$ and we call $g$ the tempering function.

Remark 1. The name “tempering function” comes from the fact that, when the additional assumption $\lim_{|x| \to \infty} g(x) = 0$ holds, the tails of the distribution $\tilde{\mu}$ are lighter than those of $\mu$. In this sense, the distribution $\tilde{\mu}$ “tempers” the tails of $\mu$. While this assumption is part of the motivation for defining such distributions, we do not require it in this paper.

Remark 2. We can always take $h(x) = 1_{\lvert x \rvert \leq 1}$. In this case $(\lvert xh(x) \rvert \vee 1) = 1$ and Assumption A2 becomes $\int_{\mathbb{R}^d} (1 - g(x)) L(dx) < \infty$. However, when we work with other $h$-functions, we need Assumption A2 to be as given.

In light of Assumptions A1 and A2, we can define the finite Borel measure

$$\rho(dx) = (1 - g(x)) L(dx).$$

Now, set

$$\eta := \rho(\mathbb{R}^d) < \infty,$$

and define the probability measure

$$\rho_1(B) = \frac{\rho(B)}{\eta}, \quad B \in \mathcal{B}(\mathbb{R}^d).$$
Let $Z_1, Z_2, \ldots$ be independent and identically distributed (iid) random variables with distribution $\rho_1$. Independent of these, let $\{N_t : t \geq 0\}$ be a Poisson process with intensity $\eta$, and set

$$V_t = \sum_{i=1}^{N_t} Z_i, \quad t \geq 0. \quad (3)$$

This is a compound Poisson process and, by Proposition 3.4 in Cont and Tankov (2004), the characteristic function of $V_t$ is given by

$$E \left[ e^{i\langle V_t, z \rangle} \right] = \exp \left\{ t \int_{\mathbb{R}^d} \left( e^{i\langle x, z \rangle} - 1 \right) \rho(dx) \right\}, \quad z \in \mathbb{R}^d.$$

Let $T = \inf\{t : N_t > 0\}$ and note that, by properties of Poisson processes, $T$ has an exponential distribution with rate $\eta$, i.e.

$$P(T > t) = e^{-\eta t}, \quad t > 0. \quad (4)$$

We now give our main result, which generalizes a result about relativistic stable distributions given in Ryznar (2002).

**Theorem 1.** Let $\mu = ID(A, L, b)_{h}$ and let $g : \mathbb{R}^d \mapsto [0, \infty)$ be a Borel function satisfying Assumptions A1 and A2. Let $\tilde{\mu} = ID(A, \tilde{L}, \tilde{b})_{h}$, $V = \{V_t : t \geq 0\}$, and $T$ be as described above. Let $\tilde{X} = \{\tilde{X}_t : t \geq 0\}$ be a Lévy process, independent of $V$, with $\tilde{X}_1 \sim \tilde{\mu}$ and set

$$X_t = \tilde{X}_t + V_t, \quad t \geq 0.$$

1. The process $X = \{X_t : t \geq 0\}$ is a Lévy process with $X_1 \sim \mu$.
2. If $0 \leq t < T$, then $X_t = \tilde{X}_t$.
3. For any $B \in \mathcal{B}(\mathbb{R}^d)$ and $t \geq 0$ we have

$$P(\tilde{X}_t \in B) \leq e^{\eta t} P(X_t \in B).$$

This theorem implies that the process $\tilde{X}$ is obtained from $X$ by throwing out the jumps that are governed by $V_t$. We call $\tilde{X}$ the tempered Lévy process, and, in this context, we refer to $X$ as the original process.

**Proof.** We begin with the first part. Since $\tilde{X}$ and $V$ are independent Lévy processes and the sum of independent Lévy processes is still a Lévy process, it suffices to check that the characteristic function of $X_t$ is the same as the

---

1Relativistic stable distributions are the distributions of $\sqrt{XZ}$, where $X$ and $Z$ are independent, $X$ has a Tweedie distribution, and $Z \sim N(0, I)$, where $I$ is the identity matrix.
characteristic function of \( \tilde{X}_t + V_t \). The characteristic function of \( \tilde{X}_t + V_t \) can be written as \( e^{tC(z)} \), where for \( z \in \mathbb{R}^d \)

\[
C(z) = -\frac{1}{2} \langle z, Az \rangle + \int_{\mathbb{R}^d} \left( e^{i \langle x, z \rangle} - 1 - i \langle x, z \rangle h(x) \right) L(dx) + i \langle \tilde{b}, z \rangle
\]

as required. The second part follows immediately from the fact that \( V_t = 0 \) when \( 0 \leq t < T \). We now turn to the third part. Since \( \tilde{X} \) and \( T \) are independent, for any \( B \in \mathcal{B}(\mathbb{R}^d) \) we can use the second part to get

\[
P(\tilde{X}_t \in B) P(T > t) = P(\tilde{X}_t \in B, T > t) = P(X_t \in B, T > t) \leq P(X_t \in B).
\]

From here, the result follows by (4).

\[ \square \]

4 Rejection Sampling

In this section, we set up a rejection sampling scheme for sampling from the tempered Lévy process \( \tilde{X}_t \), when we know how to sample from the original Lévy process \( X_t \). To begin with, assume that, for some \( t > 0 \) we want to simulate \( \tilde{X}_t \). For our approach to work, we need the distributions of both \( \tilde{X}_t \) and \( X_t \) to be absolutely continuous with respect to Lebesgue measure on \( \mathbb{R}^d \). Thus, each distribution must have a probability density function (pdf). This always holds, for instance, if \( A \) is an invertible matrix or if both

\[
\int_{\mathbb{R}^d} |\phi_\mu(z)|^t \, dz < \infty \quad \text{and} \quad \int_{\mathbb{R}^d} |\phi_{\tilde{\mu}}(z)|^t \, dz < \infty.
\]

More delicate conditions, in terms of the corresponding Lévy measures, can be found in Section 27 of Sato (1999).

Now assume that Assumptions A1 and A2 hold, and let \( f_t \) and \( \tilde{f}_t \) be the pdfs of \( X_t \) and \( \tilde{X}_t \), respectively. Since the inequality in the third part of Theorem 1 holds for all Borel sets, it holds for pdfs as well. Thus, for Lebesgue almost every \( x \),

\[
\tilde{f}_t(x) \leq e^{tn} f_t(x),
\]
where
\[ \eta = \rho(\mathbb{R}^d) = \int_{\mathbb{R}^d} (1 - g(x)) L(dx). \]

This means that we can set up a rejection sampling algorithm (see Devroye (1986)) to sample from \( \tilde{f}_t \) as follows.

**Algorithm 1.**

**Step 1.** Independently simulate \( U \sim U(0, 1) \) and \( Y \sim f_t \).

**Step 2.** If \( U \leq e^{-\eta t} \tilde{f}_t(Y) / f_t(Y) \) accept, otherwise reject and go back to Step 1.

Let \( p_t \) be the probability of acceptance on a given iteration and let \( I_t \) be the expected number of iterations until the first acceptance. By a simple conditioning argument, it follows that \( p_t = e^{-\eta t} \), and hence that \( I_t = e^{\eta t} \).

Note that both of these quantities approach 1 as \( t \to 0 \). On the other hand, when \( t \to \infty \), we have \( p_t \to 0 \) and \( I_t \to \infty \). Thus, this method works best for small \( t \).

We now describe how to use Algorithm 1 to simulate the tempered Lévy process \( \tilde{X} = \{ \tilde{X}_t : t \geq 0 \} \) on a finite mesh. For simplicity, assume that the mesh points are evenly spaced; the general case can be dealt with in a similar manner. Thus, fix \( \Delta > 0 \) and assume that we want to simulate \( \tilde{X}_{\Delta}, \tilde{X}_{2\Delta}, \ldots, \tilde{X}_{n\Delta} \) for some \( n \in \mathbb{N} \). To do this, we begin by simulating \( n \) independent increments \( Y_1, Y_2, \ldots, Y_n \) iid \( \tilde{f}_{\Delta} \) using Algorithm 1. We expect this to take \( nI_{\Delta} = ne^{\Delta \eta} \) iterations. Now, to get values of the process, we set

\[ \tilde{X}_{k\Delta} = \sum_{j=1}^{k} Y_j, \quad k = 1, 2, \ldots, n. \]  

(5)

Next, consider the case, when we only want to simulate \( \tilde{X}_t \sim \tilde{f}_t \) for some fixed \( t > 0 \). While this can be done directly using Algorithm 1, when \( t \) is large, the expected number of iterations, \( I_t = e^{\eta t} \), is large as well. Instead, we can choose some \( n \in \mathbb{N} \) and sample \( n \) independent increments \( Y_1, Y_2, \ldots, Y_n \) iid \( \tilde{f}_{t/n} \). Then the sum \( \tilde{X}_t = Y_1 + Y_2 + \cdots + Y_n \) has distribution \( \tilde{f}_t \). In this case, we only expect to need \( nI_{t/n} = ne^{\eta t/n} \) iterations. This requires fewer iterations so long as \( n < e^{\eta(t-1/n)} \). Since the function \( b(x) = xe^{\eta x/x} \) is minimized (on \( x > 0 \)) at \( x = t\eta \), it follows that the optimal choice of \( n \) is near this value. As an example, assume that we want to simulate one observation when \( t = 10 \) and \( \eta = 1 \). To do this directly, we expect to need \( I_{10} = e^{10} \approx 22026 \) iterations. On the other hand, to simulate 10 observations when \( t = 1 \) and \( \eta = 1 \) we only expect to need \( 10I_1 = 10 * e^1 \approx 27 \) iterations. Thus, the second approach is much more efficient, in this case.
5 Tempered Stable Distributions

Most, if not all, tempered Lévy processes that have appeared in the literature, are those associated with tempered stable distributions. Before discussing these, we recall that an infinite variance stable distribution on $\mathbb{R}^d$ is an infinitely divisible distribution with no Gaussian part and a Lévy measure of the form

$$M_\alpha(B) = \int_{\mathbb{R}^d} \int_0^\infty 1_{B}(t \xi) r^{-1-\alpha} dr \sigma(d\xi), \quad B \in \mathcal{B}(\mathbb{R}^d), \quad (6)$$

where $\alpha \in (0, 2)$ and $\sigma$ is a finite Borel measure on $\mathbb{S}^{d-1}$. For these distributions we will use the $h$-function

$$h_\alpha(x) = \begin{cases} 
0 & \alpha \in (0, 1) \\
1_{|x| \leq 1} & \alpha = 1 \\
1 & \alpha \in (1, 2) 
\end{cases}. \quad (7)$$

We denote the distribution $ID(0, M_\alpha, b)_{h_\alpha}$ by $S_\alpha(\sigma, b)$. For more on stable distributions, see the classic text Samorodnitsky and Taqqu (1994).

Now, following Rosiński and Sinclair (2010), we define a tempered stable distribution on $\mathbb{R}^d$ as an infinitely divisible distribution with no Gaussian part and a Lévy measure of the form

$$\tilde{M}_\alpha(B) = \int_{\mathbb{S}^{d-1}} \int_0^\infty 1_{B}(r \xi) r^{-1-\alpha} q(r, \xi) dr \sigma(d\xi), \quad B \in \mathcal{B}(\mathbb{R}^d),$$

where $\alpha \in (0, 2)$, $q : (0, \infty) \times \mathbb{S}^{d-1} \rightarrow [0, \infty)$ is a Borel function, and $\sigma$ is a finite Borel measure on $\mathbb{S}^{d-1}$. Here, the tempering function is $g(x) = q(|x|, x/|x|)$. Using the $h$-function given by (7), we denote the distribution $ID(0, M_\alpha, b)_{h_\alpha}$ by $TS_\alpha(\sigma, q, b)$. In this case,

$$\rho(B) = \int_{\mathbb{S}^{d-1}} \int_0^\infty 1_B(r \xi) r^{-1-\alpha} (1 - q(r, \xi)) dr \sigma(d\xi), \quad B \in \mathcal{B}(\mathbb{R}^d),$$

and Assumptions A1 and A2 become:

**B1.** $0 \leq q(r, \xi) \leq 1$ for all $r > 0$ and $\xi \in \mathbb{S}^{d-1}$, and

**B2.**

$$\int_{\mathbb{S}^{d-1}} \int_0^\infty r^{-1-\alpha} (1 - q(r, \xi)) dr \sigma(d\xi) < \infty.$$ 

Note that Assumption B2 implies that, for $\sigma$ almost every $\xi$, we have

$$\lim_{r \downarrow 0} q(r, \xi) = 1. \quad (8)$$
Next, we turn to the question of when both $S_\alpha(\sigma, b)$ and $TS_\alpha(\sigma, q, b)$ are absolutely continuous with respect to Lebesgue measure on $\mathbb{R}^d$. Before characterizing when this holds, we recall the following definition. The support of $\sigma$ is the collection of all points $\xi \in \mathbb{S}^{d-1}$ such that, for any open set $G \subset \mathbb{S}^{d-1}$ with $\xi \in G$, we have $\sigma(G) > 0$.

**Proposition 1.** If the support of $\sigma$ contains $d$ linearly independent vectors, then both $S_\alpha(\sigma, b)$ and $TS_\alpha(\sigma, q, b)$ are absolutely continuous with respect to Lebesgue measure on $\mathbb{R}^d$.

In particular, when $d = 1$, this holds so long as $\sigma \neq 0$.

**Proof.** By Proposition 24.17 and Theorem 27.10 in [Sato (1999)](#), it suffices to show that, for $\sigma$ almost every $\xi \in \mathbb{S}^{d-1}$,

$$
\int_0^\infty r^{-1-\alpha}dr = \infty \text{ and } \int_0^\infty r^{-1-\alpha}q(r, \xi)dr = \infty.
$$

The first of these is immediately, while the second follows from (8). □

In light of this proposition, we introduce the third assumption:

**B3.** The support of $\sigma$ contains $d$ linearly independent vectors.

We now specialize our main results to the case of tempered stable distributions.

**Corollary 1.** Let $\mu = S_\alpha(\sigma, b)$, $\tilde{\mu} = TS_\alpha(\sigma, q, \tilde{b})$, where

$$
\tilde{b} = b - \int_{\mathbb{S}^{d-1}} h_\alpha(r) (1 - q(r, \xi)) r^{-\alpha}dr \xi \sigma(d\xi),
$$

If Assumptions B1 and B2 hold, then the results of Theorem 1 hold. If, in addition, Assumption B3 holds, then we can use Algorithm 1 to simulate from the Lévy process associated with $\tilde{\mu}$.

In particular, this means that, when Assumptions B1 and B2 hold, if $\{X_t : t \geq 0\}$ is a Lévy process with $X_1 \sim \mu$ and $\{\tilde{X}_t : t \geq 0\}$ is a Lévy process with $\tilde{X}_1 \sim \tilde{\mu}$, then $X_t = \tilde{X}_t$ for $0 \leq t < T$, where $T$ is as in Theorem 1. This strengthens the well-known fact that tempered stable Lévy processes behave like stable Lévy processes in a short time frame, see [Rosiński and Sinclair (2010)](#). Algorithm 1 requires the ability to sample from a stable distribution. In the one dimensional case, this is easily done using the classical method of [Chambers, Mallows, and Stuck (1976)](#). In the multivariate case, this problem has not been fully resolved, however a method for simulating from a dense class of multivariate stable distributions is given in [Nolan (1998)](#).
6 \( p \)-Tempered \( \alpha \)-Stable Distributions

In the previous section, we allowed for tempered stable distributions with very general tempering functions. However, it is often convenient to work with families of tempering functions, which have additional structure. One such family, which is commonly used, corresponds to the case, where

\[
q(r, \xi) = \int_{(0,\infty)} e^{-sr^p} Q_\xi(ds).
\]

(9)

Here \( p > 0 \) and \( \{Q_\xi : \xi \in \mathbb{S}^{d-1}\} \) is a measurable family of probability measures on \((0, \infty)\). For fixed \( \alpha \in (0, 2) \), the corresponding tempered stable distributions are called \( p \)-tempered \( \alpha \)-stable. For \( p = 1 \) these were introduced in Rosiński (2007), for \( p = 2 \) they were introduced in Bianchi et al. (2011), and the general case was introduced in Grabchak (2012). See also the recent monograph Grabchak (2016).

Now, consider the distribution \( TS_\alpha(\sigma, q, b) \), where \( q \) is as in (9), and define the measures

\[
Q(B) = \int_{\mathbb{S}^{d-1}} \int_{(0,\infty)} 1_B(s\xi)Q_\xi(ds)d\xi, \quad B \in \mathcal{B}(\mathbb{R}^d)
\]

and

\[
R(B) = \int_{\mathbb{R}^d} 1_B \left( \frac{x}{|x|^{1+1/p}} \right) |x|^\alpha Q(dx), \quad B \in \mathcal{B}(\mathbb{R}^d).
\]

We call \( R \) the Rosiński measure of the distribution. For fixed \( p > 0 \) and \( \alpha \in (0, 2) \), \( R \) uniquely determines \( q \) and \( \sigma \). Further, Proposition 3.6 in Grabchak (2016) implies that we can recover \( \sigma \) by

\[
\sigma(B) = \int_{\mathbb{R}^d} 1_B \left( \frac{x}{|x|} \right) |x|^\alpha R(dx), \quad B \in \mathcal{B}(\mathbb{S}^{d-1}).
\]

(10)

Due to the importance of the Rosiński measure, we sometimes denote the distribution \( TS_\alpha(\sigma, q, b) \), where \( q \) is of the form (9), by \( TS^p_\alpha(R, b) \). We now characterize when Assumptions B1 and B2 hold.

**Proposition 2.** Consider the distribution \( TS_\alpha(\sigma, q, b) \), where \( q \) is of the form (9) and let \( R \) be the corresponding Rosiński measure. This distribution always satisfies Assumption B1. Further, it satisfies Assumption B2 if and only if \( 0 < \alpha < p \) and \( R \) is a finite measure on \( \mathbb{R}^d \). In this case

\[
\eta = \frac{\Gamma(1 - \alpha/p)}{\alpha} R(\mathbb{R}^d).
\]

**Proof.** The fact that Assumption B1 always holds follows from (9) and the fact that \( Q_\xi \) is a probability measure for every \( \xi \in \mathbb{S}^{d-1} \). We now turn to
Assumption B2. First assume that \(0 < \alpha < p\). In this case, the fact that \(\{Q_\xi : \xi \in S^{d-1}\}\) is a collection of probability measures implies that

\[
\int_0^\infty r^{-1-\alpha} \left(1 - q(r, \xi)\right) dr = \int_{(0,\infty)} \int_0^\infty r^{-1-\alpha} \left(1 - e^{-sr^p}\right) dr Q_\xi(ds) \\
= \int_{(0,\infty)} \frac{s^\alpha}{p} \int_0^\infty \left(1 - e^{-r}\right) r^{-1-\alpha/p} dr Q_\xi(ds) \\
= \int_{(0,\infty)} s^{\alpha/p} Q_\xi(ds) \frac{\Gamma(1 - \alpha/p)}{\alpha},
\]

where the second line follows by substitution and the third by integration by parts. It follows that

\[
\eta = \int_{S^{d-1}} \int_0^\infty r^{-1-\alpha} \left(1 - q(r, \xi)\right) dr \sigma(d\xi) \\
= \frac{\Gamma(1 - \alpha/p)}{\alpha} \int_{S^{d-1}} \int_{(0,\infty)} s^\alpha/p Q_\xi(ds) \sigma(d\xi) \\
= \frac{\Gamma(1 - \alpha/p)}{\alpha} \int_{\mathbb{R}^d} |x|^\alpha/p Q(dx) \\
= \frac{\Gamma(1 - \alpha/p)}{\alpha} R(\mathbb{R}^d),
\]

which is finite if and only if \(R(\mathbb{R}^d) < \infty\). Now assume that \(\alpha \geq p\). We again have

\[
\int_0^\infty r^{-1-\alpha} \left(1 - q(r, \xi)\right) dr = \int_{(0,\infty)} \frac{s^\alpha/p}{p} Q_\xi(ds) \int_0^\infty \left(1 - e^{-r}\right) r^{-1-\alpha/p} dr.
\]

To see that Assumption B2 does not hold in this case, observe that

\[
\int_0^\infty \left(1 - e^{-r}\right) r^{-1-\alpha/p} dr \geq .5 \int_0^1 r^{-\alpha/p} dr = \infty,
\]

where we use the fact that, for \(r \in [0,1]\), \((1 - e^{-r}) \geq .5r\), see e.g. 4.2.37 in [Abramowitz and Stegun (1972)].

\[\square\]

**Remark 3.** Perhaps, the most famous \(p\)-tempered \(\alpha\)-distributions are Tweedie distributions, which were introduced in [Tweedie (1984)]. These are sometimes also called classical tempered stable subordinators. These are one-dimensional distributions with \(p = 1\), \(\alpha \in (0,1)\), \(\sigma(-1) = 0\), \(\sigma(1) = a\), and \(Q_1(dt) = \delta_c(dt)\), where \(a, c > 0\) and \(\delta_c\) is the point-mass at \(c\). In this case \(R(dt) = ac^\alpha \delta_{1/c}(dt)\). It is not difficult to show that such distributions satisfy Assumptions B1, B2, and B3 and thus that Algorithm 1 can be used. Further, in this case, \(\eta = \Gamma(1 - \alpha)ac^\alpha/\alpha\), and it can be shown that \(e^{-q_r f_t(Y)}/f_t(Y) = e^{-cY}\). Thus, in this case, Algorithm 1 is computationally easy to perform. In fact, it reduces to the standard rejection sampling algorithm for Tweedie distributions given in e.g. [Kawai and Masuda (2011)].
In this section we perform a small scale simulation study to see how well Algorithm 1 works in practice. We focus on a parametric family of tempered stable distributions for which, up to now, there has not been an exact simulation method except for the inversion method. Specifically, we consider the family of $p$-tempered $\alpha$-stable distribution on $\mathbb{R}^1$ with Rosiński measures of the form

$$R_{\ell}(dx) = C(1 + |x|)^{-2-a-\ell}dx,$$

where $\ell > 0$ is a parameter and

$$C = \frac{\alpha}{\Gamma(1 - \alpha/p)}.$$

These distributions were introduced in Grabchak (2016) as a class of tempered stable distributions, which can have a finite variance, but still fairly heavy tails. If fact, if random variable $Y$ has a distribution of this type, then, for $\beta \geq 0$,

$$E|Y|^\beta < \infty \text{ if and only if } \beta < 1 + \alpha + \ell.$$

Thus, $\ell$ controls how heavy the tails of the distribution are. Distributions with tails of this type are useful, for instance, in modeling financial returns, since, as is well-known, returns tend to have heavy tails, but the fact that they exhibit aggregational Gaussianity suggests that their tails cannot be too heavy and that the variance should be finite, see e.g. Cont and Tankov (2004) or Grabchak and Samorodnitsky (2010).

Since $R_{\ell}$ is a finite measure, Proposition 2 implies that, when $0 < \alpha < p$, Assumptions B1 and B2 hold and

$$\eta = \frac{\Gamma(1 - \alpha/p)}{\alpha} R_{\ell}(\mathbb{R}) = 1.$$

By (10), it follows that we are tempering a symmetric stable distribution with

$$s := \sigma(-1) = \sigma(1) = C \int_0^\infty x^a(1 + x)^{-2-a-\ell}dx.$$

Let $\mu = S_\alpha(\sigma, b)$ and $\tilde{\mu} = TS_0^p(R_{\ell}, \tilde{b})$. When $p = 1$, methods for evaluating the pdfs and related quantities of both of these distribution are available in the SymTS package (Grabchak and Cao, 2017) for the statistical software R. For this reason, we focus on the case $p = 1$. In this case, we are restricted to $\alpha \in (0, 1)$.

For our simulations, we took $\alpha = .75$, $\ell = 1$, and $b = \tilde{b} = 0$. By numerical integration, we got $s = 0.0591034$. Let $\tilde{\mu} = TS_0^p(R_{\ell}, \tilde{b}) = TS_{0.75}^1(R_1, 0)$ and let $\mu = S_\alpha(\sigma, 0) = S_{0.75}(\sigma, 0)$, where $\sigma(-1) = \sigma(1) = 0.0591034$. Plots of the pdfs of $\mu$ and $\tilde{\mu}$ are given in Figure 1.
PDFs of Stable and Tempered Stable Distributions

Figure 1: The solid line is the pdf of the stable distribution $\mu$ and the dashed line is the pdf of the tempered stable distribution $\tilde{\mu}$. These are presented at two scales.

PDFs of Stable and Tempered Stable Distributions

Simulated Tempered Stable
Simulated Stable

Figure 2: Tempered Stable and Stable KDE. On the left, the solid line is the KDE of the simulated tempered stable random variables, and the dashed line is the pdf of $\tilde{\mu}$ smoothed by the kernel and bandwidth used for the KDE. On the right, the solid line is the KDE of the simulated stable random variables, and the dashed line is the pdf of $\mu$ smoothed by the kernel and bandwidth used for the KDE.
To get 1000 observations from $\bar{\mu}$ using Algorithm 1, we expect to need $1000e^{1} \approx 2718$ iterations. For simplicity, we ran 3000 iterations. Thus, we began by simulating 3000 observations from $\mu$. This was done using the method of Chambers, Mallows, and Stuck (1976). We then applied Algorithm 1 to see which observations should be rejected. Here, we used the SymTS package to evaluate the pdfs. In the end, we wound up with 1110 observations from $\bar{\mu}$.

Figure 2 (left) plots the kernel density estimator (KDE) for our samples from $\bar{\mu}$. Here, KDE used a Gaussian kernel with a bandwidth of .02463. The plot is overlaid with the pdf of $\bar{\mu}$ smoothed by the Gaussian Kernel with this bandwidth. This verifies, numerically, that we are simulating from the correct distribution. For comparison, Figure 2 (right), plots the KDE of the original 3000 samples from $\mu$. This is overlaid with the smoothed pdf of $\mu$. Here, KDE used a Gaussian kernel with a bandwidth of .006565.

Next, consider the Lévy process $\{\tilde{X}_t : t \geq 0\}$, where $\tilde{X}_1 \sim \bar{\mu}$. To simulate $\tilde{X}_1, \tilde{X}_2, \ldots, \tilde{X}_{1110}$, we apply (5) to the iid increments, which we simulated above. A plot of this Lévy process is given in the left plot of Figure 3. For comparison, the right plot of Figure 3 gives the Lévy process based on the original 3000 iid increments from $\mu$. Comparing the two processes, we see that all of the largest jumps have been rejected.

In our simulation, we used 3000 observations from $\mu$ to get 1110 observations from $\bar{\mu}$. Of course, due to the structure of the algorithm, if we run the simulation again, we may get a different number of observations from $\bar{\mu}$. We performed the simulation 500 times to see how many observations from $\bar{\mu}$ are obtained. Figure 4 gives a boxplot and a histogram for all resulting values. The smallest value observed was 1010 and the largest was 1172. The
mean was 1104.1 with a standard deviation of 25.1. Note that the observed mean is very close to the theoretical mean of $3000e^{-1} \approx 1103.6$.

Now, consider the case, where we want to simulate from $\tilde\mu^{10} = TS(10R, 0)$, which is the distribution of $\tilde{X}_{10}$. A plot of this distribution is given in Figure 5 (left). We have two choices. First, we can use Algorithm 1 directly, which requires, on average, $e^{10} \approx 22026$ iterations to get one observation. Second, we can use Algorithm 1 to simulate 10 independent observations from $\tilde{\mu}$, and then aggregate these by taking the sum. This requires, on average, $10e^{1} \approx 27$ iteration to get one observation. Clearly, the second approach is more efficient, and, hence, it is the one that we use.

Say that we want 1000 independent observations from $\tilde{\mu}^{10}$. This requires 10000 independent observations from $\tilde{\mu}$, and we expect to need $10000e^{1} \approx 27183$ iterations. We performed 30000 iterations, which gave us 11130 observations from $\tilde{\mu}$. These, in turn, gave 1113 observations from $\tilde{\mu}^{10}$. In Figure 5 (right), we plot the KDE of the simulated data. This is overlaid with the pdf of $\tilde{\mu}$ smoothed by the appropriate kernel and bandwidth. Here, KDE used the Gaussian kernel with bandwidth 0.1863.

For a comparison, we also performed simulations using the inversion method, which is implemented in the SymTS package. First, we fixed $\alpha = 0.75$, $\ell = 1.0$, and considered $t = 1, 2, 5, 10, 20$. Computation times for both approaches are reported in Table 1. Not surprisingly, when $t$ is small, Algorithm 1 is more efficient, but for large $t$ the inversion method works better. Second, we fixed $t = 1$ and considered $\alpha = 0.5, 0.75, 0.95$ and $\ell = 0.5, 1.0, 5.0$. Computation times are reported in Table 2. Both sets of simulations were performed on a desktop PC with a 3.40GHz Intel Core i7-6700 CPU. The computer was running Ubuntu 16.04.4 LTS and R version 3.2.3.
Figure 5: Plots for $t = 10$. On the left, the solid line is the pdf of the stable distribution $\mu^{10}$ and the dashed line is the pdf of the tempered stable distribution $\tilde{\mu}^{10}$. On the right, the solid line is the KDE of the simulated tempered stable random variables, and the dashed line is the pdf of $\tilde{\mu}^{10}$ smoothed by the kernel and bandwidth used for the KDE.

| $t$ | Algorithm 1 run time | Algorithm 1 iterations | Algorithm 1 obs | Inversion Method run time | Inversion Method obs | ratio |

Table 1: Comparison of the performance of Algorithm 1 and the inversion method for several values of $t$. For Algorithm 1, the iterations column gives the number of stable random variables simulated and the obs column gives the number of tempered stable random variables obtained after performing rejection and aggregation. The ratio column is the run time for Algorithm 1 divided by the run time for the inversion method.
Table 2: Comparison of the performance of Algorithm 1 and the inversion method for several values of $\alpha$ and $\ell$. For Algorithm 1, the observations column gives the number of tempered stable random variables obtained based on a sample for 3000 observations from the stable distribution. The ratio column is the run time for Algorithm 1 divided by the run time for the inversion method.

For the above simulations, we attempted to cover a large part of the parameter space. However, while the parameter $\alpha$ can, in principle, take any value in $(0, 1)$, we did not consider the case $\alpha < 0.5$. This is because we found it difficult to numerically evaluate the pdfs with enough accuracy in this case. We conjecture that this difficulty is due to the fact that, for such values of $\alpha$, stable distributions are extremely heavy tailed. On the other hand, there is no difficulty with values near 1, as is illustrated by the simulations for $\alpha = .95$.

For both Algorithm 1 and the inversion method, the most expensive part of the calculation involves evaluating the required functions. These are $f_t$ and $\tilde{f}_t$ for Algorithm 1 and the quantile function for the inversion method. When we are simulating many observations from the same distribution, both methods can be improved by precomputing these functions on a grid and then using interpolation.
