The final mass and spin of black hole mergers

Wolfgang Tichy and Pedro Marronetti
Department of Physics, Florida Atlantic University, Boca Raton, FL 33431, USA

We consider black holes resulting from binary black hole mergers. By fitting to numerical results we construct analytic formulas that predict the mass and spin of the final black hole. Our formulas are valid for arbitrary initial spins and mass ratios and agree well with available numerical simulations. We use our spin formula in the context of two common merger scenarios for supermassive galactic black holes. We consider the case of isotropically distributed initial spin orientations (when no surrounding matter is present) and also the case when matter closely aligns the spins with the orbital angular momentum. This radiation will circularize the orbits of the progenitor BHs and eventually shrink them around their common center of mass emitting gravitational radiation, which carries away energy, momentum and angular momentum. This radiation will circularize the orbits of the progenitor BHs and eventually shrink the orbits until the BHs merge and form a BH of mass $M_f$ and spin $S_f$. Thus, the initial state is described by eight parameters: the mass ratio $q \equiv M_b/M_a$, the dimensionless spins $\vec{a} = \vec{S}_a/M^2_a$, $\vec{b} = \vec{S}_b/M^2_b$ of the initial BHs and the dimensionless angular velocity $\omega = \Omega(M_a + M_b)$. Here $\omega$ specifies which point on the possibly very long inspiral trajectory is used as initial point. After the merger the final BH is characterized by seven parameters, the final mass $M_f$, spin $S_f$, and kick velocity $\vec{k}$. Predicting the final $m$ and $\vec{s}$ from the initial parameters is of great importance in many astrophysical merger scenarios. Boyle, Kesden and Nisanke \cite{1,2} propose to describe any of the final parameters as a Taylor expansion in the six initial spin components. These spin expansions (with coefficients fitted to date from numerical simulations) are based on the assumption that any dimensionless final quantity must be a function of the eight initial parameters. In this paper we use their expansions for the final dimensionless mass and spin. Note, however, that all expansion coefficients still depend on $q$ and $\omega$, since we Taylor expand only in $a_i$ and $b_i$. I.e. even if we know the coefficients for a particular mass ratio and a particular initial angular velocity we cannot predict any final quantities for different mass ratios or initial velocities. At first glance this seems to severely limit the usefulness of these expansions. However, as we will see, we have come up with a particular fit for the $q$-dependence, which seems to work rather well. Also, we will show that the final spin magnitude depends only weakly on $\omega$. The orientation of the final spin, however, does depend on $\omega$ as one would expect due to spin precession of the individual BH spins if one starts at a different $\omega$. Nevertheless, our approach can even give approximate spin orientations if we start with values for $\omega$ like the ones used here, which are typical for the current state-of-the-art simulations performed by most groups.

We use our formulas to calculate the probability density of the magnitude of the final spin for successive generations of BH mergers. We consider “gas-rich” or “wet” mergers, where a circumbinary disk surrounds the binary, and also “gas-poor” or “dry” mergers, where no matter is present \cite{3,4}.

Spin expansions. Our coordinate system is such that the $z$ axis is perpendicular to the initial orbital plane. The center of mass is initially at rest at the origin, with the $x$ axis along direction of the momentum of BH b. The $y$ axis is along the line connecting the BHs with BH a located at $y > 0$.

To construct formulas aimed at predicting the final BH mass and spin, we follow the method described in \cite{2}. To linear order, the spin expansions for the final mass and spin are:

$$m = m^0 + (m^{a_1} a_z + m^{b_1} b_z)$$
$$s_x = (s_0^{a_1} a_x + s_0^{b_1} b_x) + (s_1^{a_2} a_y + s_1^{b_2} b_y)$$
$$s_y = (s_0^{a_1} a_x + s_0^{b_1} b_x) + (s_1^{a_2} a_y + s_1^{b_2} b_y)$$
$$s_z = s_0^z + (s_0^{a_1} a_z + s_0^{b_1} b_z),$$

(1)

where the coefficients are functions of the mass ratio $q$ and the initial orbital angular velocity $\omega$. Notice that by using symmetries such as parity or exchange many terms that would appear in an unconstrained Taylor expansion have been dropped. In addition, all coefficients enclosed in common brackets are related, by $m^{a_1}(q,\omega) = m^{a_1}(1/q,\omega)$ and $s_0^{b_1}(q,\omega) = s_0^{b_1}(1/q,\omega)$.

We ignore the dependence on $\omega$ for the time being and focus first on the equal mass case. Note that for $q = 1$ the above mentioned relation between coefficients implies that all terms enclosed in common brackets have equal coefficients. In order to determine these coefficients we have performed 10 numerical simulations of equal mass binaries with spins of magnitudes between 0.1 and 0.27 with orientations as in Table XI of \cite{2}. All 10 simulations
\[ m^0 = 0.9515 \pm 0.001 \quad m^{b1} = m^{b1} = -0.013 \pm 0.007 \]
\[ s^{a1}_x = s^{b1}_x = 0.187 \pm 0.002 = +s^{a2}_y = +s^{b2}_y \]
\[ s^{a1}_y = s^{b1}_y = 0.028 \pm 0.002 = -s^{a2}_x = -s^{b2}_x \]
\[ s^{a1}_z = 0.686 \pm 0.004 \quad s^{b1}_z = s^{b1}_z = 0.15 \pm 0.03 \]

**TABLE II: Test simulations: the columns show the initial mass ratio \( q \), the progenitor spins \( a_i \) and \( b_i \), the final spin magnitude \( s \) and mass \( m \), and our predictions \( s_p \) and \( m_p \).**

\[
\vec{s}_z \propto \alpha R \left( \frac{M_y^2 a_x + M_z^2 a_y}{M_y^2 a_x + M_z^2 a_y} \right) \]
\[
\vec{m}_z \propto \alpha R \left( \frac{a_x (1 + q)^2 + q^2 b_x (1 + q)^2}{a_x (1 + q)^2 + q^2 b_x (1 + q)^2} \right)
\]

However, the latter cannot be true for extreme mass ratios, since than we would not get \( \vec{s} = \vec{a} \) for \( q = 0 \). In order to get the extreme mass ratio limit correctly, we modify the mass ratio dependence somewhat and assume that

\[
\vec{s}_x = s^{a1}_x \left[ g(q,c) a_x + g(1/q, c) b_x \right] - s^{a1}_x 4q \eta (a_y + b_y)
\]
\[
\vec{s}_y = s^{a1}_y \left[ g(q,c) a_y + g(1/q, c) b_y \right] + s^{a1}_y 4q \eta (a_x + b_x)
\]

where

\[
\eta = \frac{q}{(1 + q)^2}, \quad g(q,c) = \frac{(c + 1)^2}{(c + q)^2}, \quad c = \frac{\sqrt{s^{a1}_x}}{1 - \sqrt{s^{a1}_x}} = 0.762,
\]

are chosen such that \( \vec{s} \approx \vec{a} \) for \( q = 0 \) and \( \vec{s} \approx \vec{b} \) for \( q = \infty \).

So far we have only considered the components in \( xy \)-plane. For equal masses \( s^{a1}_x = s^{b1}_x \) so that \( s_x \) in Eq. II simplifies. As above we introduce a \( q \)-dependence given
by

\[ s_z = s_z^0(4w\eta + 16(1 - w)\eta^2) + s_z^1 \left[ g(q, c_3)a_z + g(1/q, c_3)b_z \right], \]

where \( c_3 = \sqrt{s_z^0}/(1 - \sqrt{s_z^0}) = 0.632 \). The \( \eta \) dependence of the leading coefficient is inspired by post-Newtonian (PN) expressions, and has been shown to fit runs without initial spins very well [13]. The constant \( w = 1.26 \) is fitted using the results for unequal masses discussed below.

Similarly, we build a mass ratio dependence into the final mass formula and write

\[ m = 1 + (m^0 - 1)4\eta + m^{w1}16\eta^2 \left( a_z + b_z \right). \]

The leading term is inspired by the fact that the binding energy is proportional to \( \eta \), and the linear term is chosen such that it has the correct limit in the extreme mass ratio case.

While the \( q \) dependence we have introduced so far reproduces our fits for the equal mass case and simultaneously gives the correct answers in the extreme mass ratio cases, it is not clear how well our formulas perform for intermediate mass ratios. For this reason we have performed 21 more simulations with \( q \) different from unity. As one can see from Table II the predictions are at most 0.4% from the numerical results.

So far we have only kept linear terms in our expansions. We find that our formulas agree with a wide range of test runs. Yet, for initial spin magnitudes close to 1 our formulas deviate from the extrapolated values [12, 14, 15] for the minimum and maximum possible final spin. These problems can be fixed if we add some quadratic terms to \( s_z \) alone:

\[ s_z = s_z^0(4w\eta + 16(1 - w)\eta^2) \]

\[ + s_z^1 \left[ g(q, c_3)a_z + g(1/q, c_3)b_z \right] \]

\[ + 16\eta^2(\alpha_z + b_z)^2 + (a_y + b_y)^2 - (a_z + b_z)^2) \]

These quadratic terms approximately reproduce most of the very small and very uncertain quadratic coefficients in \( s_z \). The coefficient \( k = 0.008 \) is chosen such that we get the best overall agreement with our numerical simulations.

**Results.** Our particular mapping of initial masses and spins into the final mass and spin given by Eqs. 8, 9, and 10 was fitted for the initial orbital angular velocity \( \omega = 0.05 \). If we start with the same initial spin components but at lower initial angular velocity (i.e., larger separation) the individual spins and the orbital plane will have precessed by the time we reach \( \omega = 0.05 \). In this case we cannot expect that our formulas will predict the final spin components if we simply use the initial spin components. However, the final spin magnitude should still be approximately correct, since PN calculations 10 demonstrate that the spin magnitudes are conserved at 2PN order. This expectation is borne out for the following additional \( q = 1 \) test run. It starts with \( \omega = 0.03 \), \( \vec{a} = (-0.637, -0.226, 0.325) \), \( \vec{b} = (-0.517, -0.543, 0.025) \), and yields a final spin \( \vec{s} = (-0.226, -0.146, 0.746) \) with magnitude \( s = 0.793 \). Our fitting formula predicts \( \vec{s} = (-0.194, -0.176, 0.753) \) with magnitude \( s = 0.797 \). This shows that the predicted magnitude is correct up to an error of 0.6%, while the components only agree if the predicted vector is rotated. This rotation comes from the precession during the time it takes to go from \( \omega = 0.03 \) to \( \omega = 0.05 \), during which the system completes about 4 orbits.

We have also compared with the numerical results published in [11, 12, 13, 14, 15, 17, 18, 19, 20], which all start from an \( \omega \) that is not too far from 0.05. The average deviation of all these results from our predictions is about 1%. Hence our formulas gives useful predictions for the final mass and even for the spin components if one starts near \( \omega = 0.05 \). However, if one is ever interested in the final spin components for a much larger initial separation with \( \omega \ll 0.05 \), one can still evolve the spins using PN theory up to \( \omega = 0.05 \) and then use our formula. This eliminates the need for expensive numerical simulations.

Other groups have presented formulas that, like ours, attempt to predict the final spin of the merger. The analytic estimate of Buonanno et al. [21] can give the final spin magnitude to within few percent with larger deviations for spins close to anti alignment. Starting from a number of assumptions, Rezzolla et al. [17] developed a more accurate formula with coefficients fitted to numerical results. One of their assumptions is that the components of the final spin in the initial orbital plane are obtained by summing the components of the initial spins i.e., \( S_{f, x/y} = S_{a, x/y} + S_{b, x/y} \). In our simulations we observe that this assumption is violated. From the discussion around Eqs. 2 and 3 it is clear that these components get slightly rotated and shortened by a factor \( \alpha = 0.685 \) during the merger. For instance, the run from the first line in Table I we find a value of \( s_{xy} = 0.291 \) for the in-plane component of the spin. Our formula (11) predicts a close value of \( s_{xy} = 0.284 \), the approach in [17] leads to \( s_{xy,R} = 0.375 \) which is about 30% too large, while both approaches predict almost the same spin magnitude. Thus our formulas improve the final spin orientation.

**Black hole mergers.** Using Eqs. 5, 6 and 9 we can study the properties of the spin of BHs produced by successive binary BH mergers. Two types of scenarios are likely to witness mergers: one in which the two BHs carry with them dense surrounding matter (“wet” mergers) and another where the progenitors meet in relatively empty space (“dry” mergers) [3]. In the former case the progenitors spins are likely to reach the merger aligned with the orbital angular momentum [22], while in the latter the same spins are bound to be isotropically oriented [3]. In our models we assume that the initial spin directions either have a uniform probability distribution (“dry” mergers) or that the longitudinal angle \( \theta \) obeys a normal distribution centered in the direction of the or-
The probability density for the final spin magnitude \( p(s) \) can be obtained using Monte Carlo simulations. Note that the probability density is shown in Fig. 1 for different mass ratios. The vertical bars represent the corresponding standard deviations. The straight lines are linear fits of the data points. We find that successive "wet" mergers produce a spin around 0.88, with very little spread. Similar results have also been found by Berti et al. [4] using the spin formula in [17]. This agreement is expected since our spin formulas give magnitudes in close agreement with [17]. The main difference is in the spin orientation which has been integrated out.

Discussion. By fitting to numerical results we construct formulas [Eqs. (8), (5), (9)] that predict the mass and spin of the final BH coming from binary BH mergers. We use them to determine the probability distribution of the final spin magnitude (Figs. 1, 2) after several generations of mergers of either “dry” or “wet” mergers.

It is a pleasure to thank B. Briggsmann, L. Rezzolla, E. Barausse, L. Boyle and M. Kesden for useful discussions. This work was supported by NSF grant PHY-0652874. We acknowledge TACC at UT Austin for providing HPC resources under allocations TG-PHY080022N and TG-MCA08X010.
