ABSTRACT

Aims. To investigate structure of the hot object in the symbiotic prototype Z And during its major 2000-03 active phase. Methods. Analysis of the far ultraviolet, optical low- and high-resolution spectroscopy and UBVR photometry. Reconstruction of the spectral energy distribution (SED) during the outburst. The Raman scattering process. Results. At the initial stages of the outburst the hot object was characterized by the two-temperature spectrum (a warm stellar radiation and a strong nebular emission) with signatures of a mass-outflow at moderate (∼100–200 km s$^{-1}$) and very high (∼1000–2000 km s$^{-1}$) velocities. The corresponding structure of the hot object consists of an optically thick, slowly-expanding disk-like material encompassing the accretor at the orbital plane and a fast optically thin wind over the remainder of the star. The disk-like shell persisted around the central star until 2002 August as was indicated by the eclipse effect. Then a significant dilution of the optically thick material and evolution of a fast wind from the hot star, concentrated more at the orbital plane, were detected. A striking similarity of [Fe v]λ6087 and Raman λ6825 profiles at/after the dilution of the disk suggested their origin within the interaction zone where the winds from the binary components collide.

Key words. stars: activity – binaries: symbiotics – stars: individual: Z And – stars: winds, outflows – scattering

1. Introduction

Z And is considered as a prototype of the class of symbiotic stars. The binary comprises of a late-type, M4.5 III, giant and a white dwarf accreting from the giant’s wind on the 758-day orbit (e.g. Nussbaumer & Vogel 1989; Mikolajewska & Kenyon 1996). More than 100 years of monitoring Z And (first records from 1887) demonstrated an eruptive character of its light curve (LC). It displays several active phases, during which fluctuations ranges in amplitude from a few tenths of a magnitude to about 3 magnitudes. During the strongest outbursts (1915, 1940, 1960, 1985, 2000) the star’s brightness reached values around $m_{pg} \sim 9$ and $m_{vis} \sim 8.5$ mag with the recurrence time of 15 to 25 years (see Fig. 1). Major outbursts are characterized by a decrease in the effective temperature of the hot object and the fluxes of some high ionization emission lines. Analyzing previous large eruptions, Mikolajewska & Kenyon (1996) found that an A–F absorption spectrum characterized the 1940 optical maximum and during the 1960 outburst the system resembled an F0–2 supergiant. They estimated a roughly constant luminosity and a factor of 10 lower temperature, $T_h$, for the hot object during eruptions with respect to quantities from quiescence. As concerns to the 1985 eruption, Mikolajewska & Kenyon (1996) supported the decrease in $T_h$ also by a decline of Raman scattered O vi lines at λ6825 and λ7088. This outburst was studied in detail by Fernández-Castro et al. (1995). By means of the ultraviolet spectroscopy and radio observations, they indicated a considerably cooler UV continuum with an additional attenuation below 1300 Å accompanied by a decline in the radio flux during the 1985 optical maximum. In the line spectrum they measured a broadening of all emission lines with signatures of P-Cygni type of profiles for strong resonance lines. Fernández-Castro et al. (1995) interpreted these features as a result of the ejection of an optically thick shell at moderately high velocity of 200–300 km s$^{-1}$. Radio observations also provided evidences of a mass-outflow from the active star. At the initial stage of both 1985 and 2000 outbursts the radio flux dropped below values from quiescence, then recovered along the optical decline and reached close to the quiescent level or above it.
2. Observations and reductions

2.1. Optical spectroscopy

Our spectroscopic observations were taken during the recent major 2000-03 active phase at different observatories.

Prior to the maximum of the star’s brightness a low-dispersion spectroscopy was secured at the Special Astrophysical Observatory of the Russian Academy of Sciences (SAO in Table 1) with the long slit UAGS spectrograph equipped with a fast Schmidt camera and CCD detector (530×580 pixels of 18×24 μm size) mounted at the Cassegrain focus of the Zeiss 1-m telescope. Linear dispersion was 1.5 and 3.1 Å pixel$^{-1}$ in the blue and red part of the spectrum, respectively. Basic reduction including extraction of 1D-spectra from CCD images and wavelength calibration were made by using the software-package of Vasilyuk [1993].

At the maximum of the star’s brightness a high-dispersion spectroscopy was secured at the Asiago Astrophysical Observatory (OAC) with the DEIMOS Echelle Spectrograph (RES) equipped with a Thompson THX31156 UV-coated CCD detector (1024×1024 pixels of 19 μm size) mounted at the Cassegrain focus of the 1.88-m telescope at Mt. Ekar. Two very different exposures of 120 and 3600 s were applied to obtain well defined Hα profile and the underlying continuum. The RES orders were straightened through the software package. Dispersion of the RES was 10 Å mm$^{-1}$ (0.19 Å pixel$^{-1}$) at Hα. The spectra obtained during each night cover the wavelength range of 459.5 – 909.2 nm.

After the maximum and the following transition to quiescence a high-dispersion spectroscopy was secured at the Okayama Astrophysical Observatory (OAO) with the HIgh Dispersion Echelle Spectrograph (HIDES, Izumiura [1999]) at the f/29 coudé focus of the 1.88-m telescope. Dimension of the CCD (EEV 42-80) was 2048×4096 pixels of 13.5 μm size. The spectral resolving power was 50 000 or 60 000. The dispersion was ~0.02 Å pixel$^{-1}$ (~1.2 km s$^{-1}$) and ~0.03 Å pixel$^{-1}$ (~1.4 km s$^{-1}$) in the region of 450 – 570 and 580 – 700 nm, respectively. Bias and instrumental flats were also measured and taken into account in the usual way. The reduction and analysis was performed with the IRAF-package software and our own code to reduce spectra obtained with HIDES. For example, the scattered light from the instrument was also removed. The Th-Ar comparison spectrum was fitted with a 3rd-order poly-

### Table 1. Log of spectroscopic observations

| Date      | Julian date | Phase | Region | Observatory |
|-----------|-------------|-------|--------|-------------|
| 02/11/00  | 51851.27    | 0.143 | 409.2 – 494.8 | SAO         |
| 04/11/00  | 51853.34    | 0.146 | 413.2 – 495.0 | SAO         |
| 05/11/00  | 51854.37    | 0.147 | 413.8 – 495.0 | SAO         |
| 05/11/00  | 51854.39    | 0.147 | 482.0 – 563.1 | SAO         |
| 16/11/00  | 51865.00    | 0.161 | 90.5 – 118.8  | FUSE        |
| 27/11/00  | 51876.00    | 0.176 | 90.5 – 118.8  | FUSE        |

nominal function, which reproduced the wavelength calibration to better than $10^{-3}$ Å.

At the post-outburst stage (the end of 2003) a high-resolution spectroscopy between 6258 and 6770 Å was taken at the Ondřejov Observatory using the coude spectrograph of 2-m reflector and the BROR CCD camera with the SITe 800×2030 pixels chip. The resolution power at the Hζ region was 13 000. Basic treatment of the spectra was done by using the IRAF-package software.

A correction for heliocentric velocity was applied to all spectra. The journal of spectroscopic observations is in Table 1.

2.1.1. Flux calibration of the spectra

We converted arbitrary flux units of our spectra to fluxes in erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ with the aid of the simultaneous $UBV$ photometry. Following points are relevant: (i) We summarized photometric observations carried out (nearly-)simultaneously with the spectrum under consideration. (ii) We calculated corrections $\Delta m$, which are due to emission lines in the spectrum, to get magnitudes corresponding to the continuum (see Skopal 2003b for details). (iii) Then we dereddened the continuum magnitudes with $E_{B-V} = 0.30$ by using the extinction curve of Cardelli et al. (1989) and converted to fluxes according to the calibration of Henden & Kaitchuck (1982). (iv) Finally, we dereddened the star’s continuum by fitting the $UBV$ fluxes with a 3-order polynomial function and scaled the measured spectrum to this fit.

2.2. Far ultraviolet spectroscopy

The $FUSE$ instrument was described in detail by Moos et al. (2000) and Sahnow et al. (2000). A brief useful description of the spectrograph is given in Young et al. (2005).

The data were processed by the calibration pipeline version 3.0.7, 3.0.8 and 2.4.1. We used the calibrated time-tag observations (TTAG photon collecting mode) taken through the large 2-m reflector and the $BROR$ instrument was described in detail by Moos et al. (1986, Fig. 5 there) represents only an extrapolation and thus is more uncertain. As a result we used their mean extinction law only for $\lambda > 1 100$ Å. The short-wavelength rest of the spectrum was rectified to our model SED (Fig. 6).

2.3. Broad-band photometry

Photometric observations were performed in the standard Johnson $UBV$ system with the $RC$ filter of the Cousins system. We used a single-channel photoelectric photometers mounted in the Cassegrain foci of 0.6-m reflectors at the Skalnaté Pleso and Stará Lesná observatories. We converted our $RC$ magnitude to that of Johnson system by using transformations of Bessell (1988). $Z$ And was measured with respect to the comparison SAO 53150 (BD+47 4192; $V = 8.99$, $B-V = 0.41$, $U-B = 0.14$, $V-R = 0.16$). Usually, 1-hour cycle contained about 10 to 20 individual differences between the target and the comparison. This approach reduced the internal uncertainty of such the means to ~0.01 mag in the $V$, $B$ and $R$ bands, and up to 0.025 mag in the $U$ band. Individual measurements in a form of the table were already published by Skopal et al. (2004).

In this paper we dereddened our observations with $E_{B-V} = 0.30$ and scaled relevant parameters for a distance of 1.5 kpc (Skopal 2005 and references therein).

3. Analysis

3.1. Photometric evolution

Bottom panels of Fig. 1 show the $UBV$ LCs of $Z$ And covering its recent outburst. The rise to maximum was characterized by three rapid increases in the star’s brightness and two plateaus, best seen in the $U$ band. The initial rise between 2000 September 1st and 7th ($\Delta U = 1.9$, $\Delta B = 1.5$, $\Delta V = 1.1$) was probably caused by an increase of the hot object luminosity. The $U-B$ index became more blue with respect to observations made prior to the outburst. Consequently, the profile of the optical continuum became more steep. Its nature – nebular or stellar (or a combination of both) – is important to understand the trigger mechanism of the outburst. The nebular nature of the optical light at very beginning of the outburst would require an increase in $T_{he}$ to get the necessary amount of ionizing photons, while the stellar nature of the optical radiation would be associated with a creation of a shell surrounding the hot star implying thus a decrease in $T_{he}$. Unfortunately, we do not have relevant spectroscopic observations from the initial stage of the activity to distinguish between these possibilities. Nonetheless a comparison of colour indices with those of a black body (they are well above, see Fig. 1 of Skopal 2003a) signals a contribution from other sources. The following short-term decline in the $U-B$ index at constant $B-V$ and $V-R$ indices suggested a decrease of the hot component temperature. Then during the ‘totality’ of the $U-B$ minimum ($\sim JD 2 451 800 - 2 451 865$) all the colour indices were practically constant indicating thus a constant temperature. Therefore...
the second increase in the star’s brightness, which occurred at
column indices (\(\sim\) JD 2 451 820, Fig. 1), had to result from an
increase in the luminosity at a relevant expansion of the shell.
Finally, the third brightening from the mid-November to the
maximum (i.e. the ascending branch of the \(U - B\) minimum) indicated an increase of the hot object temperature and its lu-
minosity. Quantities of the corresponding colour indices were
probably due to a composition of contributions from a nebula
and stellar source. Our SED model from the maximum sup-
ports this interpretation (Sect. 3.3.2, Fig. 7). It is of interest to
note that similar behaviour in colour indices was also observed

Fig. 1. Top: The historical 1895-2004 photographic/B-band/visual LC of Z And. It is compiled from the data published by
Payne-Gaposchkin (1946), Romano (1960), Mjalkovskii (1977), Belvakina (1983, 1992), Mikolajewska & Kenyon (1996),
Skopal et al. (2002b, 2004) and smoothed visual AFOEV data. Middle: A part of the multicolour LC covering the recent two
major outbursts (1984-86 and 2000-03). Bottom: The \(UBVR\) photometry from the major 2000-03 outburst. Left panel shows the
overall evolution in the LC. The eclipse is denoted by E. The right panel shows the LC at the initial stage of the outburst – note
its stepped profile on the rise to the maximum. Optical/FUV spectroscopic observations are denoted by vertical full/dashed bars.
The arrows mark positions at which we reconstructed the observed SED.
Fig. 2. Evolution in selected lines, mainly from the optical maximum. Fluxes are in units of $10^{-13}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ and radial velocities in km s$^{-1}$. Small numbers in panels with more profiles represent their shift with respect to the level of the local continuum. The arrows denote absorption components. The right panel shows evolution in the He I $\lambda 5876$ line (y-tics are by 100 units). The continuum from the giant, as given by the SED (Fig. 7), is compared to clarify details in lines of H$\beta$, [O III] $\lambda 5007$ and He I $\lambda 6678$.

Fig. 3. Evolution in the O I $\lambda 1032$ line (LiF1A spectra) in an appropriate logarithmic scale. Note that the P-Cygni profile with a strong absorption developed throughout the whole active phase. Positions of interstellar lines are denoted by i.

From 2001 Z And entered the decline phase during which both colour indices and the star’s brightness were evolving toward quantities of a quiescent phase at the end of 2003 (Fig. 1). In the summer of 2002 the gradual decline was interrupted by the eclipse effect. This event revealed a high orbital inclination and the profile of the minimum suggested a disk-like structure for the eclipsed object (see Skopal 2003a, in detail). In addition, a transient $\sim 0.6$ mag rebrightening lasting from the autumn 2002 to the spring 2003 was indicated in the LC (see Sect. 3.6 in more detail).

Our reconstructed SEDs, we present in the section 3.3, should aid to understand better the photometric behaviour we discussed qualitatively above.

3.2. Spectroscopic evolution

Figures 2÷6 show main characteristics of our spectroscopic observations along the outburst, from its maximum in 2000 December to its end in 2003. We comment on them as follows:

(i) The P-Cygni profiles of H I lines of the Paschen series and He I lines were present mainly at initial stages of the
Fig. 4. Evolution in the Hα, Raman λ6825 and [Fe VII] 6087 line profiles along the outburst, from the 2000-maximum to 2003-quiescence. Left panel shows profiles of the Hα line core (y-tics are by 500 units), while the middle panels show the extended wings of the profiles in detail. On the right panels y-tics are by 20 units and the horizontal dashed lines represent the approximated continuum as described in Sect. 2.1.1.
outburst, prior to and at the maximum. The main absorption component was located at about $-90\,\text{km\,s}^{-1}$. However, complex absorption features to $\sim 300\,\text{km\,s}^{-1}$ could be recognized for $\lambda 8502$, $\lambda 8545$ and $\lambda 8665$. In the far-UV Sokoloski et al. (2005) detected P-Cygni profiles in C\textsc{iii} and P\textsc{v} lines (Fig. 6 here) with terminal velocities of $\approx -200\,\text{km\,s}^{-1}$ on the first \textit{FUSE} observations. They also demonstrated evolution from absorption to emission profile of these lines as the outburst progressed to its maximum. On the other hand, the resonance line O\textsc{vii}11032 shows a strong absorption in the P-Cygni profile throughout the whole active phase (Fig. 3). This suggests its origin in the stellar wind of the hot star. During quiescence the absorption component was not present in the profile (Schmid et al. 1999). In Sect. 3.4 we examine this line in detail.

(ii) The H$\beta$ wings extended to about $1000\,\text{km\,s}^{-1}$ or more. The main emission core showed an asymmetrical profile with the peak placed at about $+30\,\text{km\,s}^{-1}$ (the systemic velocity is $-1.8\,\text{km\,s}^{-1}$). The asymmetry can result from superposition of a violet shifted absorption component created in the neutral gas at the front of the expanding material. The He\textsc{ii} profile exhibited similar behaviour. However, its wings extended to more than $+2000\,\text{km\,s}^{-1}$ and the asymmetry was more pronounced. At/after the spectroscopic conjunction the absorption component created a cut-out on the violet side of the wing at about $-40\,\text{km\,s}^{-1}$ (07/08/02) and $-50\,\text{km\,s}^{-1}$ (02/02/03). During the low-amplitude brightening (2002/03) we measured an additional extension of the He$\beta$ wings on our spectrum from 02/02/03. We ascribe their origin to the stellar wind from the hot star (Sect. 3.5).

(iii) At the maximum, the main emission core of the He\textsc{ii} $\lambda 4686$ was shifted by about $-75\,\text{km\,s}^{-1}$ at the peak and by about $-105\,\text{km\,s}^{-1}$ at its bottom with respect to the reference wavelength. The [Fe\textsc{vii}] $\lambda 6087$ line displayed similar characteristics. Its profile was very low and broad with the main emission located around $-80\,\text{km\,s}^{-1}$ (Fig. 4). On the transition from the optical maximum to quiescence these lines became stronger being located at/around their reference wavelengths (see Fig. 4 for [Fe\textsc{vii}] and Tomov et al. 2005 for the He\textsc{ii} line). The evolution in these lines is discussed in Sect. 4.

(iv) He\textsc{i} $\lambda 5876$, $\lambda 6678$ and $\lambda 7065$ emission lines can be used to diagnose the symbiotic nebula (Proga et al. 1994). We observed all these lines just at the maximum, but later, along the investigated active phase, only $\lambda 5876$ and $\lambda 6678$ were measured. At the beginning of the outburst they developed a P-Cygni type of profiles. From 2002 August absorptions affected the whole profile, mainly that of the $\lambda 5876$ line (Fig. 2). A narrow emission core without any wings and with absorption features at the top of the profile were observed. In addition, ratios of their fluxes differ significantly from those arising from net recombination. For example, we measured the ratio $\Lambda = F(5876)/F(6678) \approx 1.2 \pm 1.5$, while theoretical intensities from low-density plasma predict $\Lambda \sim 3.6$ (e.g. Smits 1996). This difference has been ascribed to collisions and optical depth due to the metastability of the $2^3\text{S}$ level, which affect the He\textsc{i} level populations in a high density plasma (e.g. Clerge 1987, Schmid 1989a, Proga et al. 1994 for the case of high density nebulae in symbiotic stars (Appendix A, Fig. A.1). This suggests that the He$+\,$region is very compact with an average density $N_e \approx 10^{12}\text{cm}^{-3}$, radiating at $T_e \approx 20000\,\text{K}$. Emissivity of such the plasma in the He\textsc{i}$\lambda 5876$ line corresponds to an effective radius, $R_{\text{eff}}(\text{He}+) \approx 5\, R_\odot$, which represents the radius of a sphere with constant density (see Appendix A in more detail).

(v) Profile of the nebular [O\textsc{iii}]$\lambda 5007$ line showed asymmetrically extended core/wings with terminal velocities of about -300 and $+250\,\text{km\,s}^{-1}$. A sequence of profiles from 2000 December 10, 11 and 12th, showed a creation of an extra emission component on the violet side of the main core. In addition, weak emission components at about $\pm 380\,\text{km\,s}^{-1}$ accompanied the main core during the maximum. Their reality is supported by the S/N ratio of about 10 at these wavelengths and a relatively low level of the continuum from the giant (cf. Figs. 2 and 7). If one associate these components to polar blobs, as interpreted by Proga et al. (1994) for the classical Nova V 1974 by Chochoł et al. (1997), the space velocity of the ejecta would be larger than $\sim 1600\,\text{km\,s}^{-1}$ for $i > 76^\circ$ (Skopal 2003).

(vi) Evolution in the Raman scattered O\textsc{vii} line at $\lambda 6825$ provides information on the ionization structure around the active object. This emission was absent on our spectra from the maximum and after it. It appeared first on the 10/02/02 spectrum as a very faint emission. During 2003 it became strong and broad (FWZI $\approx 25\pm 30\,\text{Å}$) with $1 \pm 3$ knots at the top of its profile (Fig. 4). Schmid (1989) suggested that this emission feature is due to Raman scattering of the O\textsc{vii}$\lambda 1032$ resonance line by atoms of neutral hydrogen. In Sect. 3.4 we investigate this process in detail.

(vii) Transition to quiescence was characterized mainly by a significant increase in the hot object temperature (Sect. 3.3.3). As a result fluxes of highly ionized elements increased and new appeared (e.g. Ne\textsc{vi} lines, Fig. 5). At the end of 2003 a constant
3.3. Model of the composite spectrum

According to a simple photoionization model for symbiotic stars proposed by Seaquist et al. (1984) (hereafter STB), the observed flux in the continuum, $F(\lambda)$, can be expressed as

$$F(\lambda) = F_{\text{g}}(\lambda) + F_{\text{h}}(\lambda) + F_{\text{N}}(\lambda),$$  

where $F_{\text{g}}(\lambda)$ is the nebular component of radiation and $F_{\text{g}}(\lambda)$ and $F_{\text{h}}(\lambda)$ are stellar components from the hot star and the cool giant, respectively. We approximated radiation from the giant by a synthetic spectrum, $F_{\text{synth}}(T_{\text{eff}})$ (models from Hauschildt et al. 1999), the hot stellar continuum by a black body at the temperature $T_{\text{h}}$ including the effect of Rayleigh scattering and the nebular radiation in the continuum by processes of recombination and thermal bremsstrahlung in the hydrogen plasma. Then Eq. (1) takes the form (Skopal 2005 Eq. 13)

$$F_{\lambda} = F_{\lambda}^{\text{synth}}(T_{\text{eff}}) + \theta_{h}^{2} \pi B_{\lambda}(T_{h}) e^{-n_{\text{H}}\theta_{h}^{2}} + \frac{EM}{4\pi d^{2}} \varepsilon_{\lambda}(H, T_{e}),$$  

where $\theta_{h} = R_{h}^{\text{eff}}/d$ is the angular radius of the hot stellar source given by its effective radius $R_{h}^{\text{eff}}$ and the distance $d$. Parameters determining the Rayleigh attenuation are the column density of H atoms, $n_{\text{H}}$ [cm$^{-2}$], and the Rayleigh scattering cross-section for atomic hydrogen, $\sigma_{R}^{H}$ [cm$^{2}$]. Nebular radiation is in our approximation defined by the emission measure $EM$ and the volume emission coefficient for hydrogen $\varepsilon_{\lambda}(H, T_{e})$ [erg cm$^{-3}$ s$^{-1}$ $\AA^{-1}$], which depends on the electron temperature $T_{e}$. The method of disentangling the composite spectra of symbiotic stars was recently described by Skopal 2005.

To reconstruct the continuum of the hot object we used only the flux-points of the $UBVR$ photometry and the far-UV continuum from $\lambda 1188$ to $\lambda 1100$ $\AA$. With the aid of the $FUSE$ spectra we determined the column density of the atomic hydrogen by fitting the Rayleigh attenuated hot stellar radiation to the observed continuum blueward Ly$\beta$ and Ly$\alpha$ lines (Fig. 6). This reduced free parameters in the model to $T_{h}$, $T_{e}$ and $EM$. As there was no ultraviolet spectrum available from the 2000-03 outburst, determination of $T_{e}$ is more uncertain. To satisfy the condition for an appropriate fit (Skopal 2005 Sect. 3.3) we estimated the uncertainty in $T_{h}$ within the range of $500\pm1000$ K, while $T_{e}$ can run between about 30000 and 40000 K.
3.3.2. SED at the plateau stage and the maximum

To reconstruct the SED during the time of the last plateau in the LC we used the optical spectrum from 06/11/00 and the FUSE observation from 16/11/00. For the maximum, the corresponding data are from 11/12/00 and 15/12/00, respectively. A comparison of our solutions with observations is plotted in Fig. 7 and the corresponding parameters are in Table 2.

The change in the SED from the plateau at \( U \sim 9.0 \) to the maximum (\( U \sim 8.3 \)) was due to an increase in both the hot stellar and the nebular emission. These components of radiation contributed more to the \( U \) band than to the \( BVR \) region. Therefore we observed a larger increase of the star’s brightness in \( U (\Delta U \sim 0.7) \), \( \Delta B \sim 0.4, \Delta V \sim 0.3, \Delta R \sim 0.3 \) mag, i.e. the \( U-B \) index became more blue. The temperature of the hot stellar source, \( T_h \), increased from about 26 000 K to about 28 000 K at a constant effective radius \( R_{\text{eff}} \) (Table 2). Accordingly, its luminosity increased from 3 800 to 5 300 (\( d/1.5 \) kpc\(^2\) \( L_\odot \)) during this transition. However, the emission measure also increased; significantly by a factor of 2.2.

The observed hot stellar radiation is not capable of producing the nebular emission (too low \( T_h \)). This implies that the hot ionizing source cannot be seen directly by the outer observer, but can be ‘seen’ by the surrounding nebula, which converts its radiation into the nebular emission. This suggests a disk-like structure of the optically thick material, whose outer rim occults the central hot star in the direction of the observer (also Sect. 5.3.5 of Skopal 2005). For comparison, we show the SED from the previous 1986 optical maximum, which is of the same type. In such the case the temperature of the ionizing source, \( T_{h,\text{s}} \), can be determined only indirectly from the nebular radiation, which mirrors its radiative properties. For example, Sokoloski et al. (2005) determined \( T_{h,\text{s}} \) \( \sim 95\,000 \) K from fluxes of H\( \beta \) and He\( \iota \) 4686 line observed at the maximum. However, scaling the hot radiation from the unseen ionizing source to the observed, significantly cooler, pseudophotosphere yields an erroneous (too high) luminosity of the white dwarf. According to our SED model the total luminosity produced at/around the white dwarf during the maximum is \( L_T \geq L_h + L_N = 6900\,(d/1.5\text{ kpc})^2 L_\odot \) (Table 2 here and Sect. 5.3.6 of Skopal 2005, in more detail), but Sokoloski et al. (2005) derived \( L_h = 9\,800\,(d/1.2\text{ kpc})^2 L_\odot \) for \( E_{B-V} = 0.27 \) (\( = 21\,500\,(d/1.5\text{ kpc})^2 L_\odot \) for \( E_{B-V} = 0.30 \)) by scaling the 95 000 K radiation of the ionizing source to the observed FUV fluxes from the warm pseudophotosphere. Also the best model SED of the FUV and optical continuum with the fixed stellar component radiating at \( T_{h,\text{s}} \sim 95\,000 \) K is not satisfactory (\( \chi^2 \sim 56.2 \)). For comparison, our models in mid panels of Fig. 7 have \( \chi^2 \sim 8.5 \) and \( \chi^2 \sim 13.6 \), respectively.

3.3.3. SED at the post-outburst stage

Here we selected the last observations made by the FUSE on 04/08/03 and corresponding UBVR photometric measurements. The slope of the \( B, V \) and \( R \) fluxes has an opposite trend to that from the maximum – the fluxes follow rather the SED of the giant, which dominates the spectrum from the \( B \) band to longer wavelengths (Fig. 7). The \( U \) flux-point does not obey this trend. It is higher, the ratio \( F_U/F_B \sim 1.78 \) (i.e. \( U-B = -1.16 \)). This reflects a dominant contribution from the nebula in the near-UV/U. As a result the radiation from the hot star in
the optical had to be small relatively to other sources here. This suggests a high temperature, \( T_h \approx 100,000 \text{ K} \). We adopted \( T_h = 120,000 \text{ K} \) to satisfy basic photo-ionization model of symbiotic stars (STB). At this temperature the hot star luminosity is just capable of producing the observed \( E.M. \). From this point of view \( T_h \approx 120,000 \text{ K} \). Finally, we complemented contributions from the giant and the hot stellar source by a nebular contribution with \( T_e = 25,000 \pm 5,000 \text{ K} \) and \( E.M. = 1.3 \times 10^{60} \text{ cm}^{-3} \).

Large uncertainties in \( T_e \) are given by the presence of a rather high-temperature nebulous from collisions (Gurzadyan 1997), which is consistent with the strong mass-outflow. Also, Sokoloski et al. (2005) ascribed the increased X-ray emission at the optical maximum to the shock-heated plasma as a consequence of the mass ejection from the white dwarf into the dense symbiotic nebula. Also the transient increase of the nebular emission during the low-amplitude 2002/03 rebrightening (bottom panel of Fig. 7) was also connected with a release of new emitters into the particle bounded nebula (see Sect. 3.6). Contrarily, during the plateau stages the SED did not change considerably as suggested by the stability of colour indices (Sect. 3.1). This constrains the hot object to be stable in the luminosity, temperature and also the mass outflow, because more emitters would give rise a surplus of the emission measure and thus the star’s brightness.

### 3.4. Direct and Raman scattered \( \text{O} \text{v} \lambda 1032 \) line

The Raman scattering process and its possible applications in astrophysics was introduced by Nussbaumer et al. (1989). In this process a photon excites an atom from its ground state to an intermediate state being immediately stabilized by a transition to a true bound state by emitting a photon of a different frequency. Schmid (1989a) identified the \( \lambda 6830 \) and \( \lambda 7088 \) emission bands observed in many symbiotic stars as to be due to Raman scattering of the \( \text{O} \text{v} \) resonance doublet \( \lambda 1032, \lambda 1038 \) by neutral hydrogen. Later on this process has been investigated by many authors (e.g. Schmid 1996; Harries & Howarth 1996; Schmid et al. 1999; Birriel et al. 2000). The efficiency of this scattering process and profiles of both the direct and the Raman-scattered \( \text{O} \text{v} \) lines together with polarimetric measurements provide information on the scattering geometry in symbiotic systems (Schmid 1998). Previous studies referred exclusively to quiescent phases of symbiotic stars. For \( Z \text{And} \), Birriel et al. (1998) revealed firstly a strong evidence for the Raman effect and determined its efficiency to \( \sim 7\% \) for \( \lambda 1032 \) on the basis of the \( \text{HUT} \) observations. Schmid et al. (1999) derived the efficiency of this conversion to \( 4\% \pm 6\% \) and found that the \( \lambda 6825 \) profile in \( Z \text{And} \) is by \( 30\% \) broader than the original \( \text{O} \text{v} \lambda 1032 \) line on the violet side of the profile. They used observations from the ORFEUS mission.

Here we analyze our series of Raman \( \lambda 6830 \) lines obtained along the major \( Z \text{And} \) outburst (Fig. 4) together with the archival \( \text{FUSE} \) spectra covering the same period.

### Table 2. Fitting and derived parameters from the SED during the maximum of the 1985 and 2000 outburst.

| Date         | \( T_h \) | \( \log n_\text{H} \) | \( T_e \) | \( \text{EM} \) |
|--------------|-----------|----------------------|-----------|--------------|
| \text{FUSE – Optical} | \( [K] \) | \( [\text{cm}^{-3}] \) | \( [K] \) | \( [\text{cm}^{-3}] \) |
| 24/12/85     | 19,000    | 3.4 \times 10^{-11}  | 2.3       | 590          |
| 16/11/00     | 26,000    | 4.6 \times 10^{-11}  | 3.1       | 3,800        |
| 27/11/00     | 28,000    | 4.7 \times 10^{-11}  | 3.1       | 5,300        |
| 04/08/03     | 120,000   | 1.5 \times 10^{-12}  | 0.10      | 1,800        |
| 160,000      | 1.3 \times 10^{-12} | 0.086 | 4,400 |

Here we analyze our series of Raman \( \lambda 6830 \) lines obtained along the major \( Z \text{And} \) outburst (Fig. 4) together with the archival \( \text{FUSE} \) spectra covering the same period.
Table 3. Dereddened fluxes for the O vi $\lambda$1032 line and its Raman scattered counterpart at $\lambda$6825 in units of $10^{-12}$ erg cm$^{-2}$ s$^{-1}$. The efficiency, $\eta$, was derived according to the relation (3).

| Date       | Julian date  | Phase | $F_{O \, vi}$ | $F_{Ram}$ | $\eta$ [\%] |
|------------|--------------|-------|---------------|-----------|--------------|

*i/e – interpolated/extrapolated value, 
† – no detection, upper limits only

3.4.1. Raman scattering efficiency

The scattering efficiency for the Raman process is defined as the photon ratio, $\eta(O \, vi) = N_{Ram}/N_{O \, vi}$, between the Raman scattered and the initial O vi line component, i.e. the fraction of emitted O vi photons converted to Raman photons. As we measured only the Raman $\lambda$6825 line we investigate here the conversion $\lambda$1032 $\rightarrow$ $\lambda$6825. In the simplest case the efficiency of this transition can be written as

$$\eta(O \, vi) = 6.614 \frac{F_{Ram}}{F_{O \, vi}},$$

where the factor 6.614 = $\lambda$1031.92/$\lambda$6825.44. In the real case $\eta$ depends on the geometry of H i atoms within the binary and the binary position with respect to the observer (Schmid 1996). Thus the relation (3) represents just an empirical measure of the line photon ratio we call efficiency. Table 3 and Fig. 8 summarize the results. As the FUSE and our optical observations were not simultaneous, we interpolated FUSE fluxes to dates of optical observations and vice versa. Below we comment on the variation in $\eta$ along the outburst as follows:

(i) At the initial stages (2000-01) the not-measurable Raman’s band could be a consequence of a very low O vi $\lambda$1032 flux. Assuming the conversion efficiency of a few percent, the incident flux of $45 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ (Table 3) produces a few times $10^{-13}$ erg cm$^{-2}$ s$^{-1}$ at $\lambda$6825, which implies the height of the Raman feature above the local continuum only of a few times $10^{-14}$ erg cm$^{-2}$ s$^{-1}$, which is under the detection. On the other hand, the signal to noise ratio S/N $\sim$ 20 around the Raman line suggests a limiting flux of $\sim 1 \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$ $\AA^{-1}$ to recognize a real detail in the spectrum. Then, assuming the Raman line to be flat and broad as $\sim$ 20 $\AA$, its flux we cannot detect is $\lesssim 2 \times 10^{-12}$ erg cm$^{-2}$ s$^{-1}$. Corresponding upper limits for efficiencies $\eta$ are relatively large, because of low initial O vi fluxes at the optical maximum (Table 3, Eq. (3), Appendix B).

(ii) In the period of 2002, prior to the spectroscopic conjunction, the emergence of the Raman features and the enhancement of the O vi fluxes (Table 3, Fig. 8) require a relevant extension of the scattering region to get the measured efficiencies of $3\pm4\%$. Note that the flux increase of the $\lambda$1032 line itself would result in a decrease of the conversion efficiency (Eq. (3)). A comparison of the derived efficiencies to a grid of model calculations published by Schmid (1996) suggests that a kind of his $XB3$ model could be relevant, i.e. nearly one third of the sky, as seen from the O vi ionized zone, is covered by the neutral scattering region.

(iii) A significant increase in the Raman conversion efficiency during the first quadrature after the spectroscopic conjunction (2002 autumn – 2003 spring, orbital phases 0:0.25, Fig. 8) reflects an enlargement of the neutral region seen from the O vi zone. The observed O vi $\lambda$1032 flux decreased, while its Raman scattered counterpart at $\lambda$6825 increased (Table 3). Here the efficiency of 10-$12\%$ are similar to that of the XC3 model of Schmid’s (1996) simulations, in which at least one half of the ‘O vi sky’ is occupied by atoms of neutral hydrogen. This change in distribution of the neutral material in the binary could be connected with an enhancement of the hot star wind near the equatorial plane as a result of dilution of the optically thick disk-like shell during this period (Sect. 4). According to hydrodynamical calculations that include effects of the orbital motion, a dense S-shaped wind-wind collision region can be formed between the stars where the fast wind pushes the giant wind (e.g. Fig. 3 of Walder 1995). This interaction zone can divide the binary space into two approximately equal parts of the neutral and ionized wind. Such a distribution of neutral giant’s wind in the active binary satisfies conditions required by a larger efficiency of the Raman scattering process.

(vi) During the post-outburst period (2003, orbital phase $\sim$ 0.5), observed O vi fluxes increased, while the $\lambda$1032 $\rightarrow$ $\lambda$6825 conversion efficiency decreased. This indicates a decrease of the size of the scattering region as ‘seen’ by the O vi photons. Derived efficiencies of $\sim$ 5% are similar to those from quiescence (Birriel et al. 1998, Schmid et al. 1999).

3.4.2. Comparison of line profiles

Evolution in the Raman scattered O vi $\lambda$1032 line along the outburst is shown in Fig. 4. A comparison of both direct and Raman scattered line is plotted in Fig. 9 for near-simultaneous optical/far-UV observations. Table 4 summarizes their basic parameters ($RV_c$, FWHM). Well-measurable Raman $\lambda$6825 line developed from 07/08/02 on our spectra, i.e. nearly two years after the beginning of the outburst. Profiles consist of a central peak at $\sim$ 6832 $\AA$ and a violet and red shoulder at $\sim$ 6823 $\AA$ and $\sim$ 6837 $\AA$, respectively. On 02/02/03 the red adjacent component developed in a separate peak of a comparable intensity to the main peak. The directly measured O vi $\lambda$1032 line was characterized by a strong central emission shifted...
by about +58 km s\(^{-1}\) with respect to the systemic velocity. Such a large redshift was measured also during a quiescent phase by Schmid et al. (1999) who explained this effect by radiative transfer in strong resonance lines throughout an expanding medium. During the active phase, this line absorption/scattering effect attenuated the violet wing from about +50 to −350 km s\(^{-1}\) and produced a P-Cygni type of the profile (Fig. 3). This suggests its origin in the densest part of the hot star wind. Other variations along the active phase (Fig. 9) are discussed below.

We compare the line profiles in the radial velocity (RV) space considering the principle of energy conservation of the Raman scattering process. According to Nussbaumer et al. (1989) a broadening \(\Delta \lambda_i\) of the incident line \(\lambda_i\) is transferred to a broadening \(\Delta \lambda_f\) of the scattered line \(\lambda_f\) as

\[
\frac{\Delta \lambda_f}{\Delta \lambda_i} = \frac{\Delta \lambda_i \lambda_f}{\Delta \lambda_f \lambda_i}.
\]  

We propose the following explanation of our observations (Fig. 9):

(i) The first measured Raman \(\lambda 6825\) line (10/02/02, \(\varphi = 0.76\)) was compared with the direct \(\text{O} \text{I}\) line from 30/09/01 (\(\varphi = 0.58\)). Unusually, with respect to later observations, both profiles nearly overlapped each other. So there were no significant motions of the scattering region relative to the direction of the incoming \(\text{O} \text{I}\) photons. This implies that the \(\text{O} \text{I}\) photons could not impact the neutral wind at the orbital plane moving toward them. Otherwise the \(\sim 40\) km s\(^{-1}\) shift of the Raman line relative to the original line had to be observed. Schmid et al. (1999) explained this effect by a self-absorption near to the hot object. Note that the major part of the \(\text{O} \text{I}\) flux is created in the densest regions of the wind encompassing the hot star (cf. Appendix B). Another peculiarity is that the violet wing of the \(\lambda 1032\) line was not so strongly absorbed in the wind medium as we observed later during the outburst. As a result the total profile was shifted only to \(\sim 35\) km s\(^{-1}\) (Table 4). A shallow minimum in the \(\lambda 1032\) line at \(\sim +18\) km s\(^{-1}\) could be caused by a self-absorption near to the hot object. Note that the radial velocity of the hot component orbital motion at the time of the observation (\(\varphi = 0.76\)) is comparable to this shift (parameters from Mikolajewska & Kenyon 1996), which thus places its origin at/around the hot star, in agreement with our assumption (a) above.

(ii) Next available pair of \(\text{O} \text{I}\) \(\lambda 1032\) and \(\lambda 6825\) lines was taken just prior to the inferior conjunction of the red giant (\(\varphi = 0.95\) and 0.99). The line flux at \(\lambda 1032\) was the largest from our sample and its profile was characterized by a narrow redshifted core (RV\(_c\) \(\sim +67\) km s\(^{-1}\)), while its scattered counterpart at \(\lambda 6825\) was rather faint. The profile of the initial \(\text{O} \text{I}\) line was probably modified by an occultation of the \(\text{O} \text{I}\) nebula, which thus reduced its violet wing for the outer observer. Note that from \(\varphi = 0.94\) a decrease of the optical light due to the eclipse effect was observed (Fig. 2 of Skopal 2005). On the other hand, the \(\text{O} \text{I}\) zone was not subject to occultation for the scattering region spread within the H\(\alpha\) zone in the binary. So this could ‘see’ the un-affected \(\text{O} \text{I}\) \(\lambda 1032\) line profile and thus convert it to a standard type of the \(\lambda 6825\) line profile as measured at other orbital phases later on. The significant

![Fig. 8. Evolution of the Raman conversion efficiency \(\lambda 1032\rightarrow \lambda 6825\) along the outburst of Z And (full diamonds). Open triangles connected with dotted line denote upper limits for too low Raman fluxes that were beyond our detection (see the text). Data are from Table 3.](image)

† Birriel et al. (2000), ‡ Schmid et al. (1999)
close to the orbital plane and thus met a massive neutral wind from the giant moving against it. This lead to the appearance of the violet adjacent component in the \( \lambda 6830 \) profile and an enhancement of the \( \eta(\text{O} \, \text{vi}) \) efficiency.

(iii) After the spectroscopic conjunction (the far-UV and optical observation made at \( \varphi = 0.09 \) and 0.23, respectively; Table 3), during the 2002/03 transient increase in the star’s brightness, we observed the largest efficiency of the \( \lambda 1032 \rightarrow \lambda 6825 \) transition, well developed three-peaked structure of the Raman line and a relatively broad line core of the direct \( \text{O} \, \text{vi} \) line with superposition of a wind component at \( \sim +180 \) km s\(^{-1}\) (Fig. 9). The Raman line was broader by the blue adjacent component. Its wing was shifted by about \(-40\) km s\(^{-1}\) relatively to that of the \( \lambda 1032 \) line. This emission is produced by the \( \text{H} \, \text{i} \) atoms of the giant’s wind, which are located along the binary axis and move toward the \( \text{O} \, \text{vi} \) region. The absorption component in the emission core of the \( \text{H} \, \text{ii} \) profile at the position of \( \approx -45 \) km s\(^{-1}\) (Sect. 3.2 (ii)) supports this interpretation. In addition, a dense neutral region could be created as an enhanced hot star wind pushes the neutral giant’s wind between the binary components. This can increase the effective number of the hydrogen atoms and thus also the efficiency \( \eta(\text{O} \, \text{vi}) \). The outer part of the neutral wind and the \( \text{H} \, \text{i} \) atoms in the collisional zone moving from the incoming \( \text{O} \, \text{vi} \) photons then extend the red side of the Raman line profile. The red wind component in the \( \lambda 1032 \) profile has no Raman counterpart. This portion of the \( \text{O} \, \text{vi} \) emission has an origin at outer part of the hot wind, i.e. further away from the scattering region, which reduces the scattering efficiency.

(iv) Similar profiles were observed also later at the orbital phase \( \varphi = 0.5 \) (nearly simultaneous observations, bottom panel of Fig. 9). This suggests the difference between the direct and the Raman line profile to be of the same nature as we discussed above in the point 3.

The shift between the red wings of the Raman-scattered and the direct \( \text{O} \, \text{vi} \) line during a quiescent phase was larger than we observed during this activity. FWHM of the Raman line from the activity exceeded this quantity from quiescence by about \( 10\div30 \) km s\(^{-1}\), while the width of the incident \( \text{O} \, \text{vi} \) line did not change so much (Schmid et al. 1999; Birriel et al. 2000, Table 4 here). This reflects a different kinematics of the scattering region during active and quiescent phases. Because of a strong wind from the hot star developed during the active phase, this could be due to the wind-wind interaction zone in the binary. Therefore, in the following section, we discuss possible connections between profiles of the \( \text{[Fe} \, \text{vi]} \lambda 6087 \) and Raman \( \lambda 6825 \) line.

### 3.4.3. Raman \( \lambda 6825 \) and \( \text{[Fe} \, \text{vi]} \lambda 6087 \) profiles

A comparison of \( \text{[Fe} \, \text{vi]} \lambda 6087 \) and Raman \( \lambda 6825 \) line profiles is shown in Fig. 9. The former was shifted by \( +45 \) km s\(^{-1}\) to eliminate the redshift in the Raman line (Sect. 3.4.2). Similarity of both profiles is obvious, mainly in 2002 and 2003 when also their line fluxes were comparable. Their profiles – a large FWHM of \( \approx 120\div140 \) km s\(^{-1}\), steep wings with a multi-peak structure at the top – suggest them to be due to kinematics of emitting regions. Wings of both the lines practically overlap.
each other at least up to the half of the maximum. Striking is the nearly equality of the extended red wings with a pattern of the red adjacent component (bottom panels of Fig. 9).

These common signatures of both line profiles suggest a similar kinematics for the responsible emitting regions, but differing drastically in conditions of ionization — one region has to contain H\textsc{ii} atoms at high density, while the other one the Fe\textsuperscript{+6} ions at a low density. This can be satisfied if these lines are formed within the wind-wind interaction zone. The Raman line can be created at/around the interaction surface from the giant’s side, where its neutral wind is pushed by the hot star wind, while the [Fe\textsc{ii}]\,\textalpha\, line can arise in a collisionally ionized boundary layer between the two winds. The observed change in the line width at \(\varphi \sim 0.25\) (02/02/03, a maximum width) and \(\varphi \sim 0.5\) (31/07/03, a narrower width) is consistent with the main wind flow velocity aligned approximately perpendicular to the line connecting the stars. Previous works also support such origin of [Fe\textsc{ii}] lines. Nussbaumer & Walder (1993) showed that line profiles of forbidden lines from highly ionized atoms could result from interaction nebula of wind-wind collision in a binary system. The observed profile of the [Fe\textsc{ii}]\,\textalpha\, line in V1016\,Cyg was very similar to our observations from 2003 (see their Fig. 4). Also hydrodynamical calculations of the colliding zone of the two winds by Nussbaumer & Walder (1993) showed a wide variety of resulting line profiles, some of which are similar to our observations (e.g. the overall broadening with steep sides of profiles).

Accordingly the observed broadening of the Raman line profile together with profiles of highly ionized forbidden lines can provide a diagnostic tool in studying motions in the wind-wind interaction zone during active phases. Note that a Raman photon may escape easily from the neutral region, because this elastic process cannot be repeated (in contrast to Rayleigh scattering) and thus reflects motions in the densest (a small cross-section) outer layers illuminated by O\textsc{vi} photons.

3.5. On the origin of the broad H\textalpha\ wings

Nussbaumer et al. (1989) pointed out that the broad H\textalpha\ wings in symbiotic stars could be formed through Raman scattering of Ly\beta\ photons by atomic hydrogen. Lee (2000) and Lee & Hyung (2000) elaborated a relevant model. They showed that the wing profile formed through the Raman scattering can be approximated by the curve proportional to \(f(\Delta v) \propto \Delta v^{-2}\) in the velocity co-ordinates. On the other hand, Skopal et al. (2002a) derived an expression of the same type (see their Eq. 11) to fit the broad components of the hydrogen line profiles that form in an optically thin and spherically symmetric stellar wind. Therefore it is not possible to distinguish the wind emission from the scattered features in the H\alpha\ wind directly. In addition, the observed Ly\beta\ profile can be influenced by other processes in the circumstellar medium.

In our case the observed Ly\beta\ profile is not able to produce the H\alpha\ wings through the Raman scattering process. The width of the scattered H\alpha\ wings is proportional to the width of the Ly\beta\ line as \(\Delta v_{\text{Ly}\beta} \approx \Delta v_{\text{H}\alpha}/6.4\). Then the full extension of H\alpha\ wings \(\geq 4000\text{km s}^{-1}\) (Fig. 4) requires \(\Delta v_{\text{Ly}\beta} > 625\text{km s}^{-1}\) or \(\Delta v_{\text{Ly}\beta} > 2.1\text{Å}\), which is a factor of ~2 larger than the observed FWZI(Ly\beta) < 1.0\,Å. In the case of an optically thick Rayleigh scattering region the Ly\beta\ photons may undergo many Rayleigh scatterings until they are converted into Raman photons and escape. Thus in such the special case only Raman features can be detected, but no original Ly\beta\ emission. The real case is complicated with the presence of a strong and variable geocoronal component of Ly\beta, which is difficult to isolate from the circumstellar one. As a result we have to investigate other possibilities to identify the main source of radiation contributing to the broad H\alpha\ wings. For example, Ikeya et al. (2004) found that polarization profile of H\alpha\ does not agree with that of the Raman \(\lambda 6830\) line for Z\,And on 25/10/02 (i.e. during the 2002/03 brightening). This finding suggests that the H\alpha\ line does not include the Raman-scattered component that originates from Ly\beta. Also a relationship between the emission from H\alpha\ wings and the emission measure of the symbiotic nebula supports the origin of the broad H\alpha\ wings in the ionized stellar wind (Skopal 2006).

Therefore we suggest that the extended H\alpha\ wings, which developed during the investigated active phase of Z\,And, are due to kinematics of the ionized hydrogen rather than the Raman scattered Ly\beta\ photons. However, this problem deserves further investigation.

3.6. Optical rebrightening in 2002/03

After 2002 September/October, when the hot object was arising up from the eclipse, a rebrightening in the LC (\(\Delta U \sim 0.6, \Delta B \sim 0.4, \Delta V \sim 0.3\)) was observed for about 5 months. Our estimate of its magnitude increase takes into account the depth of the eclipse and the brightness level prior to it (Skopal 2003a). During this event we measured an additional extension of the H\alpha\ wings on our spectrum from 02/02/03 and Tomov et al. (2005) observed such broadening also in the emission wings of the H\textalpha\ line profile with FWZI~2400\,km s\(^{-1}\).

The observed indices from the maximum (around 15/12/2002) were \((U-B)_{\text{obs}} \equiv -0.70\) and \((B-V)_{\text{obs}} \equiv 0.85\). If we deredden these observations with \(E(B-V) = 0.30\), correct for emission lines (we adopted \(\Delta U_{\text{f}} = 0.25, \Delta B_{\text{f}} = 0.45\) and \(\Delta V_{\text{f}} = 0.18\) corresponding to a standard emission line spectrum for classical symbiotics (Skopal 2003b) and subtract contributions from the giant, \(F_{\gamma}(B) = 1.3 \times 10^{-13}\text{ erg cm}^{-2}\text{s}^{-1}\)\text{Å}^{-1}\) and \(F_{\gamma}(V) = 2.9 \times 10^{-13}\text{ erg cm}^{-2}\text{s}^{-1}\)\text{Å}^{-1}\) (see Fig. 7), we get indices of the extra light that causes the optical rebrightening as \((U-B)_{\text{extra}} = -1.27\) and \((B-V)_{\text{extra}} = 0.59\). These quantities reflect a large contribution from the nebula radiating at high electron temperature (e.g. Menzies et al. 1982). We demonstrate this case in Fig. 7. The \(UBVR\) flux-points from the maximum of the 2002/03 rebrightening suggest the same type of the SED as in the mid-2003, but with a factor of ~2 stronger contribution from the nebula \((EM)_{\text{rebrightening}} \approx 2.6 \times 10^{6}\text{ cm}^{-3}\).

Assuming a particle-bounded nebula (i.e. geometrically open in the sense of the STB model), a maximum increase of its radiation at a constant flux of ionizing photons can be produced by an injection of new particles into it, that will convert a relevant amount of the ionizing photons into the neb-
lar radiation to yield a radiation-bounded (closed) nebula. The particle-bounded nebula in Z And during 2002-03 is supported by a high quantity of the hydrogen ionizing photons of $\gtrsim 1.2 \times 10^{47} \text{s}^{-1}$ given by the hot object luminosity ($L_h > 1800 L_\odot$) and its temperature ($T_h > 120 000 \text{K}$, Table 2). A large value of the parameter $X \approx 14$ during quiescence corresponding to an open nebula was noted by Fernández-Castro et al. (1988). Within this scenario we interpret the small optical rebrightening as a consequence of a dilution of the optically thick shell around the hot star. This event supplied additional emitters into the particle-bounded nebula, which can convert a relevant part of the far-UV radiation through $f - b$ and $f - f$ transitions to the optical. By other words, the material became more transparent and thus was subject to ionization by the hot central star even at the orbital plane, which led to a transient increase of the nebular emission. We add that similar brightening was also observed in the LC of AX Per at its transition from the active to quiescent phase (Figs. 3 and 10 of Skopal et al. (2001)). A dilution of an optically thick shell in this case was directly confirmed by the change of the narrow eclipses into very broad minima occurring just after the event (cf. Fig. 3 there).

Dumm et al. (1999) analyzed it for RW Hya. Skopal (2005) interpreted the 2002/03 rebrightness as a result of a decrease in $T_h$ (from around 150 000 K to approximately 120 000 K) due to a slight expansion of the white-dwarf photosphere. They based this view on that both the FUSE and VLA fluxes were unusually low during the optical rebrightness and the $U - B$ index varied from about $-0.45$ to $-0.8$ from the beginning to the end of the event. We put following arguments against this interpretation: (i) The decrease in the FUV fluxes and $T_h$ implies a decrease in both the stellar and the nebular component of radiation from the hot object. Note that such small temperature decrease at $T_h > 100 000 \text{K}$ induces a negligible (i.e. not measurable) change in the SED (e.g. Munari & Busson 1992). So, we should observe a decrease of the optical brightness. (ii) There is an additional attenuation of the UV continuum that is well pronounced for eclipsing systems at positions around the inferior conjunction of the giant. This extinction process was first noticed by Mürset et al. (1999) and Dumm et al. (1999). found this effect to be present in all IUE spectra of Z And in the range of phases $\varphi \approx 0 \pm 0.15$. Therefore the ‘unusually’ low FUSE fluxes from 22/10/2002 ($\varphi = 0.093$) result from this effect. (iii) The observed fading in the radio fluxes is consistent with that in $EM: EM(\text{maximum}) / EM(2002/03) \approx F_{5GHz}(\text{maximum}) / F_{5GHz}(2002/03)$ within the corresponding uncertainties (Table 2 here and Table 5 of Sokoloski et al. 2005). (iv) A redder $U - B$ index at the beginning of the rebrightness (−0.45) and a more blue values at after the maximum (−0.8) could qualitatively reflect variation in optical properties of the ionized medium during/after the shell dilution.

(i) The two-temperature-type of the hot object spectrum. The cooler one was produced by a relatively warm stellar source radiating at 20 000−30 000 K (Fig. 7, Table 2) and the hotter one was represented by the highly ionized emission lines (e.g. Hα, O vi, [Fe v]) and a strong nebular continuum radiation ($EM \gtrsim 10^6 \text{cm}^{-3}$, Table 2). The former is not capable of producing the observed amount of the nebular emission and thus the latter signals the presence of a hot ionizing source ($\gtrsim 10^5 \text{K}$) in the system, which is not seen directly by the outer observer.

(ii) Signatures of a mass-outflow at moderate velocities ($\approx 100 - 200 \text{km s}^{-1}$), as indicated by the P-Cygni profiles (Sect. 3.2 (i), Figs. 2 and 6; also Sokoloski et al. 2005), and at very high velocities ($\approx 1000 - 2000 \text{km s}^{-1}$) having a pattern in broad emission wings of Hα (Fig. 4).

The two-temperature spectrum and the two-velocity type of the mass-outflow from the hot object suggest an optically thick disk-like structured material surrounding the central hot star and expanding at moderate velocities at the orbital plane, while at higher latitudes a fast optically thin wind escapes the star. Due to a high orbital inclination the outer observer can see just the optically thick matter of the disk-like shaped warm pseudophotosphere, whose outer flared rim occults the central ionizing source. Only the surrounding medium from above/below the disk can ‘see’ directly the ionizing source and thus convert its radiation to the nebular emission. As a result, the temperature of the ionizing source, $T_h^{\text{Is}}$, can be obtained only through emission lines (Sokoloski et al. 2005) derived $T_h^{\text{Is}} \approx 95 000 \text{K}$, while the observed UV/optical continuum determines the temperature of the stellar source (i.e. the warm pseudophotosphere), $T_h \approx 27 000 \text{K}$ (Sect. 3.3). Thus this stage was characterized by

$$T_h \ll T_h^{\text{Is}}.$$  \hspace{1cm} (5)

Also the low fluxes of highly ionized elements, whose profiles were shifted blueward (Sect. 3.2 (iii), Fig. 2 for He ii, Fig. 4 for [Fe v]), are consistent with the disk-like structure of the hot object. A small size of the corresponding ionized zone (see Appendix B) produced relatively weak emission and the optically thick disk-like extended source, inclined at 75−80° (Skopal 2003d), blocked a fraction of radiation from an outflow at its back side in the direction of the observer. As a result the blue-ward shifted emission dominated the profile. This basic structure of the active object persisted probably until about 2002 August, when the eclipse effect in the LC was the last indication of the presence of the optically thick disk-like shell around the hot star (Skopal 2003d).

Finally, we note that such the structure of the hot object is common for all active S-type symbiotics with a high orbital inclination (Skopal 2005, Fig. 27).

4.2. Evolution after 2002 August

During this period we indicated a more significant dilution of the optically thick material around the accretor and evolution of a fast wind from the hot star nearby the orbital plane. The latter is a direct consequence of the former event, because the flux of the hot radiation and particles from the accretor was
less blocked in directions of the orbital plane. These events are supported by the following results:

(i) A significant increase in the temperature of the stellar component of radiation, $T_h$, we indicated through the model SED (Sect. 3.3.2) and by stronger fluxes of highly ionized elements (e.g. Fig. 5). Consequently, we have

$$T_h \sim T_h^{\text{rel}}$$

in contrast to the evolution at/around the maximum (Eq. 5).

(ii) The optical rebrightening during 2002.7-2003.3, which led to an enhancement of the nebular emission (Sect. 3.6).

(iii) An additional extension of the Hα wings on our spectrum from 02/02/03. Its temporarily larger terminal velocity and flux (Fig. 4) are consistent with the evolution of the hot star wind nearby the orbital plane and the enhancement of $E_M$ (Sect. 3.6). Similar broadening was measured also for He $\lambda 4686$ line by Tomov et al. (2005).

(iv) Appearance of a fast wind from the hot star nearby the equator plane was also suggested by the [Fe vII] $\lambda 6087$ line profile, which evolved to that arising from the wind-wind interaction zone (Sect. 3.4.3).

(v) A sudden increase of the Raman conversion efficiency (Sect. 3.4.1, Fig. 8) and the appearance of the pronounced violet shifted component in the Raman line profile (Sect. 3.4.2, Fig. 9). Both events need an increase of the scattering acts; the latter one also negative velocities between the H I atoms and O vI photons. This can be satisfied if a fast wind from the accretor and ionizing photons appear near the orbital plane and thus interact with the densest portion of the neutral wind from the giant around the binary axis that moves against the O vI photons.

Finally, the model SED from 2003 suggests that we still could not see just the bare white dwarf, because of a large effective hot stellar radius ($R_h^{\text{eff}} \sim 0.1 R_\odot$, Table 2).

5. Conclusions

We studied the symbiotic prototype Z And by using the far-UV, optical low- and high-resolution spectroscopy and $UBVR$ broad-band photometry carried out along its major 2000-03 outburst. We summarize the main results as follows:

(i) An expansion of the hot object and an enhanced mass loss from the system was indicated by the change in the SED during the transition from the second plateau stage to the maximum (Sect. 3.3.2). A complex mass-outflow from the system was recognized in the structure of the [O III] $\lambda 5007$ profiles (ejection of blobs, creation of adjacent emission components; Sect. 3.2, Fig. 2) and of the absorption components in C II and P v lines in the $FUSE$ spectra.

(ii) Evolution of the two-temperature type of the spectrum at the initial stages of the outburst having signatures of a mass-outflow at moderate and high velocities suggested that the active object consists of an optically thick slowly expanding disk-like structured material encompassing the white dwarf at the orbital plane and of a fast optically thin wind escaping the star at higher latitudes (Sect. 4.1). The optically thick disk-like shell persisted probably until 2002 August. Afterwards we indicated its dilution and evolution of a fast hot star wind concentrated more at the orbital plane (Sect. 4.2).

(iii) A striking similarity of [Fe vII] $\lambda 6087$ and Raman $\lambda 6825$ profiles after the dilution of the disk suggested their origin within the interaction zone, where the winds from both the stars collide (Sect. 3.4.3). This unusual symbiosis of these lines and properties of the Raman scattering process can be helping to study streaming along the zone of interaction between the two winds.

Acknowledgements. The authors thank the anonymous referee for several helpful comments. Hans Martin Schmid is thanked for useful discussion about Raman scattering process. M.W. thanks M. Šlechta for initial reduction of the spectra taken at the Ondřejov Observatory. A.S. acknowledges the hospitality of the Capodimonte Astrophysical Observatory in Naples.

Appendix A: He I flux ratios

To predict flux ratios of He I emission lines, $F(7065)/F(5876)$ and $F(6675)/F(5876)$, Proga et al. (1994) solved the statistical equilibrium equation for a given level in their (19 level) He I atom including the radiative and three-body recombinations and effects of collisional ionization and collisional transfer between other levels of the model atom. The model requires as input parameters the electron temperature, $T_e$, the electron density, $N_e$, the rate of photons capable of ionizing He I atom and the optical depth in the He I 13889 line, $\tau_{3889}$, as a measure of the population of the metastable $2^2 S$ level. Modeled and observed ratios are shown in Fig. A.1. The location of the flux ratios from the optical maximum in 2000 December suggests that the He I emitting region is very dense, $N_e \gtrsim 10^{12}$ cm$^{-3}$, and radiates at $T_e \gtrsim 20000$ K. Comparing the observed luminosity in the $\lambda 5876$ line, $4\pi d^2 F(5876)$, with that predicted by its emissivity, $N_e^{\text{flux}} V$, we can determine the effective radius of a spherical nebula as

$$R_{\text{eff}}(\text{He I}) = \left( \frac{3 F(5876) d^2}{N_e^{\text{flux}} V} \right)^{1/3} \times 10^{-26} \text{ cm}^3 \text{s}^{-1}$$

where the emission coefficient $\epsilon_{5876} \approx 1 \times 10^{-26}$ erg cm$^{-3}$ s$^{-1}$ for $N_e = 10^{12}$ cm$^{-3}$ and $\tau_{3889} = 100$ (Proga et al. 1994). Then $F(5876) = 73 \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$ (Table A.1), and $d = 1.5$ kpc yield $R_{\text{eff}}(\text{He I}) \approx 5 R_\odot$.

During the recent major outburst He I fluxes evolved toward lower $F(7065)/F(5876)$, whereas during the smaller 1986-eruption the fluxes evolved toward lower $F(6675)/F(5876)$ at nearly constant $F(7065)/F(5876)$ (Fig. A.1). In general, this reflects different properties of the nebula, which develops during outbursts around the hot active object. Qualitatively, during strong outbursts the velocity field of the hot star wind can make large differences in the density throughout the nebula. As a result, contributions from the outer, low-density part of the nebula will enhance more the $\lambda 5876$ line relatively to other lines and thus make lower the considered flux ratios. According to Smits (1994) the relative fluxes $F(5876)/F(6675)/F(7065)$ is $2.519/0.682/0.637$ for $N_e = 10^6$ cm$^{-3}$ and $T_e = 20000$ K (open...
Fig. A.1. Dependencies of He \( i \) flux ratios, \( F(7065)/F(5876) \) and \( F(6678)/F(5876) \), for \( N_e = 10^{8} \, \text{cm}^{-3} \) (dotted lines), \( N_e = 10^{10} \, \text{cm}^{-3} \) (dashed lines) and \( N_e = 10^{12} \, \text{cm}^{-3} \) (solid lines), for \( T_e = 10000 \, \text{K}, \ 15000 \, \text{K} \) and \( 20000 \, \text{K} \) (light, medium and heavy lines, respectively). Crosses indicate

\[
\text{Quiescence} \quad 1986-\text{outburst} \\
2000-\text{maximum} \\
\text{Smits (1996)}
\]

Open circle corresponds to a low-density nebula (Table 5 of Proga et al. 1994). Observed fluxes are from heavy lines, respectively. Crosses indicate

\[
\text{Fig. A.1.}
\]

Therefore the real size of the He + nebula will probably exceed the effective radius derived for a constant density distribution. In addition, its shape is not spherical due to the presence of the optically thick disk-like matter at the orbital plane, which prevents ionization in these directions (Sect. 4).

### Appendix B: Radius of the O \( \text{v} \) zone

Radius of the O \( \text{v} \) zone, \( R(\text{O} \, \text{v}) \), can be obtained from the equation of the equilibrium between the flux of photons, \( L_{\text{ph}}(\text{O} \, \text{v}) \), capable of ionizing O \( \text{v} \) ions and the number of re-

\[
L_{\text{ph}}(\text{O} \, \text{v}) = \frac{4\pi}{3} R(\text{O} \, \text{v})^3 \alpha_{\text{B}}(\text{O} \, \text{v}) N_e \phi_{\text{B}}(\text{O} \, \text{v}),
\]

where \( \alpha_{\text{B}}(\text{O} \, \text{v}) \) is the abundance of O \( \text{v} \) ions, \( \phi_{\text{B}}(\text{O} \, \text{v}) \) is the recombination coefficient of a free electron with the O \( \text{v} \) ion for the case \( B \) and \( N_e \) and \( N_c \) are concentrations of protons and electrons. In determining \( L_{\text{ph}}(\text{O} \, \text{v}) \) values we integrated the Plank curve from the ionization limit of 113.896 eV \( (v_0 = 27.54 \times 10^{15} \, \text{s}^{-1}) \) to \( \infty \). Figure B.1 shows the \( L_{\text{ph}}(\text{O} \, \text{v}) \) quantity as a function of the temperature for the luminosities of the ionizing source of 1000 \( L_\odot \). Further we assumed that all oxygen atoms are ionized to O \( \text{v} \) within the zone, i.e. \( A(\text{O} \, \text{v}) = A(\text{O} \, \text{i}) \), for which we adopted the solar photospheric abundance of 4.6 \times 10^{-4} (Asplund et al. 2004) and \( \phi_{\text{B}}(\text{O} \, \text{v}) = 9.5 \times 10^{-12} \, \text{cm} \, \text{s}^{-1} \) for \( T_e = 30000 \, \text{K} \) (Gurzadyan 1997). According to Sokoloski et al. (2005), the temperature of the ionizing source \( T^{\text{i}}_{\ell} = 95000 \, \text{K} \) and 160000 \( \text{K} \) during the optical maximum and the 2003 post-outburst stage, which implies \( L_{\text{ph}}(\text{O} \, \text{v}) = 6.4 \times 10^{43} \) and 2.6 \times 10^{45} photons \, \text{s}^{-1} \) for luminosities of 7000 and 4400 \( L_\odot \), respectively (Fig. B.1, Table 2). Finally, for the particle concentration of the order of 10^{12} \, \text{cm}^{-3} \), which can be expected in a close vicinity of the ionizing source due to the mass loss via the stellar wind at rates of a few \( \times 10^{-7} \, M_\odot \, \text{yr}^{-1} \) (Skopal et al. 2006), one can derive

\[ R(\text{O} \, \text{v}) \simeq a \times R_\odot \]  

during the optical maximum. In a more rigorous approach we integrate densities of the hot star wind from a radius \( r_1 \) above its origin, \( R_a \), to the end of the O \( \text{v} \) zone (i.e. the \( R(\text{O} \, \text{v}) \) radius). Then Eq. (B.1) takes the form

\[
L_{\text{ph}}(\text{O} \, \text{v}) = 4\pi \alpha_{\text{B}}(\text{O} \, \text{v}) A(\text{O} \, \text{v}) \int_{r_1}^{R(\text{O} \, \text{v})} N(r)^2 \, r^2 \, dr,
\]

where \( N(r) = \dot{M}/4\pi r^2 \mu m_{\text{H}} v(r) \) is determined via the continuous mass loss rate \( \dot{M} \) from the hot star with the velocity field \( v(r) = v_{\infty}(1 - R_a/r)^{\beta} \) (Castor et al. 1975). This allows to express the last equation as

\[
L_{\text{ph}}(\text{O} \, \text{v}) = \frac{\alpha_{\text{B}}(\text{O} \, \text{v}) A(\text{O} \, \text{v})}{4\pi (\mu m_{\text{H}})^2} \left( \frac{\dot{M}}{v_{\infty}} \right)^2 \frac{1}{R_a} \times I,
\]
of the increase in 2001 July (Table 3), which thus can be understood as a result of the increase in the O\textsc{vi} zone as a function of $L_{ph}(O\textsc{vi})$ photons for particle distribution in a form of the stellar wind from the ionizing source (Eq. B.4). Horizontal bars indicate quantities from the optical maximum (2000 December) and the 2003 post-outburst stage.

where the integral

$$ I = \frac{1}{(2\beta - 1)} \left( 1 - \frac{R_w}{r_1} \right)^{1-2\beta} - \left( 1 - \frac{R_w}{R(O\textsc{vi})} \right)^{1-2\beta}. \tag{B.5} $$

Solution of Eq. (B.4) is shown in Fig. B.2 for three different $M$. Parameters $\beta = 1.7$, $v_o = 2000\text{ km s}^{-1}$, $R_w = 1.7 R_\odot$ and $r_1 \sim 1.4 R_w$ were estimated from the modeling the broad H$\alpha$ wings during the maximum. Also in this case the $R(O\textsc{vi})$ radius can be small, $< 3 R_\odot$, for mass-loss rates between $1 \times 10^{-6}$ and $5 \times 10^{-7} M_\odot$ yr$^{-1}$ and the observed flux of ionizing photons $L_{ph}(O\textsc{vi}) = 6.4 \times 10^{43}$ s$^{-1}$. However, for $L_{ph}(O\textsc{vi}) \gtrsim 10^{44} - 10^{45}$ s$^{-1}$ the O\textsc{vi} zone can expand to infinity. This is in a qualitative agreement with the observed significant and fast increase in the O\textsc{vi}$\lambda1032$, 1038 fluxes from the optical maximum (2000 December) to the next FUSE observation in 2001 July (Table 3), which thus can be understood as a result of the increase in $T_{9,5}$ to 120,000–150,000 K at approximately constant luminosity [Sokoloski et al. 2005].
