Arbitrary-rate relaxation techniques for the numerical modeling of compressible two-phase flows with heat and mass transfer

Marica Pelanti

Abstract

We describe compressible two-phase flows by a single-velocity six-equation flow model, which is composed of the phasic mass and total energy equations, one volume fraction equation, and the mixture momentum equation. The model contains relaxation source terms accounting for volume, heat and mass transfer. The equations are numerically solved via a fractional step algorithm, where we alternate between the solution of the homogeneous hyperbolic portion of the system via a HLLC-type wave propagation scheme, and the solution of a sequence of three systems of ordinary differential equations for the relaxation source terms driving the flow toward mechanical, thermal and chemical equilibrium. In the literature often numerical relaxation procedures are based on simplifying assumptions, namely simple equations of state, such as the stiffened gas one, and instantaneous relaxation processes. These simplifications of the flow physics might be inadequate for the description of the thermodynamical processes involved in various flow problems. In the present work we introduce new numerical relaxation techniques with two significant properties: the capability to describe heat and mass transfer processes of arbitrary relaxation time, and the applicability to a general equation of state. We show the effectiveness of the proposed methods by presenting several numerical experiments.

Key words: Multiphase compressible flows, relaxation processes, liquid-vapor phase transition, finite volume schemes, Riemann solvers.

1. Introduction

The modeling of multifluid and multiphase flows has applications in numerous fields of science, largely in many sectors of engineering such as aerospace, naval and nuclear technologies. In the present work we are interested in the simulation of compressible multiphase flows that might involve shocks, interfaces, and phase transition processes. Examples of flows of interest are those occurring in underwater explosions [13], nuclear power plants, and fuel injection systems. We describe these flows by a hyperbolic single-velocity six-equation compressible two-phase flow model that we have first studied in [53], and which is a variant of...
the six-equation model presented in [63]. We employ a diffuse-interface approach, cf. [61]. The model system is composed of the phasic mass and total energy equations for the two phases, one volume fraction equation, and the mixture momentum equation. The model contains mechanical, thermal and chemical relaxation source terms, accounting respectively for volume, heat and mass transfer. The considered model belongs to the class of Baer–Nunziato-type [4] multiphase compressible flow models. The seven-equation two-phase flow model of Baer–Nunziato [4] (and the variant of Saurel–Abgrall [57]) is the most general model able to account for velocity, pressure, temperature and chemical potential disequilibria between the phases. From this full non-equilibrium seven-equation model endowed with relaxation source terms a hierarchy of relaxed models can be established by considering combinations of infinite-rate relaxation processes driving the flow to different levels of equilibrium [41]. The six-equation model considered in the present work represents the relaxed velocity equilibrium model obtained from the seven-equation Baer–Nunziato model in the limit of instantaneous kinetic equilibrium.

From the six-equation single-velocity model a sub-hierarchy of relaxed models can be then obtained [22, 43]. In the limit of instantaneous mechanical relaxation we obtain the five-equation pressure equilibrium model of Kapila et al. [29]. In the limit of instantaneous mechanical and thermal relaxation we obtain a four-equation pressure and temperature equilibrium two-phase model [44, 31, 58, 11, 19], and in the limit of full instantaneous thermodynamic equilibrium we obtain the three-equation Homogeneous Equilibrium Model (HEM) [69]. Let us note that the numerical solution method for the six-equation model must be able to approximate solutions of the relaxed models in the hierarchy when appropriate instantaneous relaxation processes are activated. We also recall a different four-equation two-phase flow model of the Baer–Nunziato class, the liquid-vapor Homogeneous Relaxation Model (HRM) with mass transfer of [7, 20], which does not enter in the aforementioned hierarchy. The thermodynamic closure of this model consists in the assumption of mechanical equilibrium and vapor phase at saturation, and the model accounts for thermal disequilibrium.

The considered class of models with relaxation source terms in the literature is classically solved numerically via a fractional step algorithm where one alternates between the solution of the homogeneous hyperbolic portion of the model system and the solution of a sequence of systems of ordinary differential equations for the relaxation source terms [57, 60, 63, 62, 70, 75, 44, 53, 14, 33, 56, 51, 37, 31, 58, 11, 9, 64, 65, 23]. We also adopt here this operator splitting approach for the numerical approximation of the six-equation model, and for the solution of the homogeneous system we employ a second-order accurate finite volume wave propagation scheme [40, 39] based on the HLLC-type Riemann solver that we have presented in [53] (and which later we have also re-interpreted as a Suliciu-type Riemann solver [42]).

For the numerical approximation of the mechanical, thermal and chemical relaxation processes often in the literature it is assumed that these processes are instantaneous [63, 62, 75, 33, 56, 31, 58, 11, 14, 65], and this assumption was also made in our previous six-equation numerical model [53, 51]. This simplifying hypothesis is advantageous because in this case one does not need to solve the system of ordinary equations that govern the relaxation process, but it suffices to impose equilibrium conditions to obtain a system of algebraic equations to be solved for the unknown relaxed equilibrium state. The assumption of instantaneous mechanical equilibrium can be indeed considered appropriate for the flows of interest (see also for instance the discussion on characteristic relaxation scales in [29]). On the other hand, the hypothesis of instantaneous thermo-chemical relaxation might be inadequate for the description of the thermodynamical processes involved in several flow problems. For instance, in some transient phenomena such as fast depressurizations the delay of vaporization and the appearance of
metastable states are key features in the flow evolution, and they can be described only by models that account for non-instantaneous mass transfer, such as those in [20, 21, 44, 16]. Another simplification often considered in the literature is the choice of a simple equation of state, the stiffened gas equation of state [63, 62, 75, 56, 31, 14, 9, 64, 65], which results from a linearization of the more general Mie–Grüneisen pressure law [46]. The stiffened gas equation of state is very convenient for numerical purposes, however it might not allow an accurate flow characterization over a wide temperature range, and in particular for liquid-vapor flows it might not provide a precise estimation of the saturation conditions [32]. Some more recent multiphase numerical models for liquid-vapor flows adopt a slightly more accurate equation of state, the Noble–Abel stiffened gas equation of state [34, 58, 11, 23], and few models adopt complex and very precise equations of state such as the IAPWS Industrial Formulation 1997 for Water and Steam [73], which we have used in previous work [16, 17, 18].

One main objective of the present work is to develop new relaxation techniques for heat and mass transfer capable to model processes of any relaxation rate, both instantaneous infinite-rate processes and slow finite-rate ones. We are primarily interested in arbitrary-rate mass transfer and the capability to model metastable states in vapor-liquid flows with phase transition. Another objective is the design of relaxation techniques efficiently applicable to a general equation of state. A known difficulty encountered in the numerical solution of a system of ordinary equations with a relaxation source term is the stiffness of the problem in case of nearly instantaneous relaxation, which would require computationally expensive implicit time integration techniques. Our idea consists in describing the relaxation processes by systems of ordinary equations obtained from the governing two-phase equations that admit analytical semi-exact exponential solutions. Similar approaches using exponential solutions to solve stiff relaxation systems were used for instance in [20, 26, 52, 3, 16, 17]. Let us remark some differences with respect to our previous work [17, 18] on relaxation techniques for non-instantaneous heat and mass transfers and general equation of state. The principal thermal and chemical relaxation procedures proposed in [17, 18] were based on relaxation systems derived from physical principles solved numerically via explicit Runge–Kutta methods with adaptive step size. These explicit methods were not suited for stiff problems, and the employment of implicit solvers was found too computationally expensive, thus the procedures were not adequate for stiff instantaneous or nearly instantaneous processes. To solve problems with infinite-rate transfers alternative techniques based on exponential solutions were briefly proposed in the Appendix of [17]. Nonetheless these techniques were specifically aimed at the limit case of infinitely fast relaxation and built differently with respect to the procedures of the present work. In particular it was assumed a priori an exponential decay of the pressure, temperature and chemical potential differences, whereas in the present work the relaxations systems with exponential solution are obtained from the equations of the two-phase parent and relaxed models after assuming some quantities constant during the relaxation process.

The relaxation procedures developed here results to be simple, robust and effective, and by construction they can be also used for other two-phase models belonging to the hierarchy established from the Baer–Nunziato model. Moreover, the techniques guarantee consistency of the values of the relaxed states with the mixture pressure law, so that the numerical method is mixture-energy-consistency in the sense defined in [53].

This article is structured as follows. In Section 2 we present the six-equation two-phase flow model under study. In Section 3 we recall the hierarchy of relaxed models established from the parent six-equation model. Examples of equations of state to close the model systems used in the numerical experiments are reported in Section 4. In Section 5 we outline the fractional step
method employed to solve the two-phase equations. In Section 5 we illustrate the HLLC-type scheme used for the solution of the homogeneous system, and we detail then in Section 7 the new relaxation techniques to treat the phase transfer source terms. Numerical experiments are finally presented in Section 8 including tests with shocks, interfaces, evaporation waves and metastable states.

2. Single-velocity six-equation two-phase compressible flow model

We consider a compressible flow composed of two phases that we assume in kinetic equilibrium with velocity \( \vec{u} \). The volume fraction, density, pressure, specific internal energy of each phase will be denoted by \( a_k, \rho_k, \rho_k \), \( k = 1,2 \), respectively. We will denote the phasic internal energy per unit volume with \( \mathcal{E}_k = \rho_k \mathcal{E}_k \), and the phasic total energy per unit volume with \( E_k = \mathcal{E}_k + \rho_k \mathcal{E}_T^k \). The saturation condition is \( a_1 + a_2 = 1 \). The mixture density is \( \rho = \sum_{k=1}^{2} a_k \rho_k \), the mixture internal energy per unit volume \( E = \sum_{k=1}^{2} a_k \mathcal{E}_k \), and the mixture total energy \( E = \sum_{k=1}^{2} a_k E_k \). The nomenclature of the variables is summarized in Table 1. We describe the two-phase flow by the following system consisting of \( 5 + d \) equations, where \( d \) denotes the spatial dimension:

\[
\begin{align*}
\partial_t a_1 + \vec{u} \cdot \nabla a_1 &= \mathcal{P}, \\
\partial_t (a_1 \rho_1) + \nabla \cdot (a_1 \rho_1 \vec{u}) &= M, \\
\partial_t (a_2 \rho_2) + \nabla \cdot (a_2 \rho_2 \vec{u}) &= -M, \\
\partial_t (\rho \vec{u}) + \nabla \cdot (\rho \vec{u} \otimes \vec{u} + (a_1 \rho_1 + a_2 \rho_2) \vec{u}) &= 0, \\
\partial_t (a_1 E_1) + \nabla \cdot (a_1 (E_1 + p_1) \vec{u}) + \Sigma &= -p_1 \mathcal{P} + Q + \left( g_1 + \frac{\alpha_1}{2} \right) M, \\
\partial_t (a_2 E_2) + \nabla \cdot (a_2 (E_2 + p_2) \vec{u}) - \Sigma &= p_1 \mathcal{P} - Q - \left( g_1 + \frac{\alpha_1}{2} \right) M,
\end{align*}
\]  

(1a) (1b) (1c) (1d) (1e) (1f)

where the non-conservative term \( \Sigma \) appearing in the phasic total energy equations is given by

\[
\Sigma = -\vec{u} \cdot \vec{\Xi}, \quad \vec{\Xi} = Y_2 \nabla (a_1 \rho_1) - Y_1 \nabla (a_2 \rho_2).
\]  

(1g)

Here \( Y_k = \frac{a_k \rho_k}{\rho} \) is the mass fraction of phase \( k \). Above we have denoted with \( \mathcal{P}, Q \) and \( M \) the volume, heat and mass transfer terms between the two phases. These transfer terms are expressed as relaxation terms:

\[
\mathcal{P} = \mu (p_1 - p_2), \quad Q = \theta (T_2 - T_1), \quad M = \nu (g_2 - g_1),
\]  

(2)

where \( T_1 \) denotes the phasic temperature, and \( g_k \) the phasic chemical potential. \( \mu, \theta, \) and \( \nu \) are parameters or more generally functions expressing the rate of mechanical, thermal and chemical relaxation, respectively. Here we are interested in modeling flows in mechanical equilibrium, hence we will always consider that mechanical relaxation is an instantaneous process, thus we assume \( \mu \to +\infty \). Indeed, following the same idea of [62,63,53], the parent non-equilibrium two-phase flow model with instantaneous pressure relaxation [1] is used to approximate solutions to the limiting pressure-equilibrium flow model (see model (11) in section 3.1), which is the physical flow model of interest. Concerning thermal and chemical relaxation, in contrast to [62,53], no specific assumption is made for the heat and mass transfer rate, and hence for \( \theta \) and \( \nu \). The quantity \( p_1 \) is an interface pressure and \( g_1 \) is an interface chemical potential. The definition
of the relaxation parameters or functions and of the interface quantities needs to be consistent with the second law on thermodynamics, namely the entropy production for the mixture must be positive. Sufficient conditions are (see proof in [22]):

\[ \mu \geq 0, \quad \theta \geq 0, \quad \nu \geq 0, \]

and

\[ p_1 \in [\min(p_1, p_2), \max(p_1, p_2)], \quad g_1 \in [\min(g_1, g_2), \max(g_1, g_2)]. \]

Hence, it suffices to define the interface quantities \( p_1 \) and \( g_1 \) as convex combinations of the respective phasic quantities. Concerning \( p_1 \), for our numerical tests we have used the definition proposed in [59, 63], which we already used in [53]:

\[ p_1 = \frac{\sum_k p_k^\alpha Y_k}{\sum_k Y_k}, \]

where \( Z = p_k c_k \) is the acoustic impedance of phase \( k \). Other definitions are possible, for instance the one suggested in [57], \( p_1 = \alpha_1 p_1 + \alpha_2 p_2 \). Concerning \( g_1 \), we will see that we do not need to define it in our numerical scheme. To close the model system an equation of state for each phase must be provided, for instance through the specification of the pressure relations \( p_k(E_k, \rho_k) \) and the temperature relations \( T_k(p_k, \rho_k) \). If thermo-chemical transfer terms are not considered, then the specification of the pressure laws \( p_k(E_k, \rho_k) \) (incomplete equation of state) suffices to solve the model system.

The two-phase model above is hyperbolic and the eigenvalues associated to the direction \( \vec{n} \) are given by \( \lambda_{1,5+6} = \vec{u} \cdot \vec{n} \mp c_1, \quad \lambda_l = \vec{u} \cdot \vec{n} + \vec{u} \cdot \vec{d}_l, \quad \text{for } l = 2, \ldots, 4 + d \) (eigenvalue of multiplicity \( 3 + d \)).

Here \( c_1 \) is the non-equilibrium (frozen) speed of sound, defined by

\[ c_1^2 = \left( \frac{\partial p_m}{\partial \rho_{\alpha,1,1}} \right)_{Y_1, \alpha,1,1,2}, \]

where \( s_k \) denotes the entropy of phase \( k \), and where we have introduced the mixture pressure \( p_m(\rho, s_1, s_2, Y_1, \alpha_1) = \sum_{k=1}^2 \alpha_k p_k \left( s_k, \rho \frac{Z_k}{\rho_k} \right) \). From this we obtain:

\[ c_1 = \sqrt{Y_1 c_1^2 + Y_2 c_2^2}. \]

Here \( c_k \) is the speed of sound of phase \( k \), defined by \( c_k^2 = \left( \frac{\partial p_k}{\partial \rho_k} \right)_{\rho_k} \), which can be expressed as:

\[ c_k = \sqrt{\Gamma_k h_k + \chi_k}, \]

where \( h_k = (E_k + p_k)/\rho_k \) is the specific enthalpy of phase \( k \), and

\[ \Gamma_k = \left( \frac{\partial p_k}{\partial E_k} \right)_{\rho_k}, \quad \chi_k = \left( \frac{\partial p_k}{\partial \rho_k} \right)_{\rho_k}. \]

Note that the sum of the phasic total energy equations recovers a conservation law for the mixture total energy \( E = \sum_{k=1}^2 \alpha_k E_k \):

\[ \partial_t E + \nabla \cdot (E \vec{u} + (\alpha_1 p_1 + \alpha_2 p_2) \vec{d}) = 0. \]

For later use, let us also write here the equations for the phasic pressures:

\[ \partial_t p_k + \vec{u} \cdot \nabla p_k + \rho_k c_k^2 \vec{u} \cdot \vec{n} = \frac{\epsilon_k}{\omega_k} \left\{ p_k - \rho_k^2 \left( \frac{\partial u_k}{\partial \rho_k} \right)_{p_k} \right\} \mathcal{P} + Q + g_1 M \left( -1 \right)^{k-1}, \quad k = 1, 2. \]
\( \rho_k \) = phasic density \\
\( \alpha_k \) = volume fraction of phase \( k \) (\( \alpha_1 + \alpha_2 = 1 \)) \\
\( \vec{u} \) = velocity vector \\
\( \kappa_k \) = phasic specific internal energy \\
\( E_k = \rho_k \kappa_k \) = phasic internal energy per unit volume \\
\( E_i = E_k + \frac{\rho_k \vec{u}^2}{2} \) = phasic total energy per unit volume \\
\( p_k \) = phasic pressure \\
\( p_m = \alpha_1 p_1 + \alpha_2 p_2 \) \\
\( p \) = mixture equilibrium pressure \\
\( \rho \) = mixture density \\
\( Y_k = \alpha_k / \rho_k \) = mass fraction of phase \( k \) (\( Y_1 + Y_2 = 1 \)) \\
\( \kappa = \frac{\kappa_v}{\rho} \) = specific heat capacity at constant volume \\
\( C_{pk} = \alpha_k \kappa_k \) = phasic extensive heat capacity at constant pressure \\
\( 1 \leq p_{ik} \leq p_{max} \) \\
\( \Gamma_k = \left( \frac{\partial p}{\partial \rho} \right)_{T_k} \) = Grüneisen coefficient of phase \( k \) \\
\( \chi_k = \left( \frac{\partial p}{\partial T} \right)_{\kappa_k} \) \\
\( \phi_k = \left( \frac{\partial \beta_k}{\partial T_k} \right)_{p_k} \) = phasic coefficient of thermal expansion \\
\( \xi_k = \left( \frac{\partial T_k}{\partial p} \right)_{\kappa_k} \) = phasic isothermal compressibility \\
\( \mathcal{K}_{Sk} = \frac{1}{p_{ik}} \) = phasic isentropic compressibility \\
\( \kappa_{pk} = T_k \left( \frac{\partial \kappa_k}{\partial T_k} \right)_{p_k} \) = specific heat capacity at constant pressure \\
\( \kappa_{vk} = T_k \left( \frac{\partial \kappa_v}{\partial T_k} \right)_{p_k} \) = specific heat capacity at constant volume

Table 1: Nomenclature of variables.
3. Hierarchy of single-velocity relaxed two-phase flow models

From the parent six-equation non-equilibrium model \( \text{(1)} \) presented in the previous section we can establish a hierarchy of hyperbolic relaxed single-phase two-phase flow models by considering the limit of combinations of instantaneous relaxation processes, see \([22, 43]\). The \( p \)-relaxed and \( pT \)-relaxed model equations recalled below will be used in the construction of the relaxation procedures in Section 7.2.

3.1. Five-equation \( p \)-relaxed two-phase flow model

We assume that the flow is driven instantaneously to mechanical equilibrium, \( p_1 = p_2 = p \), hence we consider \( \mu \to +\infty \). The \( p \)-relaxed (pressure equilibrium) model, corresponding to the well known Kapila et al. model \([29]\) (see also \([47]\)), consists of 4 + 2 equations:

\[
\begin{align*}
\partial_t (\alpha_1 \vec{u}) + \nabla \cdot (\alpha_1 \vec{a}_1) = & \quad \frac{1}{\rho_1} \left( \alpha_2 \Gamma_1 + \alpha_1 \Gamma_2 \right) \vec{Q} + \frac{1}{\rho_1} \left( \alpha_2 c_{l_1}^2 + \alpha_1 c_{l_2}^2 \right) \vec{M}, \\
\partial_t (\alpha_2 \rho_2) + \nabla \cdot (\alpha_2 \rho_2 \vec{u}) = & \quad -\vec{M}, \\
\partial_t (\rho_2 \vec{u}) + \nabla \cdot (\rho_2 \vec{u} \otimes \vec{u} + p \vec{I}) = & \quad 0, \\
\partial_t \vec{E} + \nabla \cdot ((\rho_1 \vec{E} + p) \vec{u}) = & \quad 0,
\end{align*}
\]

where

\[
D = \alpha_1 p_2 c_{l_1}^2 + \alpha_2 \rho_1 c_{l_1}^2 \tag{12}
\]

and

\[
c_{l_{ik}}^2 = \Gamma_k (g_k - h_k) + c_{l_k}^2 = \Gamma_k g_k + \chi_k, \quad k = 1, 2. \tag{13}
\]

The derivation of the above \( p \)-relaxed system from the parent system \( \text{(1)} \) is detailed in Appendix A and it has been also illustrated in our work \([54]\) for a more general \( N \)-phase model. Given the phasic energy laws \( E_k(\rho_k, p_k) \), the mixture pressure law \( p = p(\rho_1, \rho_2, a_1) \) for this model is determined by the mixture energy relation

\[
E = \alpha_1 E_1(p, \rho_1) + \alpha_2 E_2(p, \rho_2), \tag{14}
\]

where we have used the isobaric condition \( p_1 = p_2 = p \). The speed of sound associated to the model is defined by

\[
c_{p}^2 = \left( \frac{\partial \rho}{\partial p} \right)_{\rho_1, \rho_2, k=1,2},
\]

which gives the well known Wood’s speed of sound

\[
c_p = \left( \rho \sum_{k=1}^{2} \frac{\alpha_k}{\rho_k c_{l_k}^2} \right)^{-\frac{1}{2}}. \tag{15}
\]

Note that the term \( D \) \( \text{(12)} \) can be written in terms of \( c_p, \frac{1}{\rho} = \frac{p^2_{l_1}}{\rho_1 c_{l_1}^2} \). The pressure equation is:

\[
\begin{align*}
\partial_t p + \vec{u} \cdot \nabla p + p c_p^2 \Delta \cdot \vec{u} = & \quad \frac{1}{\rho} \left( \Gamma_1 p_2 c_{l_1}^2 - \Gamma_2 p_1 c_{l_1}^2 \right) \vec{Q} + \left( \rho_2 c_{l_1}^2 + \rho_1 c_{l_2}^2 \right) \vec{M}.
\end{align*}
\]

\[
\tag{17}
\]
Let us now write the equations for the phasic temperatures $T_k$, $k = 1, 2$, which we will use in the following:

$$
\partial_t T_k + \vec{u} \cdot \nabla T_k + \frac{\rho c_p^2}{\phi_k} \left( -\zeta_k + \frac{1}{c_k^2} \right) \nabla \cdot \vec{u}
$$

$$
= \frac{1}{\phi_k D} \left[ (-1)^k \frac{\rho_k^1}{\phi_k} (\alpha_2 \Gamma_1 + \alpha_1 \Gamma_2) - \zeta_k (T_k \rho_2 c_2^2 - T_2 \rho_1 c_1^2) \right] Q
$$

$$
+ \frac{1}{\phi_k} \left\{ \left( \frac{(-1)^{k-1}}{\alpha_k} + \frac{1}{D} \right) \left[ (-1)^k \frac{\rho_k^1}{\phi_k} (\alpha_2 c_2^2 \xi_{11} + \alpha_1 c_1^2 \xi_{22}) - \zeta_k (\rho_2 c_2^2 c_2^1 \xi_{11} - \rho_1 c_1^2 c_1^2) \right] \right\} M,
$$

where we have introduced the derivatives

$$
\phi_k = \frac{\partial (\rho_k^1)}{\partial T_k} \bigg|_{p_0} = -\rho_k^1 \beta_k \quad \text{and} \quad \zeta_k = \left( \frac{\partial \rho_k^1}{\partial p_k} \right)_{T_k} = \rho_k^1 \mathcal{K}_{Tk},
$$

where $\beta_k$ denotes the coefficient of thermal expansion and $\mathcal{K}_{Tk}$ the isothermal compressibility. Note also that we have the relations:

$$
\beta_k = \frac{\Gamma_k \kappa_{pk}}{c_k^2} = \frac{\Gamma_k C_{pk}}{\rho_k \kappa_{pk}} \quad \text{and} \quad \mathcal{K}_{Tk} = \mathcal{K}_{S_k} + \frac{\beta_k^2 T_k}{\rho_k \kappa_{pk}} = \frac{1}{\rho_k c_k^4} + \frac{\beta_k^2 T_k \alpha_k}{C_{pk}},
$$

where $\mathcal{K}_{S_k} = \frac{1}{\rho_k c_k^4}$ is the isentropic compressibility, and where $C_{pk} = \alpha_k \rho_k \kappa_{pk}$ and $\kappa_{pk} = \frac{\partial \rho_k}{\partial p_k} \bigg|_{T_k} = T_k \frac{\partial \rho_k}{\partial p_k} \bigg|_{p_0}$.

**Remark.** In our previous work \cite{53} an additional source term of the form $M/\rho_1$ was written in the equation for the volume fraction $\alpha_1$ of the above six-equation two-phase model \cite{1}, with $\rho_1$ representing an interface density. Similar to \cite{22}, this term is not included in the present model. The purpose of the term $M/\rho_1$ in \cite{53} was to indicate the influence of the mass transfer process on the evolution of the volume fraction. Nonetheless, the rigorous derivation of the pressure-relaxed model \cite{11} from the system \cite{1} (see Appendix \cite{A}) reveals that indeed mass transfer terms affect $\alpha_1$ via the pressure relaxation process, as we observe from the contribution of $M$ appearing in \cite{11a}. Note that the presence of the term $M/\rho_1$ eventually does not affect the numerical model and the numerical results presented in \cite{53} since there $\nu = 0$ or $\nu \to +\infty$, and the procedure for treating instantaneous chemical relaxation consists in imposing directly algebraic thermodynamic equilibrium conditions.

### 3.2. Four-equation $pT$-relaxed two-phase flow model

We now assume that the flow is driven instantaneously to both mechanical and thermal equilibrium, $p_1 = p_2 = p$, $T_1 = T_2 = T$. Hence we consider the limit $\mu \to +\infty$ and $\theta \to +\infty$. We obtain the following reduced model composed of 3 + $d$ equations (used for instance in \cite{44,51,58,11,19}):

$$
\partial_t (\alpha_1 \rho_1) + \nabla \cdot (\alpha_1 \rho_1 \vec{u}) = M,
$$

$$
\partial_t (\alpha_2 \rho_2) + \nabla \cdot (\alpha_2 \rho_2 \vec{u}) = -M,
$$

$$
\partial_t (\rho_0 \vec{u}) + \nabla \cdot (\rho_0 \vec{u} \otimes \vec{u} + p \vec{I}) = 0,
$$

$$
\partial_t E + \nabla \cdot ((E + p) \vec{u}) = 0.
$$
The mixture pressure law \( p = p(E, \rho_1, \rho_2) \) is determined by the energy relation (14), together with the isothermal condition \( T_1(p, \rho_1) = T_2(p, \rho_2) \). The speed of sound for this model is defined by

\[
c^2_{pr} = \left\{\frac{\partial p}{\partial \rho}\right\}_{s=1, s_2},
\]

where \( s \) is the mixture specific entropy \( s = Y_1 s_1 + Y_2 s_2 \). This gives

\[
\frac{1}{c^2_{pr}} = \frac{1}{c^2_p} + \frac{\rho T C_p}{C_p + C_p \left( \frac{\Gamma_2}{\rho_2 c^2_p} - \frac{\Gamma_1}{\rho_1 c^2_p} \right)^2} + \frac{\Gamma_1}{\rho_1 c^2_p} \left( \frac{T}{\rho_1 c^2_p} + \frac{T}{\rho_2 c^2_p} \right) \frac{\partial \rho}{\partial T},
\]

where we recall \( C_{ph} = \alpha_s \rho_2 \delta p_{ph} \) (extensive heat capacities). Let us finally write also the equations for the volume fraction \( \alpha_1 \), the temperature \( T \) and the pressure \( p \):

\[
\begin{align*}
\partial_t \alpha_1 + \bar{u} \cdot \nabla \alpha_1 + \rho \rho c^2_{pr} \left[ \alpha_1 \alpha_2 \left( \frac{1}{\rho_2 c^2_p} - \frac{1}{\rho_1 c^2_p} \right) + \frac{T C_p}{C_p + C_p \left( \frac{\Gamma_2}{\rho_2 c^2_p} - \frac{\Gamma_1}{\rho_1 c^2_p} \right)^2} \right] \nabla \cdot \bar{u} &= \mathcal{M} S_a, \quad (24) \\
\partial_t T + \bar{u} \cdot \nabla T + \rho \rho c^2_{pr} \left( \frac{C_p}{C_p + C_p} \left( \frac{\Gamma_1}{\rho_1 c^2_p} + \frac{\Gamma_2}{\rho_2 c^2_p} \right) \right) \nabla \cdot \bar{u} &= \mathcal{M} S_T, \quad (25) \\
\partial_t p + \bar{u} \cdot \nabla p + \rho \rho c^2_{pr} \nabla \cdot \bar{u} &= \mathcal{M} S_p,
\end{align*}
\]

where

\[
\begin{align*}
S_a &= \frac{1}{D_T} \left[ \frac{\alpha_1}{\Gamma_1} \left( \frac{\alpha_2}{\Gamma_2} \right) (\alpha_1 \phi_1 + \alpha_2 \phi_2) + \alpha_1 \alpha_2 \left( \frac{\chi_1}{\Gamma_1} - \frac{\chi_2}{\Gamma_2} \right) (\phi_1 \phi_2 - \phi_2 \phi_1) \right], \\
S_T &= \frac{1}{D_T} \left[ \frac{\alpha_1}{\Gamma_1} \frac{\chi_1}{\Gamma_1} (\alpha_1 \phi_1 + \alpha_2 \phi_2) + \left( \frac{\rho_1 c^2_p}{\Gamma_1} - \frac{\rho_2 c^2_p}{\Gamma_2} \right) (\alpha_1 \phi_1 + \alpha_2 \phi_2) + \left( \frac{\alpha_1}{\Gamma_1} + \frac{\alpha_2}{\Gamma_2} \right) (\phi_1 \phi_2 - \phi_2 \phi_1) \right], \\
S_p &= \frac{1}{D_T} \left[ \frac{\alpha_1}{\Gamma_1} \frac{\chi_1}{\Gamma_1} (\alpha_1 \phi_1 + \alpha_2 \phi_2) + \left( \frac{\rho_1 c^2_p}{\Gamma_1} - \frac{\rho_2 c^2_p}{\Gamma_2} \right) (\alpha_1 \phi_1 + \alpha_2 \phi_2) \right],
\end{align*}
\]

with

\[
D_T = \alpha_1 \alpha_2 \left( \frac{\rho_1 c^2_p}{\Gamma_1} - \frac{\rho_2 c^2_p}{\Gamma_2} \right) (\phi_1 \phi_2 - \phi_2 \phi_1) + \left( \frac{\alpha_1}{\Gamma_1} + \frac{\alpha_2}{\Gamma_2} \right) (\alpha_1 \phi_1 + \alpha_2 \phi_2). \quad (27d)
\]

The derivation of these expressions of \( S_a, S_T, S_p \) will be illustrated in Appendix.

3.3. Three-equation \( p T g \)-relaxed two-phase flow model

For completeness, we also recall the relaxed model obtained by assuming full thermodynamic equilibrium, \( p_1 = p_2 = p, T_1 = T_2 = T \), and \( g_1 = g_2 \). Hence we consider the limit \( \mu \to +\infty \), \( \delta \to +\infty \), and \( \nu \to +\infty \). We obtain the homogeneous equilibrium model (HEM) composed of 2 + 3 equations (see e.g. [69, 12, 16, 24]):

\[
\begin{align*}
\partial_t p + \nabla \cdot (\rho \bar{u}) &= 0, \quad (28a) \\
(\rho \bar{u}) + \nabla \cdot (\rho \bar{u} \otimes \bar{u} + p \mathbb{I}) &= 0, \quad (28b) \\
\partial_t E + \nabla \cdot ((E + p) \bar{u}) &= 0. \quad (28c)
\end{align*}
\]
The mixture pressure law $p = p(\mathcal{E}, \rho)$ is determined by the energy relation (14), the isothermal condition $T_1(p, \rho_1) = T_2(p, \rho_2)$, and the equilibrium condition $g_1(p, T) = g_2(p, T)$. The speed of sound is defined by:

$$c_{pTg}^2 = \left( \frac{\partial p}{\partial \rho} \right)_s,$$

which gives (see for instance the systematic derivation of the speeds of sound of the various models in the hierarchy in [54])

$$\frac{1}{c_{pTg}} = \frac{1}{c_{pT}} + \frac{\rho T}{C_p + C_v} \left[ \frac{\Gamma_1 C_{p1}}{\rho_1^2 c_1^2} + \frac{\Gamma_2 C_{p2}}{\rho_2^2 c_2^2} - \frac{1}{T} \left( \frac{dT}{dp} \right)_{sat} (C_{p1} + C_{p2}) \right]^2. \quad (30)$$

We remark that subcharacteristic conditions hold for the speeds of sound of the two-phase flow models in the hierarchy [22]:

$$c_{pTg} \leq c_{pT} \leq c_{f} \leq c_t. \quad (31)$$

As expected, the speed of sound is reduced whenever an additional equilibrium assumption is introduced.

4. Equation of State (EOS)

The numerical techniques that we will present in the following sections can be employed for any choice of the equations of state. Nonetheless, for the numerical experiments we will consider two particular equations of state, which can both be written in the form of the Mie–Grüneisen equation of state recalled hereafter.

4.1. Mie–Grüneisen equation of state

The incomplete Mie–Grüneisen equation of state has the form (see e.g. [46]):

$$p(\mathcal{E}, \rho) = \Gamma(\rho)(\mathcal{E} - \rho e_\rho(\rho)) + p_\rho(\rho), \quad (32)$$

where $\Gamma(\rho)$ is the Grüneisen coefficient defined for a general EOS as in [5], and $e_\rho(\rho), p_\rho(\rho)$ are reference specific energy and pressure functions, respectively. An extension of this incomplete EOS to a complete one can be found in [45]. Many equations of state can be written in the form (32), including the JWL and NASG equations of state reported below.

For two-phase flows in mechanical equilibrium where each phase is governed by an equation of state with the form of the Mie–Grüneisen EOS, it is possible to obtain an explicit expression for the mixture pressure law (14):

$$p(\mathcal{E}, \rho_1, \rho_2, \alpha_1) = \frac{\mathcal{E} - (\alpha_1 \rho_1 e_\rho(\rho_1) + \alpha_2 \rho_2 e_\rho(\rho_2)) + \left( a_1 \frac{p_\rho(\rho_1)}{T_1(\rho_1)} + a_2 \frac{p_\rho(\rho_2)}{T_2(\rho_2)} \right)}{\frac{\alpha_1}{T_1(\rho_1)} + \frac{\alpha_2}{T_2(\rho_2)}}. \quad (33)$$

This is an important advantage from the numerical point of view, since solving an implicit equation for the pressure can be computationally expensive.
4.2. Jones–Wilkins–Lee (JWL) Equation of State

The Jones–Wilkins–Lee (JWL) EOS [36] has been extensively used to model gaseous or solid explosives, and it has the form (32) with:

\[ \Gamma(\rho) = \Gamma_0, \quad (34a) \]
\[ \epsilon_r(\rho) = \frac{\alpha}{\rho_0} e^{-r_1 \frac{\rho}{\rho_0}} + \frac{\beta}{\rho_0} e^{-r_2 \frac{\rho}{\rho_0}} - \epsilon_0, \quad (34b) \]
\[ p_r(\rho) = a e^{-r_1 \frac{\rho}{\rho_0}} + b e^{-r_2 \frac{\rho}{\rho_0}}. \quad (34c) \]

4.3. Noble–Abel Stiffened Gas (NASG) Equation of State

The Noble–Abel Stiffened Gas (NASG) Equation of State introduced in [34] combines the stiffened gas EOS [46] and the Noble–Abel EOS. It has the form:

\[ p(E, \rho) = \frac{1}{\gamma - 1} \left( \frac{1 - \rho \kappa}{\rho} + \eta \right) + \eta, \quad (35a) \]
\[ T(p, \rho) = \frac{(1 - \rho b)(p + \sigma)}{\kappa_p(\gamma - 1)}. \quad (35b) \]

Here \( \gamma, \eta, \kappa, \kappa_p \) are material-dependent constant parameters. The coefficient \( b \) represents the covolume of the fluid and the choice \( b = 0 \) gives the classical stiffened gas equation of state. We can observe that the pressure law in (35a) has the form (32) with

\[ \Gamma(\rho) = \frac{\gamma - 1}{1 - \rho b}, \quad \epsilon_r = \eta, \quad p_r = -\gamma \sigma. \quad (36) \]

Let us also write the expression of the specific entropy \( s \), the specific enthalpy \( h \), and the chemical potential (equal for a pure constituent to its specific Gibbs free energy) \( g = h - Ts \):

\[ s(p, T) = \kappa_t \log \frac{T^\gamma}{(p + \sigma)^{\gamma - 1}} + \tilde{\eta}, \quad (37a) \]
\[ h(T, p) = \kappa_p T + \gamma + \eta, \quad (37b) \]
\[ g(p, T) = (\gamma \kappa - \tilde{\eta}) T - \gamma T \log \frac{T^\gamma}{(p + \sigma)^{\gamma - 1}} + \eta + b p. \quad (37c) \]

where \( \kappa_p = \gamma \kappa_t \) (specific heat capacity at constant pressure) and \( \tilde{\eta} \) are constant parameters. Let us note that the speed of sound can be written:

\[ c = \sqrt{\frac{\gamma (p + \sigma)}{\rho(1 - \rho b)}}. \quad (38) \]

Finally, we can write the expressions for the derivatives in (19):

\[ \phi = -\frac{p}{T(1 - \rho b)} \quad \text{and} \quad \xi = \frac{1}{T(\gamma - 1) \kappa_t + b(p + \sigma)(1 - \rho b)}. \quad (39) \]
4.3.1. Saturation curves

For applications to two-phase flows with liquid-vapor transition, given the equation of state for each phase, the theoretical pressure-temperature saturation curve is determined by the equilibrium conditions \( p_1 = p_2 = p, \ T_1 = T_2 = T, \ g_1(p, T) = g_2(p, T) \). Assuming here each phase governed by a NASG EOS, the equilibrium relations give the following equation:

\[
A_s + \frac{B_s}{T} + C_s \log T + D_s \log(p + \sigma_1) - \log(p + \sigma_2) + \frac{p E_s}{T} = 0,
\]

where

\[
A_s = \frac{k_{p_1} - k_{p_2} - \hat{n}_1 + \hat{n}_2}{k_{p_2} - k_{p_2}}, \quad B_s = \frac{\eta_1 - \eta_2}{k_{p_2} - k_{p_2}}, \quad C_s = \frac{k_{p_2} - k_{p_1}}{k_{p_2} - k_{p_2}}, \quad D_s = \frac{k_{p_1} - k_{p_1}}{k_{p_2} - k_{p_2}}, \quad E_s = \frac{b_1 - b_2}{k_{p_2} - k_{p_2}} \tag{41}
\]

The constant parameters in the NASG equations of state of the two phases are determined so that the associated theoretical saturation curves match the experimental saturation curves for the considered material, at least in a certain temperature range, see [34]. The Tables 3-5 reported in Section 8 contain sets of parameters determined in [34] for water, Table 4 contains a slightly modified set of parameters for dodecane taken from [34].

5. Numerical method

We now consider the numerical solution of the six-equation model (1), which we rewrite here in compact vectorial form, denoting with \( q \in \mathbb{R}^{5+e} \) the vector of the unknowns:

\[
\partial_t q + \nabla \cdot f(q) + \sigma(q, \nabla q) = \psi_{\mu}(q) + \psi_{\phi}(q) + \psi_{\nu}(q),
\]

\[
q = \begin{bmatrix}
\alpha_1 \\
\alpha_1 \rho_1 \\
\alpha_2 p_2 \\
\alpha_2 p_2 \\
\alpha_1 E_1 \\
\alpha_2 E_2
\end{bmatrix}
, \quad f(q) = \begin{bmatrix}
0 \\
\alpha_1 \rho_1 \vec{u} \\
\alpha_2 \rho_2 \vec{u} \\
\rho \vec{v} \otimes \vec{u} + (\alpha_1 p_1 + \alpha_2 p_2) \vec{I} \\
\alpha_1 (E_1 + p_1) \vec{u} \\
\alpha_2 (E_2 + p_2) \vec{u}
\end{bmatrix}
, \quad \sigma(q, \nabla q) = \begin{bmatrix}
\vec{u} \cdot \nabla \alpha_1 \\
0 \\
0 \\
0 \\
\Sigma \\
-\Sigma
\end{bmatrix}
, \quad (42a)
\]

\[
\psi_{\mu}(q) = \begin{bmatrix}
p \\
0 \\
0 \\
0 \\
-p_n \vec{P} \\
p \vec{P}
\end{bmatrix}
, \quad \psi_{\phi}(q) = \begin{bmatrix}
0 \\
0 \\
0 \\
0 \\
Q \\
-Q
\end{bmatrix}
, \quad \psi_{\nu}(q) = \begin{bmatrix}
0 \\
M \\
-\bar{M} \\
0 \\
\left(g_1 + \frac{|Q|^2}{2}\right) M \\
-\left(g_1 + \frac{|Q|^2}{2}\right) M
\end{bmatrix}
, \quad (42b)
\]

with \( \Sigma(q, \nabla q) \) defined in [12]. Above we have put into evidence the conservative portion of the spatial derivative contributions in the system as \( \nabla \cdot f(q) \), and we have indicated the non-conservative term as \( \sigma(q, \nabla q) \). The source terms \( \psi_{\mu}(q), \psi_{\phi}(q), \psi_{\nu}(q) \) contain mechanical, thermal and chemical relaxation terms, respectively, as expressed in [2].

To numerically solve this system we use a classical fractional step method, where we alternate between the solution of the homogeneous hyperbolic portion of the system via a wave-propagation finite volume scheme and the solution of a sequence of ordinary differential equations accounting for the relaxation source terms. Denoting with \( \tau_{\mu}, \tau_{\phi}, \tau_{\nu} \) the characteristic
times for mechanical, thermal, and chemical relaxation, respectively, let us note that the underlying assumption here is \( \tau_\mu \ll \tau_\vartheta \ll \tau_\nu \) (cf. for instance [29]). The algorithm consists of the following steps:

1. Solution of the homogeneous hyperbolic system
   \[
   \partial_t q + \nabla \cdot f(q) + \sigma(q, \nabla q) = 0. \tag{43}
   \]
   In the following we will denote with the superscript 0 the quantities computed in this step.

2. Relaxation steps

2(a) Instantaneous mechanical relaxation. We solve in the limit \( \mu \to +\infty \) the system of ODEs
   \[
   \partial_t q = \psi_\mu(q). \tag{44}
   \]
   This step drives instantaneously the flow to pressure equilibrium. We will denote with superscript * the quantities computed in this step.

2(b) Thermal relaxation. We solve
   \[
   \partial_t q = \psi_\mu(q) + \psi_\vartheta(q), \tag{45}
   \]
   with \( \mu \to +\infty \). This step drives the phases towards thermal equilibrium, while maintaining pressure equilibrium. We will denote with superscript ** the quantities computed in this step.

2(c) Chemical relaxation. We solve
   \[
   \partial_t q = \psi_\mu(q) + \psi_\vartheta(q) + \psi_\nu(q), \tag{46}
   \]
   with \( \mu \to +\infty \). This step drives the phases towards full thermodynamical equilibrium, while maintaining pressure equilibrium. We will denote with superscript ⊗ the quantities computed in this step.

Let us first observe that the step 2(a) is always activated since we model flows in mechanical equilibrium. The steps 2(b) and 2(c) might be activated or not depending on the problem of interest, and, moreover, they might be activated only at selected locations, typically at interfaces, identified by \( \min_k \alpha_k > \epsilon \), where \( \epsilon \) is a given tolerance (e.g. \( 10^{-6} \)). If thermal and chemical relaxation are activated unconditionally then the numerical model approximates solutions to the \( pTg \)-relaxed model (28).

5.1. Mixture-energy-consistency

In the design of the fractional step method indicated above it is important to ensure mixture-energy-consistency, in the sense defined in [53]. Let us denote with superscript # the quantities computed in any of the relaxation steps of the above algorithm, # = *, **, ⊗. Let us then denote with \( E^{0C} \) discrete values of the mixture total energy that come from a conservative approximation of the conservation law for \( E \) in (9). We say that the numerical scheme based on the fractional step algorithm above is mixture-energy-consistent if the following two properties are satisfied:

13
(i) Mixture total energy conservation consistency, i.e. conservation at the discrete level of the mixture total energy:

\[ E^0 = E^{0,c}, \]  

where \( E^0 = (\alpha_1 E_1)^0 + (\alpha_2 E_2)^0. \)

(ii) Relaxed pressure consistency, i.e. consistency of the values of the relaxed states with the mixture pressure law for pressure-equilibrium flows \([14]\):

\[ E^0 = \alpha_1^* E_1(p^*, \rho_1^*) + \alpha_2^* E_2(p^*, \rho_2^*), \]  

where \( E^0 = E^0 - \frac{(\alpha_1^* \rho_1^*)^0 - (\rho_2^*)^0}{\rho_2^0}. \)

6. Solution of the homogeneous system

To solve the hyperbolic homogeneous portion of \([42]\) we employ the wave-propagation algorithms of \([40][39]\), which are a class of Godunov-type finite volume methods to approximate hyperbolic systems of partial differential equations. We shall consider here for simplicity the one-dimensional case in the \(x\) direction \((d = 1)\), and we refer the reader to \([40]\) for a comprehensive presentation of these numerical schemes. Hence we consider here the solution of the one-dimensional system \(\partial_t q + \partial_x f(q) + \sigma(q, \partial_x q) = 0, q \in \mathbb{R}^6\) (as obtained by setting \(\vec{a} = u\) and \(\nabla = \partial_x\) in \([42]\)). We assume a grid with cells of uniform size \(\Delta x\), and we denote with \(Q_i^0\) the approximate solution of the system at the \(i\)th cell and at time \(t^n, i \in \mathbb{Z}, n \in \mathbb{N}\). The second-order wave propagation algorithm has the form

\[ Q_i^{n+1} = Q_i^n - \frac{A_T}{\Delta x} (\mathcal{R}^T \mathcal{A} Q_{i-1/2} + \mathcal{R} \mathcal{A} Q_{i+1/2}) - \frac{A_T}{\Delta x} (F_{i+1/2}^h - F_{i-1/2}^h). \]  

(iii) Where \(\mathcal{R}\) \& \(\mathcal{A}\) are the so-called fluctuations arising from Riemann problems at cell interfaces \((i + 1/2)\) between adjacent cells \(i\) and \((i + 1)\), and \(F_{i+1/2}^h\) are correction terms for (formal) second-order accuracy. To define the fluctuations, a Riemann solver (cf. \([25][71][40]\)) must be provided. The solution structure defined by a given solver for a Riemann problem with left and right data \(q_l\) and \(q_r\) can be expressed in general by a set of \(\mathcal{M}\) waves \(\mathcal{W}\) and corresponding speeds \(s^l\), \(\mathcal{M} \geq 3N\). For the HLLC-type solver described below \(\mathcal{M} = 3\). The sum of the waves must be equal to the initial jump in the vector \(q\) of the system variables:

\[ \Delta q \equiv q_r - q_l = \sum_{i=1}^{\mathcal{M}} \mathcal{W}^i. \]  

Moreover, for any variable of the model system governed by a conservative equation the initial jump in the associated flux function must be recovered by the sum of waves multiplied by the corresponding speeds. In the considered model the conserved quantities are \(\alpha_k \rho_k, k = 1, 2, \) and \(\rho u\), therefore in order to guarantee conservation we need:

\[ \Delta f^{(i)} \equiv f^{(i)}(q_r) - f^{(i)}(q_l) = \sum_{i=1}^{\mathcal{M}} s^l_i \mathcal{W}^{(i)} \]  

for \(\xi = 2, 3, 4\), where \(f^{(i)}\) is the \(i\)th component of the flux vector \(f\), and \(\mathcal{W}^{(i)}\) denotes the \(i\)th component of the \(l\)th wave, \(l = 1, \ldots, \mathcal{M}\). It is clear that conservation of the partial
densities ensures conservation of the mixture density \( \rho = \sum_{k=1}^{2} \alpha_k \rho_k \). In addition, we must ensure conservation of the mixture total energy,

\[
Af_E \equiv f_E(q_r) - f_E(q_l) = \sum_{i=1}^{M} s^i(W^h_i) + W^h_{i+1/2},
\]

(52)

where \( f_E = u(E + \sum_{k=1}^{2} \alpha_k \rho_k) \) is the flux function associated to the mixture total energy \( E \). The relation (52) ensures the fulfillment of the property (47), and it is necessary for mixture-energy-consistency (but not sufficient). Once the Riemann solution structure \( \{W^l_i, s^i_i, W^l_{i+1/2}\}_{i=1}^{M} \) arising at each cell edge \( x_{i+1/2} \) is defined through a Riemann solver, the fluctuations \( A^\pm A_{i+1/2} \) and the higher-order (second-order) correction fluxes \( F_{i+1/2}^h \) in (49) are computed as

\[
A^\pm A_{i+1/2} = \sum_{i=1}^{M} (s^i_i + 1/2) W^h_{i+1/2},
\]

(53)

where we have used the notation \( s^+ = \max(s, 0) \), \( s^- = \min(s, 0) \), and

\[
F_{i+1/2}^h = \frac{1}{2} \sum_{i=1}^{M} (s^i_i - s^i_{i+1/2}) \left( 1 - \frac{A t}{dx} \right) W^h_{i+1/2},
\]

(54)

where \( W^h_{i+1/2} \) are a modified version of \( W^l_{i+1/2} \) obtained by applying to \( W^l_{i+1/2} \) a limiter function (cf. [40]).

6.1. A simple HLLC-type solver

In the wave propagation scheme (49) we use a simple HLLC-type Riemann solver, which we first presented in [53]. Here we give more details on the derivation since the illustration of the derivation in [53] contained some imprecision (although the final formulas were correct).

The Riemann solution structure of the solver is similar to the classical HLLC solver for the Euler equations [72, 71], and it consists of three waves \( W^l_i \), \( i = 1, 2, 3 \), moving at speeds

\[
s^1 = S_l, \quad s^2 = S^*, \quad \text{and} \quad s^3 = S_r,
\]

(55)

Figure 1: Solution structure of the HLLC-type solver.
which separate four constant states $q_\ell$, $q^{*\ell}$, $q^{*r}$ and $q_r$ (see Figure [1]). In the following we will indicate with $()_\ell$ and $()_r$ quantities corresponding to the states $q_\ell$ and $q_r$, respectively. Moreover, we will indicate with $()^{*\ell}$ and $()^{*r}$ quantities corresponding to the states $q^{*\ell}$ and $q^{*r}$ adjacent, respectively on the left and on the right, to the middle wave propagating at speed $S^*$. With this notation, the waves of the HLLC solver are

$$
W^1 = q^{*\ell} - q_\ell, \quad W^2 = q^{*r} - q^{*\ell}, \quad \text{and} \quad W^3 = q_r - q^{*r}.
$$

(56)

Invariance conditions for the normal velocity $u$ and for the effective pressure $p_m = \alpha_1 p_1 + \alpha_2 p_2$, which characterize the exact Riemann solution, are imposed across the middle wave:

$$
 u^{*\ell} = u^{*r} \equiv S^* \quad \text{and} \quad p^{*\ell}_m = p^{*r}_m \equiv p^*. 
$$

(57)

Let us stress however that the single terms $\alpha_k p_k$ in general vary across this middle wave. The middle states $q^{*\ell}$, $q^{*r}$ are determined by imposing Rankine–Hugoniot conditions across the external waves moving at speeds $S_\ell$ and $S_r$, based on the equations for the partial densities $\alpha_k p_k$ and the conservative portion of the equations governing the phasic momenta $\alpha_k p_k u$ and the phasic total energies $\alpha_k p_k E_k$, $k = 1, 2$. Note that the homogeneous equations governing the phasic momenta $q_{k\ell}^\alpha = \alpha_k p_k u$, $k = 1, 2$, have the non-conservative form (here in one dimension):

$$
\partial_t q_{k\ell}^\alpha + \partial_x f_{k\ell}^\alpha + (-1)^{j-1} \Xi(q, \partial_x q) = 0, \quad k = 1, 2, 
$$

(58)

where $f_{k\ell}^\alpha = \alpha_k p_k u^2 + \alpha_k p_k$ and $\Xi(q, \partial_x q) = Y_1 \partial_x (\alpha_2 p_2) - Y_2 \partial_x (\alpha_1 p_1) = Y_1 \partial_x p_m - \partial_x (\alpha_1 p_1) = -Y_2 \partial_x p_m + \partial_x (\alpha_2 p_2)$, as defined in (13). Hence we impose:

$$
\begin{align*}
&f_{k\ell}^{(\ell)}(q_\ell) - f_{k\ell}^{(r)}(q^{*r}) = S_\ell (q_{k\ell}^{(\ell)} - q^{*r(\ell)}), \quad \xi = 2, 3, 5, 6, &(59a) \\
&f_{k\ell}^{(r)}(q_r) - f_{k\ell}^{(\ell)}(q^{*\ell}) = S_r (q_{k\ell}^{(r)} - q^{*\ell(\ell)}), \quad \xi = 2, 3, 5, 6, &(59b) \\
&f_{k\ell}^{(\ell)}(q^{*\ell}) - f_{k\ell}^{(r)}(q_\ell) = S_\ell (q^{*\ell(\ell)} - q_{k\ell}^{(\ell)}), \quad \xi = 2, 3, 5, 6, &(59c) \\
&f_{k\ell}^{(r)}(q^{*r}) - f_{k\ell}^{(\ell)}(q_r) = S_r (q^{*r(\ell)} - q_{k\ell}^{(r)}), \quad \xi = 2, 3, 5, 6. &(59d)
\end{align*}
$$

where $q^{(\ell)}$ and $f^{(\ell)}$ are the components of $q$ and $f(q)$ in (42b) in the $d = 1$ case. Let us remark that in writing the conditions above (59) we neglect the contribution of the non-conservative terms $\Xi$ appearing in the phasic momentum and energy equations. We observe however that the conditions (59) imply correct Rankine–Hugoniot conditions for the conservative equations for the mixture momentum $\rho u$ and the mixture total energy $E$ (and hence (57) is satisfied).

The Rankine–Hugoniot conditions for the partial densities (59a)–(59d) ($\xi = 2, 3$) determine the intermediate partial densities. Then the conditions for the conservative portion of the phasic momentum equations (59b)–(59d) determine the intermediate partial pressures:

$$
(\alpha_k p_k)^{*\ell} = (\alpha_k p_k)_\ell + (\alpha_k p_k)_r (S_\ell - u_\ell) (S^* - u_\ell), \quad \ell = \ell, r, 
$$

(60)

where we have also used the invariance relation for the velocity in (57). Then, using these expression in the invariance relations for the effective pressure in (57) we obtain the expression for the speed $S^*$:

$$
S^* = \frac{p_r - p_\ell + \rho_\ell u_\ell (S_\ell - u_\ell) - \rho_\ell u_\ell (S_r - u_\ell)}{\rho_\ell (S_\ell - u_\ell) - \rho_\ell (S_r - u_\ell)},
$$

(61)
where we have used $p_{nf} = p_f$ and $p_{nf} = p_r$ since initial Riemann states are characterized by pressure equilibrium. A definition for the wave speeds must be provided, see e.g. \[71\] [5]. One classical and simple definition proposed by Davis [15] is

$$S_\ell = \min(u_\ell - c_{\ell\ell}, u_r - c_{\ell r}) \quad \text{and} \quad S_r = \max(u_\ell + c_{\ell\ell}, u_r + c_{\ell r}),$$  

(62)

where $c_{\ell}$ is defined in [6]. Another more robust definition has been proposed for instance by Bouchut [8] (see [42]). The Rankine–Hugoniot conditions for the conservative portion of the total energy equations \[59a\]–\[59c\] ($\xi = 5, 6$) together with \[60\] determine then the intermediate states for the total energies. Finally, we observe that the exact Riemann solution is characterized by the invariance of the volume fraction across the external waves (the volume fraction is simply advected):

$$\alpha^\ell = \alpha^\ell_1 \quad \text{and} \quad \alpha^r = \alpha^r_1, \; \; k = 1, 2 .$$  

(63)

Hence the solution structure for the volume fractions $\alpha_k$ simply consists of single jumps $\alpha_k^\ell - \alpha_k^r$ across the 2-wave moving at speed $S^\star$. As we reported in \[53\], the expressions for the middle states are:

$$q^{\star \xi} = \left\{ \begin{array}{c} \frac{S_k - u_k}{S_k - S_1} (\alpha_1 p_1) + \frac{S_k - S_1}{S_k - S_2} (\alpha_2 p_2) \\ \frac{S_k - u_k}{S_k - S_1} + \frac{S_k - S_1}{S_k - S_2} (S^\star + \frac{p_k}{\rho_k(S_k - u_k)}) \end{array} \right\},$$  

(64)

where $S_k = S_k^\ell$ or $S_k = S_k^r$. Note that in the above formulas $\rho_k = \rho_k$, $k = 1, 2$, since initial Riemann states satisfy pressure equilibrium conditions. As seen above the Rankine–Hugoniot conditions are satisfied by construction for all the physically conserved quantities across the external waves. We now also observe that Rankine–Hugoniot conditions are satisfied for the conserved quantities across the middle wave:

$$f^{\xi}(q^{\star \xi}) = f^{\xi}(q^{\star (\ell r)}) = S^\star (q^{\star (\ell r)} - q^{\star (\ell \ell)}), \; \; \xi = 2, 3, 4 ,$$  

(65a)

$$F^{\xi}(q^{\star \xi}) = F^{\xi}(q^{\star (\ell r)}) = S^\star (E^{\star \xi} - E^{\star (\ell \ell)}),$$  

(65b)

where $f^E = (E + \alpha_1 p_1 + \alpha_2 p_2)u$ is the flux function associated to the mixture total energy $E$. Let us remark that instead Rankine–Hugoniot conditions for the conservative portion of the equations of the non-conserved quantities $\alpha_1 p_2 u$ and $\alpha_2 E_k$ hold by construction across the external waves, but do not hold in general across the middle wave. This was inexactly reported in [53], where we wrote incorrectly Rankine–Hugoniot conditions for the phasic energies $\alpha_k E_k$ across the middle wave. As a final summarizing remark, we note that the simple HLLC-type solver illustrated here is obtained by neglecting the non-conservative term $\Sigma$ appearing in the phasic energy equations and in the phasic momentum equations in the jump conditions for the external 1-wave and 3-wave of the Riemann solution, but not for the 2-wave. The solver construction implies indeed an approximation of the non-conservative terms in the jump relations for the middle wave which can be deduced by observing:

$$f^{\star (\ell r)}(q^{\star \xi}) - f^{\star (\ell r)}(q^{\star (\ell \ell)}) = ((\alpha_1 E_k + \alpha_3 p_k)\, u) = (\alpha_1 E_k + \alpha_3 p_k)\, u)S^\star \quad (66a)$$

$$= S^\star (q^{\star (\ell r)} - q^{\star (\ell \ell)}) + S^\star ((\alpha_1 p_k)\, u) - (\alpha_3 p_k)\, u)S^\star , \; \; k = 1, 2 .$$  

(66b)
We find that the contribution to the jump across the 2-wave representing the non-conservative term is approximated by this HLLC solver as

\[-S^*((\alpha_k p_k)^r - (\alpha_k p_k)^f).\] (67)

This is a reasonable approximation since across the 2-wave \(p_m = \text{constant}\), hence the non-conservative term \(\Xi\) in (1g) reduces to \(\Xi = -\partial_x(\alpha_1 p_1)\) (and \(-\Xi = \partial_x(\alpha_2 p_2)\)), and (67) can be then considered as a jump across the middle wave associated to the non-conservative terms \(-u\partial_x(\alpha_k p_k)\), \(k = 1, 2\). Let us finally remark that the simple HLLC-type that we have illustrated above belongs to a more general class of HLLC-type Riemann solvers for the six-equation two-phase flow model [42], which we have introduced and assessed in [42] by defining a Suliciu-type Riemann solver.

7. Relaxation processes

As indicated in Section 5, after solving the homogeneous system (43), we solve a sequence of systems of ordinary differential equations accounting for the relaxation source terms, namely the systems (44), (45), and (46). First of all, we observe that for any relaxation process we have

\[\partial_t \rho = 0,\] (68a)
\[\partial_t (\rho \vec{u}) = 0,\] (68b)
\[\partial_t E = 0.\] (68c)

Therefore, the mixture density, velocity, total energy and internal energy remain constant during the transfer processes:

\[\rho = \text{const.}, \quad \vec{u} = \text{const.}, \quad E = \text{const.}, \quad \mathcal{E} = \text{const.}\] (69)

Moreover, if chemical relaxation is not activated, also the partial densities remain constant, since \(\partial_t (\alpha_k \rho_k) = 0\), \(k = 1, 2\):

\[\alpha_k \rho_k = \text{const.}.\] (70)

To completely determine the relaxed states in the mechanical and thermal relaxation steps we need to determine two independent variables (here we choose as unknowns the volume fraction \(\alpha_1\) and the equilibrium pressure \(p\)). In the chemical relaxation step we have to determine instead three variables, since the partial densities vary. It is important to note that for consistency with the mixture equation of state for flows in mechanical equilibrium (14) the equilibrium pressure \(p\) determined in the all the relaxation steps should satisfy the energy relation (48).

7.1. Instantaneous relaxation processes

Before illustrating our new relaxation procedures, let us recall briefly the methods presented in our previous work [53] for instantaneous transfer processes. The idea is to use for each process the invariance relations (69), with also (70) for mechanical and thermal relaxation, and the corresponding equilibrium conditions to obtain an algebraic system for the unknown relaxed variables. Similar relaxation procedures for instantaneous processes can be also found for instance in [33, 31]. We summarize here the equations to be used for each step of the algorithm in Section 5.
2(a) Instantaneous mechanical relaxation. We use the invariance relations (69) and (70) plus the mechanical equilibrium condition $p_1 = p_2 = p$. In this step we also need to integrate the phasic energy equations $\partial_t E_k = (-1)^k p_0 \partial_t \alpha_1$, $k = 1, 2$ between the states 0 and *. To simplify the integration we make an assumption on the interface pressure $p_I$, which we define as a convex combination of the initial value $p_0$ and the equilibrium value $p^*$, $p_I = \beta p_0 + (1 - \beta) p^*$, $\beta \in [0, 1]$. In our previous work we set $\beta = \frac{1}{2}$ or $\beta = 0$. We obtain an algebraic system of equations to be solved for two variables, for instance $\alpha_1^*$ and $p^*$. In the case of the stiffened gas EOS, the system can be reduced to the solution of a quadratic equation for the equilibrium pressure $p^*$.

2(b) Instantaneous mechanical and thermal relaxation. We use the invariance relations (69) and (70) plus the mechanical equilibrium condition $p_1 = p_2 = p$ and the thermal equilibrium condition $T_1 = T_2 = T$. We obtain an algebraic system of equations to be solved for two variables, for instance $\alpha_1^*$ and $p^*$. For the stiffened gas EOS, the system can be reduced to the solution of a quadratic equation for $p^*$.

2(c) Instantaneous mechanical, thermal and chemical relaxation. We use the invariance relations (69) plus the mechanical equilibrium condition $p_1 = p_2 = p$, the thermal equilibrium condition $T_1 = T_2 = T$, and the chemical equilibrium condition $g_1 = g_2$. We obtain an algebraic system to be solved for three variables, for instance $\alpha_1^*$, $p^*$, and $T^*$. In general, an iterative method is necessary for the solution.

Let us remark that in all these relaxation procedures the energy relation (48) is ensured by construction, and the resulting algorithm is mixture-energy-consistent (we recall that (47) is guaranteed by the HLLC method).

7.2. Arbitrary-rate relaxation processes

As we have explained, we will always consider instantaneous mechanical relaxation processes, so we could adopt the mechanical relaxation procedure used in [53] and described above. Nonetheless, we will present below a new procedure for pressure relaxation based on an analytical semi-exact exponential solution, which is particularly advantageous for complex equations of state. It could be also potentially used for finite-rate pressure relaxation processes (e.g. [48]), which however are not of interest here.

Concerning heat and mass transfer, we wish to model here processes with arbitrary relaxation times, hence we wish to design algorithms capable of handling both instantaneous (stiff) processes and slow finite-rate ones. Let us consider the systems of ODEs in (45) and (46). We see that during thermal and chemical relaxation we need to guarantee pressure equilibrium, as represented by the presence in these systems of the pressure relaxation term $\psi_\mu$ with $\mu \to +\infty$. In addition, during chemical relaxation, we need to account for the thermal relaxation effect, and in the limit of instantaneous thermal relaxation ($\theta \to +\infty)$, we need to guarantee temperature equilibrium, as represented by the presence of the thermal source term $\psi_\theta$ in (46). Due to these constraints, for thermal and chemical relaxation it is not possible to use a simple fractional step method where each source term $\psi_\theta$ and $\psi_\mu$ in the six-equation model is integrated individually. On the other hand it appears very complicated to try to solve the ODEs with all the relaxation terms, which have very different characteristic time scales. Our idea consists in modifying the thermal and chemical relaxation terms $\psi_\theta$ and $\psi_\mu$ of the six-equation model to translate on them the effect of the instantaneous pressure relaxation term $\psi_\mu$, and also to translate the effect of
the thermal relaxation term $\psi_\theta$ on $\psi_\nu$. Hence, we replace the system in (45) with a new system $\partial_t q = \bar{\psi}_\theta$, where $\bar{\psi}_\theta$ models thermal relaxation under pressure equilibrium, and we replace the system in (46) with a new system $\partial_t q = \bar{\psi}_\nu$, where $\bar{\psi}_\nu$ models chemical relaxation under pressure equilibrium and a thermal constraint, in particular thermal equilibrium. Our technique consists in employing in this approach the equations of the $p$-relaxed (11) and $pT$-relaxed (21) two-phase models. By using then some simplifying assumptions, analytical semi-exact exponential solutions are obtained to describe the relaxation processes.

7.2.1. Mechanical relaxation

We propose here a new numerical procedure to model instantaneous mechanical relaxation. We start by writing the ordinary differential equations governing the relaxation process in terms of the volume fraction $\alpha_1$ and the phasic pressures $p_1$ and $p_2$. Based on (1a) and (10) we have the equations:

$$\partial_t \alpha_1 = \mu(p_1 - p_2), \quad (71a)$$
$$\partial_t p_1 = \mu \Gamma_1 \left( p_1 - \rho_1 (\partial \epsilon_1 / \partial p_1)_{p_1} \right) (p_2 - p_1), \quad (71b)$$
$$\partial_t p_2 = -\mu \Gamma_2 \left( p_1 - \rho_2 (\partial \epsilon_2 / \partial p_2)_{p_2} \right) (p_2 - p_1), \quad (71c)$$

where $\mu$ is considered a constant. The initial condition for the above system corresponds to the solution of the homogeneous system, denoted with superscript 0. Let us now introduce the quantities $\xi_{pk}$, whose inverse values correspond to the terms multiplying $(p_2 - p_1)$ in the last two equations of the system (71):

$$\frac{1}{\xi_{1p}} = \frac{\Gamma_1}{\alpha_1} \left( p_1 - \rho_1 (\partial \epsilon_1 / \partial p_1)_{p_1} \right) = \frac{\Gamma_1}{\alpha_1} \left( p_1 - p_k + \rho_k c_{2k}^2 / T_k \right) = \frac{\rho_k c_{2k}^2}{\xi_{1p}}, \quad k = 1, 2. \quad (72)$$

Here we have used the relation $\rho_1 c_{2k}^2 (\partial \epsilon_1 / \partial p_1)_{p_1} = p_k - \frac{\rho_k c_{2k}^2}{T_k}$, and we have defined

$$c_{2k}^2 = \Gamma_k \frac{\epsilon_k}{\rho_k} + \frac{p_k}{\rho_k} + \chi_k, \quad k = 1, 2. \quad (73)$$

We now introduce an approximation by assuming $\xi_{1p}$ constant in time, $\xi_{1p} = \xi_{1p}^{(0)}$. Note that this means that we consider constant the impedance $\rho_k c_{1p}$ (since $\alpha_k \rho_k$ is constant). Hence we consider the solution of

$$\partial_t p_1 = \mu \frac{1}{\xi_{1p}^{(0)}} (p_2 - p_1), \quad (74a)$$
$$\partial_t p_2 = -\mu \frac{1}{\xi_{2p}^{(0)}} (p_2 - p_1). \quad (74b)$$

From (74) we obtain the following ordinary equation for the pressure difference $\Delta p = p_2 - p_1$:

$$\partial_t \Delta p = -\mu \left( \frac{1}{\xi_{1p}^{(0)}} + \frac{1}{\xi_{2p}^{(0)}} \right) \Delta p, \quad (75)$$
which has the exact solution after a time interval $\Delta t$:

$$\Delta p^* = \Delta p^0 e^{-K_p \Delta t}, \quad (76)$$

where

$$K_p = \mu \left( \frac{1}{\xi p_0} + \frac{1}{\xi p_2} \right). \quad (77)$$

We can now solve the partial differential equation for the volume fraction in (71a) by using the solution for $\Delta p^*$ in (76). By integrating we find

$$\alpha^*_1 = \alpha^0_1 - \frac{\Delta p^0}{\frac{1}{\xi p_1} + \frac{1}{\xi p_2}} (1 - e^{-K_p \Delta t}). \quad (78)$$

In the limit of instantaneous pressure relaxation $\mu \to +\infty$ the above expression for $\alpha_1$ gives the equilibrium value

$$\alpha^*_{1, \mu \to \infty} = \alpha^0_1 - \frac{\Delta p^0}{\frac{1}{\xi p_1} + \frac{1}{\xi p_2}}, \quad (79)$$

and the limit equilibrium pressure is:

$$p^*_{\mu \to \infty} = \frac{\xi p_1 p^0_1 + \xi p_2 p^0_2}{\xi p_1 + \xi p_2}. \quad (80)$$

We might then use the two equilibrium quantities (79) and (80) to define the $p$-relaxed solution in the step (2a) of the algorithm. However, in contrast to the techniques for instantaneous relaxation described in Section 7.1, in general the pair $\alpha^*_{1, \mu \to \infty}$ and $p^*_{\mu \to \infty}$ does not satisfy by construction the relation (48) (with $\# = \ast$), due to the approximations in the ODEs solution. Hence here we define the updated volume fraction $\alpha^*_1$ by using the exponential solution (79), but we update the equilibrium pressure by using the value $p^*$ determined by the energy relation

$$E^0 = \alpha^*_1 E_1 \left( p^*, \frac{(\alpha_1 \rho_1)^0}{\alpha^*_1} \right) + \alpha^*_2 E_2 \left( p^*, \frac{(\alpha_2 \rho_2)^0}{\alpha^*_2} \right). \quad (81)$$

The pressure relaxation procedure presented here is particularly convenient when complex equations of state are used. In fact the procedure used in [53] and recalled in Section 7.1 might lead to a complex algebraic system needing an iterative method for its solution. In Appendix C we also show that the relaxation procedure proposed here allows us to ensure velocity and pressure invariance at material interfaces at least when the stiffened gas equation of state is used. Let us finally observe that a similar mechanical relaxation procedure was proposed in [17]. However, in [17] the exponential solution for $\alpha_1$ is assumed a priori, whereas here it is deduced from the model equations by assuming the quantities $\xi p_k$ constant in time during the relaxation process. Moreover in [17] the instantaneous equilibrium case was modeled by an exponential solution with very small relaxation time, whereas here we use the analytical limit (79).
7.2.2. Thermal relaxation

To describe the thermal relaxation process under the constraint of mechanical equilibrium $p_1 = p_2$ we consider here the ordinary differential equations with heat transfer source term corresponding to the reduced five-equation pressure equilibrium model (11). Specifically, we write the ODEs governing the thermal relaxation process for this model in terms of the volume fraction $\alpha_1$, and the phasic temperatures $T_1$ and $T_2$. Based on (11a) and (18) we have the equations:

\[ \partial_t \alpha_1 = \frac{\partial}{\partial D} Z (T_2 - T_1), \]  
\[ \partial_t T_1 = \frac{1}{\phi_1 D} \left[ -\frac{\rho_1}{\alpha_1} Z - \xi_1 (\Gamma_1 \rho_2 c_2^2 - \Gamma_2 \rho_1 c_1^2) \right] (T_2 - T_1), \]  
\[ \partial_t T_2 = \frac{1}{\phi_2 D} \left[ \frac{\rho_2}{\alpha_2} Z - \xi_2 (\Gamma_1 \rho_2 c_2^2 - \Gamma_2 \rho_1 c_1^2) \right] (T_2 - T_1). \]

where $D$ is given in (12) and we have defined:

\[ Z = \alpha_2 \Gamma_1 + \alpha_1 \Gamma_2. \]

The initial condition here corresponds to the pressure equilibrium solution coming from the mechanical relaxation step, denoted with the superscript $\ast$. Let us introduce the quantities $\xi^T_k$, whose inverse values correspond to the terms multiplying $(T_2 - T_1)$ in the last two equations of the above system:

\[ \xi^T_k = -\frac{\phi_k D}{\alpha_k} Z + (-1)^{k-1} \xi_0 (\Gamma_1 \rho_2 c_2^2 - \Gamma_2 \rho_1 c_1^2), \quad k = 1, 2. \]

Analogously to the pressure relaxation step we assume that the quantities $\xi^T_k$ are constant in time, $\xi^T_k = \xi^T_k \ast$. Hence we consider the solution of

\[ \partial_t T_1 = \frac{1}{\xi^T_1} (T_2 - T_1), \]  
\[ \partial_t T_2 = -\frac{1}{\xi^T_2} (T_2 - T_1). \]

We also consider that $\theta$ is a constant. If $\theta$ is a given function of some variables instead of a constant parameter, then we fix $\theta$ to its value at the state $\ast$. From (85) we obtain the following ordinary equation for the temperature difference $\Delta T = T_2 - T_1$:

\[ \partial_t \Delta T = -\theta \left( \frac{1}{\xi^T_1} + \frac{1}{\xi^T_2} \right) \Delta T, \]

which has the following exact solution after a time step $\Delta t$:

\[ \Delta T^{\ast} = \Delta T^{\ast} \ast e^{-K_T \Delta t}, \]

where

\[ K_T = \theta \left( \frac{1}{\xi^T_1} + \frac{1}{\xi^T_2} \right). \]
We now need to solve the partial differential equation for the volume fraction in (82a). Assuming that \(Z/D\) is constant and by using the solution for \(\Delta T^*\) in (87) we obtain

\[
\alpha_1^{**} = \alpha_1^* + \left(\frac{Z}{D}\right)^* \frac{\Delta T^*}{\left(\frac{1}{\xi_1^*} + \frac{1}{\xi_2^*}\right)} (1 - e^{-K_T \Delta t}).
\]

(89)

In the limit of instantaneous temperature relaxation \(\theta \to +\infty\) the above expression for \(\alpha_1\) gives the equilibrium value

\[
\alpha_{1,\theta\to\infty} = \alpha_1^* + \left(\frac{Z}{D}\right)^* \Delta T^* \left(\frac{\xi_1^*}{\xi_1^*} + \frac{\xi_2^*}{\xi_2^*}\right).
\]

(90)

and the equilibrium temperature is:

\[
T_{\theta\to\infty} = \frac{\xi_1^* \xi_2^*}{\xi_1^* + \xi_2^*}.
\]

(91)

To update the solution at the step (2b) of the algorithm we use the relaxed value \(\alpha_1^{**}\) in (89) (or in (90) in case of instantaneous relaxation), and the pressure value \(p^{**}\) determined by the energy relation

\[
E = \alpha_1^{**} E_1 \left(\rho_1 \frac{(\alpha_1^*)^0}{\alpha_1^{**}}\right) + \alpha_2^{**} E_2 \left(\rho_2 \frac{(\alpha_2^*)^0}{\alpha_2^{**}}\right)
\]

(92)

in order to ensure mixture-energy-consistency.

7.2.3. Chemical relaxation

The chemical relaxation process occurs under mechanical equilibrium and it is coupled to a thermal relaxation process which is assumed much faster than the chemical relaxation one. Hence, it is often reasonable to consider a chemical relaxation process occurring under both mechanical and thermal equilibrium, and here we consider this case. To describe this process we use then the ordinary differential equations with mass transfer source term corresponding to the reduced four-equation pressure and temperature equilibrium model (21). Specifically, we wish to write the ODEs governing the phasic chemical potentials \(g_k\), by writing

\[
\partial_t \alpha_1 = \nu S \alpha_1 \left(g_2 - g_1\right),
\]

(93a)

\[
\partial_t g_1 = \nu \left(\frac{S_p}{\rho_1} - s_1 S_T\right) (g_2 - g_1),
\]

(93b)

\[
\partial_t g_2 = \nu \left(\frac{S_p}{\rho_2} - s_2 S_T\right) (g_2 - g_1),
\]

(93c)

\[
\partial_t (\alpha_1 \rho_1) = \nu (g_2 - g_1).
\]

(93d)

Note that the interface chemical potential \(g_I\) does not appear anymore in the equations (cf. also the \(pT\)-relaxed model), hence a definition for this quantity is not needed. The initial condition
for (93) corresponds to the solution coming from the thermal relaxation step, denoted with superscript \( \ast \ast \). Let us introduce the quantities \( \xi_k^g \), whose inverse values correspond to the terms multiplying \((g_2 - g_1)\) in the two equations for \( g_k \) of the above system:

\[
\frac{1}{\xi_k^g} = \pm \frac{1}{\rho_k} S_p - s_k S_T, \quad k = 1, 2.
\]  

(94)

Analogously to the pressure and temperature relaxation step we assume that the quantities \( \xi_k^g \) are constant in time, \( \xi_k^g = \xi_k^{g \ast \ast} \). Hence we consider the solution of

\[
\partial_t g_1 = \nu_1 \frac{1}{\xi_1^{g \ast \ast}} (g_2 - g_1),
\]  

(95a)

\[
\partial_t g_2 = -\nu_1 \frac{1}{\xi_2^{g \ast \ast}} (g_2 - g_1).
\]  

(95b)

We also consider that \( \nu \) is a constant. If \( \nu \) is a given function of some variables instead of a constant parameter, then we fix \( \nu \) to its value at the state \( \ast \ast \). From (95) we obtain the following ordinary equation for the chemical potential difference \( \Delta g = g_2 - g_1 \):

\[
\partial_t \Delta g = -\nu \left( \frac{1}{\xi_1^{g \ast \ast}} + \frac{1}{\xi_2^{g \ast \ast}} \right) \Delta g,
\]  

(96)

which has the exact solution after a time interval \( \Delta t \):

\[
\Delta g \otimes \Delta t = \Delta g \ast \ast e^{-K_g \Delta t},
\]  

(97)

(98)

We now need to solve the partial differential equation for the volume fraction in (93a) and the partial density \( \alpha_1 \rho_1 \) in (93d). By using the solution for \( \Delta g \otimes \) in (97) we immediately obtain

\[
(\alpha_1 \rho_1) \otimes (\alpha_1 \rho_1) = (\alpha_1 \rho_1) \ast \ast + \Delta g \ast \ast \left( \frac{1}{\xi_1^{g \ast \ast}} + \frac{1}{\xi_2^{g \ast \ast}} \right) (1 - e^{-K_g \Delta t}).
\]  

(99)

Assuming now that \( S_\alpha \) is constant, for the volume fraction we get

\[
\alpha_1 \otimes = \alpha_1 \ast \ast + S_\alpha \ast \ast \left( \frac{1}{\xi_1^{g \ast \ast}} + \frac{1}{\xi_2^{g \ast \ast}} \right) (1 - e^{-K_g \Delta t}).
\]  

(100)

In the limit of instantaneous chemical relaxation \( \nu \to +\infty \) the above expressions for \( \alpha_1 \rho_1 \) and \( \alpha_1 \) give the equilibrium values

\[
(\alpha_1 \rho_1)_{\nu \to \infty} = (\alpha_1 \rho_1) \ast \ast + \left( \frac{1}{\xi_1^{g \ast \ast}} + \frac{1}{\xi_2^{g \ast \ast}} \right) \Delta g \ast \ast,
\]  

(101)

\[
\alpha_1,_{\nu \to \infty} = \alpha_1 \ast \ast + S_\alpha \ast \ast \left( \frac{1}{\xi_1^{g \ast \ast}} + \frac{1}{\xi_2^{g \ast \ast}} \right).
\]  

(102)
and the equilibrium chemical potential is:

\[ \gamma_{\nu \to \infty} = \frac{\xi_{g}^{\ast 1} \xi_{g}^{\ast 2} + \xi_{g}^{\ast 1} \xi_{g}^{\ast 2}}{\xi_{g}^{\ast 1} + \xi_{g}^{\ast 2}}. \]

(103)

To update the solution at the step (2c) of the algorithm we use the relaxed values \((\alpha_{1} \rho_{1})^{\circ}\) and \(\alpha_{2}^{\circ}\) in (99) and (100) (or in (101) and (102) in case of instantaneous relaxation), and the pressure value \(p^{\circ}\) is determined by the energy relation

\[ E^{0} = \alpha_{1}^{\circ} E_{1}\left(\rho^{\circ}, \frac{(\alpha_{1} \rho_{1})^{\circ}}{\alpha_{1}^{\circ}}\right) + \alpha_{2}^{\circ} E_{2}\left(\rho^{\circ}, \frac{(\alpha_{2} \rho_{2})^{\circ}}{\alpha_{2}^{\circ}}\right) \]

(104)

in order to ensure mixture-energy-consistency. Let us remark that although the equations (93) above have been obtained by assuming temperature equilibrium \(T_{2} = T_{1} = T\) (in addition to pressure equilibrium), they hold more generally in the hypothesis of a chemical relaxation process occurring at constant temperature difference \(T_{2} - T_{1} = \Delta T\), since in this case \(\partial T_{1} = \partial T_{2}\) and the derivation of (27) in Appendix B can be easily extended to the case in which the variables associated to the phase \(k\) are functions of \(p\) and \(T_{k}\) with the constraint \(T_{2} = T_{1} + \Delta T\), \(\Delta T = \text{constant}\). Hence the procedure described in this Section could be also employed to model chemical relaxation processes with thermal disequilibrium, provided consistent relaxation times are chosen, since thermal relaxation is physically faster than chemical relaxation.

**Complete evaporation or condensation**

It is physically possible that the mass transfer process leads to complete evaporation or complete condensation, thus to the disappearance of one phase. In such a case the computation via (100) (or (102)) produces a value \(\alpha_{1}^{\circ} \notin (0, 1)\). To handle this case numerically we proceed as follows. First, let us remark that in our numerical model both phases must always be present, therefore we model a pure phase \(k\) as a mixture with a volume fraction \(\alpha_{k} = 1 - \epsilon_{\alpha}\), where \(0 < \epsilon_{\alpha} \ll 1\) (for instance \(\epsilon_{\alpha} = 10^{-3}\)). If in the numerical computation we find \(\alpha_{1}^{\circ} \notin (0, 1)\) we consider that one phase vanishes hence we set \(\tilde{\alpha}_{1} = \tilde{\alpha}_{1}\) where \(\tilde{\alpha}_{1} = \epsilon_{\alpha}\) if \(s_{2}^{\ast} > s_{1}^{\ast}\) (vanishing of phase 1), or \(\tilde{\alpha}_{1} = 1 - \epsilon_{\alpha}\) if \(s_{1}^{\ast} > s_{2}^{\ast}\) (vanishing of phase 2). Then we determine the value of the relaxation parameter \(K_{g}\) that gives the value \(\tilde{\alpha}_{1}\) through the formula (100). We find:

\[ \tilde{K}_{g} = \frac{1}{\Delta t} \log \left(1 - \frac{\tilde{\alpha}_{1} - \alpha_{1}^{\ast}}{S_{g}^{\ast} \left(\frac{\delta_{\gamma}}{\gamma_{\nu} + \delta_{\gamma}}\right)}\right). \]

(105)

Finally we set \((\alpha_{1} \rho_{1})^{\circ}\) by using the formula (99) with \(K_{g} = \tilde{K}_{g}\). Let us remark that if an unphysical value of \(\alpha_{1}\) is computed in the pressure and temperature relaxation procedures previously presented, it suffices to set \(\alpha_{1} = \tilde{\alpha}_{1}\).

8. Numerical experiments

We present in this section several numerical experiments in one and two dimensions. The algorithm has been implemented by using the basic routines of the **clawpack** software [38]. All the computations have been performed with the second-order wave propagation scheme with the
minmod limiter. In some one-dimensional Riemann problems we plot the exact solution for the $p$-relaxed model \cite{11} (see \cite{55}) and the $pT$-relaxed model \cite{21}. These exact solutions have been computed by extending to the models \cite{11} and \cite{21} the methodology detailed in \cite{28,27} for the compressible single-phase Euler equations with general equation of state.

8.1. Numerical tests with only mechanical relaxation

We begin by presenting some numerical experiments where we activate only instantaneous mechanical relaxation. The aim in particular is to show the good performance of the numerical model when complex equations of state are employed in problems with strong shocks and interfaces.

8.1.1. Detonation gas-water shock tube

We consider a two-fluid one-dimensional shock tube problem over the domain $[-10, 10]$ m. There is an initial discontinuity at $x = 0$ that separates a left region filled with detonation gases with density $\rho_{\text{gas}} = 2000$ kg m$^{-3}$ and pressure $p_{\text{gas}} = 4.6406 \times 10^{10}$ Pa, and a right region filled with liquid water with density $\rho_{\text{liq}} = 1044$ kg m$^{-3}$ and pressure $p_{\text{liq}} = 10^5$ Pa. Detonation gases are modeled by the JWL equation of state with the parameters in Table 2 (taken from \cite{57}), and the liquid water is modeled by the NASG equation of state with the parameters in Table 3. In each region we consider a nearly pure fluid with volume fraction $1 - 10^{-8}$. The initial velocity is $u = 0$. We compute the solution with 500 grid cells and CFL number $= 0.46$. In Figure 2 we show results at $t = 0.9$ ms for the density, velocity, pressure, and gas volume fraction, together with the exact solution for this problem. We observe the agreement with the exact solution and in particular the ability of the method to preserve velocity and pressure invariance across and around the material interface.

Table 2: Material properties for the JWL equation of state modeling explosive.

| Parameter | Value (Explosive) | Units |
|-----------|-------------------|-------|
| $\rho_0$  | 1840              | kg/m$^3$ |
| $\Gamma_0$| 0.25              |       |
| $a$       | $854.5 \times 10^9$ | Pa    |
| $b$       | $20.5 \times 10^9$  | Pa    |
| $r_1$     | 4.6               |       |
| $r_2$     | 1.35              |       |
| $\varepsilon_0$ | 0          | J/kg  |

Table 3: Parameters for the NASG EOS for liquid and vapor water in the temperature range 300-500 K

| phase | $\gamma$ | $\sigma$ [Pa] | $\eta$ [J/kg] | $\eta_0$ [J/(Kg \cdot K)] | $\kappa_0$ [J/(Kg \cdot K)] | $b$ [m$^3$/kg] |
|-------|----------|---------------|---------------|--------------------------|----------------------------|---------------|
| liquid| 1.187    | $7028 \times 10^2$ | $-1177788$ | 0                        | 3610                      | $6.61 \times 10^{-6}$ |
| vapor | 1.467    | 0             | $2077616$    | $14317$                  | 955                       | 0             |

8.1.2. Underwater explosion close to a rigid wall

We now perform a two-dimensional experiment. In this test we simulate a cylindrical underwater explosion (UNDEX) close to a rigid upper surface. Following \cite{74}, we consider
Figure 2: Detonation gas-water shock tube problem. Computed results for the density $\rho$, velocity $u$, pressure $p$, and gas volume fraction $\alpha_1$ at time $t = 0.9$ ms (blue marks *), compared with the exact solution (solid red line).

an initial bubble of highly pressurized gas (combustion products) surrounded by liquid water and located near an upper flat wall. Combustion gases are modeled by the JWL equation of state with the parameters in Table 2, while liquid water is modeled by the NASG EOS with the parameters in Table 3. The considered domain is $[-1.35, 1.35] \times [-1.5, 0]$ m$^2$, with the wall at $y = 0$ m. The bubble initially is located at $(x_b, y_b) = (0, -0.22)$ m, and it has radius $r_b = 0.05$ m. Inside the bubble we set initially a pressure $p = 4.6406 \cdot 10^{10}$ Pa, a gas density $\rho_{\text{gas}} = 2000$ kg/m$^3$, and a gas volume fraction $\alpha_{\text{gas}} = 1 - 10^{-6}$. Outside the bubble we set a pressure $p = 10^5$ Pa, a liquid density $\rho_{\text{liq}} = 1044$ kg/m$^3$ and a liquid volume fraction $\alpha_{\text{liq}} = 1 - 10^{-6}$. This explosion problem is characterized by a complex pattern of shocks and rarefaction waves [74]. We use $721 \times 400$ grid cells with CFL number $= 0.4$. We show in Figure 3 plots of the pressure at six different times. At $t = 0.02$ ms (upper right plot) we can observe the circular shock created by the explosion. At $t = 0.05$ ms (middle left plot) this shock has reflected from the wall. The shock reflection gives rise to strong rarefactions that cause the formation of a low pressure region close to the wall, which is later re-compressed.
Figure 3: Underwater explosion near a rigid upper flat surface. Computed pressure field at times $t = 0, 0.02, 0.05, 0.07, 0.11, 0.16$ ms. The thick solid line (magenta color) indicates the water/bubble interface.
8.2. Numerical tests with thermo-chemical relaxation

We now present several numerical experiments where we activate thermal and chemical relaxation, simulating both instantaneous and finite-rate transfer processes. Concerning non instantaneous transfers we report primarily tests with finite-rate mass transfer under thermal equilibrium, which is our principal interest.

8.2.1. Water two-phase cavitation tube

We consider a one-dimensional water cavitation tube problem, which is a variant of a numerical test taken from [62] that we performed in [53] with the stiffened gas equation of state and instantaneous relaxation processes. Initially we have a tube over the interval [0, 1] m filled with liquid water at pressure \( p = 10^5 \) Pa and temperature \( T = T_1 = T_2 = 353 \) K. The liquid contains a uniformly distributed small amount of vapor, with a volume fraction \( \alpha_{\text{vap}} = 10^{-2} \) in the whole domain. A velocity discontinuity is set at \( x = 0.5 \) m at initial time, with \( u = -2 \) m/s on the left and \( u = 2 \) m/s on the right. We use here the NASG equation of state for the liquid water and water vapor phases, with the parameters in Table 3. We perform computations with five different levels of relaxation by using the techniques detailed in Section 7.2: only instantaneous mechanical relaxation (case denoted as \( p \)-relax in the plots), instantaneous mechanical relaxation and finite-rate thermal relaxation with \( \vartheta = 2000 \) Pa/(s·K) (\( pT(f) \)), instantaneous mechanical and thermal relaxation (\( pT \)), instantaneous mechanical and thermal relaxation and finite-rate chemical relaxation with \( \nu = 10^{-4} \) Pa·kg²/(s·J²) (\( pTg(f) \)), and full thermodynamic relaxation (\( pTg \)). Phase transition is hence activated only in the two last cases. Let us remark also that in this test (following [62]) chemical relaxation is activated when the equilibrium temperature is greater than the saturation temperature, \( T > T_{\text{sat}}(p) \) (this happens in the middle region of the tube). We use 5000 grid cells and we set the CFL number = 0.5. Results for the pressure, velocity, vapor volume fraction and vapor mass fraction at time \( t = 0.003 \) s are displayed in the top and middle rows of Figure 4. In all the cases the solution involves two rarefactions going in opposite directions that cause a decrease of the pressure in the middle of the tube, and correspondingly an increase of the vapor volume fraction. Let us note that if mass transfer is not activated then the vapor mass fraction remains constant, and the cavitation process is only mechanical. In contrast, if mass transfer is activated then the solution involves also two evaporation waves. In this case the vapor mass fraction increases in the middle of the tube, and moreover here the pressure is driven to its saturation value, whereas without mass transfer the pressure continues to decrease in the center of the tube. In the bottom row of Figure 4 we show the equilibrium temperature and the chemical potentials for the three test cases with instantaneous pressure and temperature equilibrium (\( pT, pTg(f), pTg \)), with or without mass transfer. Computed liquid and vapor temperatures are found to be overlapped, this proving the ability to impose numerically thermal equilibrium. By observing the plot of the liquid and vapor chemical potentials we notice the region of chemical potential equilibrium in the middle of the tube for the \( pTg \)-relaxation case, corresponding to the region of activation of chemical relaxation under the evaporation condition \( T > T_{\text{sat}} \). For the case with finite rate mass transfer (\( pT(f) \)-relaxation) we notice that liquid and vapor chemical potentials are being driven to equilibrium and their difference is correctly reduced with respect to the case with no mass transfer (\( pT \)-relaxation). In Figure 4 we also plot the exact solution for this problem of the five-equation pressure equilibrium model (11) and of the four-equation pressure and temperature equilibrium model (21). We observe good agreement of the results computed with activation of instantaneous mechanical relaxation with the exact solution of the five-equation \( p \)-relaxed model, and of the results computed with activation of
instantaneous mechanical and thermal relaxation with the exact solution of the four-equation $pT$-relaxed model. This shows the capability of the numerical model to approximate solutions of the limit equilibrium models in the limit on instantaneous relaxation processes. Let us also observe that the different speeds of the leading edges of the rarefactions for different levels of activation of relaxation processes is consistent with the subcharacteristic condition in $c_{pT} \leq c_p$. Note that also in the tests with phase transition in correspondence of these leading edges chemical relaxation is not activated since $T < T_{sat}$, hence for the tests with mass transfer the sound speed in these regions is the pressure and temperature equilibrium sound speed $c_{pT}$.

8.2.2. Dodecane liquid-vapor shock tube

We consider here a dodecane liquid-vapor shock tube problem also proposed in [62], which we solved in [53] with the stiffened gas equation of state. This test involves a unit length shock tube with an initial discontinuity located at $x = 0.75$ m that separates a left region filled with liquid dodecane and a right region filled with vapor dodecane. As in [62], for numerical reasons each fluid region contains a small amount of the phase that fills the region on the other side of the discontinuity ($\alpha = 10^{-8}$). The initial condition consists of two constant states on the two sides of the discontinuity with pressure $p = 10^{8}$ Pa on the left and $p = 10^{5}$ Pa on the right. The initial velocity is $u = 0$, and the initial values of the vapor and liquid densities are $\rho_{vap} = 2 \text{ kg} \cdot \text{m}^3$ and $\rho_{liq} = 500 \text{ kg} \cdot \text{m}^3$, respectively. The liquid and vapor phases of dodecane are modeled by the NASG equation of state with the parameters given in Table 4. Figure 5 shows numerical results at time $t = 473 \mu s$ obtained by employing our numerical model with and without heat and mass transfer effects. More precisely, we plot results for two different levels of relaxation: instantaneous mechanical relaxation ($p$-relax in the plots), and instantaneous full thermodynamical relaxation ($pTg$-relax). Let us note that for the latter case thermo-chemical relaxation is activated only at interfaces, defined by $\text{min}(\alpha_{vap}, \alpha_{liq}) > \epsilon$, $\epsilon = 10^{-4}$, and chemical relaxation is activated under the condition $T > T_{sat}$. We can observe for both cases with and without phase transition that the solution consists of a leftward going rarefaction wave, a rightward going contact discontinuity, and a shock wave. Moreover, when thermal and chemical effects are activated liquid-vapor phase change occurs, generating an additional evaporation wave between the rarefaction wave and the contact discontinuity. This evaporation front produces a liquid-vapor saturation region at higher speed. Note that the left-going rarefaction occurs in a region of almost pure liquid ($\alpha_{vap}$ nearly zero) and, as noted above, only mechanical relaxation is activated in this zone for any case ($p$- and $pTg$-relaxation), hence the phases have different temperatures. Let us also remark that in this left zone the vapor temperature has no physical meaning, and since the value that it reaches is unphysically high, of the order of $10^6$ K, we have plotted the temperatures in Figure 5 only over the physical range with a maximum temperature value of 1200 K, to be able to observe the relevant liquid and vapor temperature curves. For the $pTg$-relaxation case the liquid-vapor transition leads to complete evaporation (handled with the technique illustrated in Section 7.2.3, see [105]), and on the right end of the interval there is a region of nearly pure vapor. Again, in this region of nearly pure vapor ($\alpha_{liq}$ nearly zero) only mechanical relaxation is activated. We can notice from the temperatures plot in Figure 5 the small liquid-vapor mixture zone where thermo-chemical relaxation is activated and where thermal and chemical equilibrium is imposed. This corresponds to the zone where the vapor and liquid temperature curves of the $pTg$-relaxed computation overlap around $x = 0.83$ m (solid and dashed blue lines). In the plots we also display the exact solution of the five-equation pressure equilibrium model for this problem, and we observe good agreement with this solution of our results with mechanical relaxation only.
Figure 4: Water cavitation tube test, results at $t = 0.003$ s. 1st and 2nd rows: pressure $p$, velocity $u$, vapor volume fraction $\alpha_2$, vapor mass fraction $Y_2$ for five levels of relaxation. 3rd row: temperature $T$ and chemical potentials $g_k$ for the cases with temperature equilibrium. $p$-relax (violet solid line): instantaneous mechanical relaxation; $pT(f)$ (dashed light green line): instantaneous mechanical relaxation and finite-rate thermal relaxation; $pT$ (solid dark green line): instantaneous mechanical and thermal relaxation; $pTg(f)$ (dashed light blue line): instantaneous mechanical and thermal relaxation and finite-rate chemical relaxation; $pTg$ (solid dark blue line): instantaneous mechanical, thermal, and chemical relaxation. Only in the plot of the chemical potentials $g_k$ the solid line indicates the liquid ($l$) and the dashed line the vapor ($v$). The exact solution of the $p$-relaxed model (solid black line) and of the $pT$-relaxed model (dashed black line) is also plotted.
Table 4: Parameters for the NASG EOS for liquid and vapor dodecane in the temperature range 400-600 K

| phase | γ     | σ  [Pa]  | η [J/kg] | ˜η [J/(Kg · K)] | κv [J/(Kg · K)] | b [m³/kg] |
|-------|-------|----------|----------|-----------------|-----------------|-----------|
| liquid| 1.206 | 1681×10⁵ | -996054  | 0               | 2532            | 7.51×10⁻⁴ |
| vapor | 1.021 | 0        | -384592  | -4301           | 2274            | 0         |

8.2.3. Barták’s depressurization experiment

We simulate here the Barták’s blowdown experiment presented in [5]. This laboratory experiment consists in the rapid depressurization of a pressurized water pipe initiated by a disk rupture. The study of this type of blowdown experiment is relevant in particular in the context of the hazard assessment of water-cooled reactors of nuclear power plants. One characteristic feature of the flow in this test is the rapid fall of the pressure to a value below the saturation pressure, so that for a certain time there is metastable superheated liquid, before vaporization starts. As we observe numerically, to simulate this problem it is important to be able to model non-instantaneous mass transfer processes. Initially in the tube there is liquid water at a pressure $p = 12.5 \times 10^6$ Pa and at temperature $T = T_1 = T_2 = 563.15$ K. There is an initial uniformly distributed small amount of vapor in the tube, with volume fraction $\alpha_v = 10^{-3}$. The tube has a length of 1700 mm, and it is permanently closed on one side, here the right side. On the other side, here the left side, the tube is suddenly opened, hence we consider atmospheric pressure conditions at the left boundary, with $p = 10^5$ Pa. We use the NASG equation of state for water with the parameters in Table 5.

We compute solutions for this test with 1000 grid cells until a final time $t = 17.5$ ms (note that in this test we study the very first stage of this type of transient flow). In Figure 6 we plot results for the pressure history (left) and the vapor mass fraction history (right) at a fixed location corresponding to the first pressure gauge of the experimental apparatus, at $x = 48$ mm. The solid dark blue line represents results obtained by activating instantaneous heat transfer ($\vartheta \to \infty$) and finite-rate mass transfer with the mass transfer relaxation function $\nu$ expressed by the following relation, which is a modified version of the relations presented in [20, 16]:

$$
\nu = C_r \alpha_v^{0.6} \left( \frac{p_{sat} - p}{p_{sat} - p_{crit}} \right)^{1.76}, \quad C_r = 1 \text{ Pa} \cdot \text{kg}^2/(s \cdot J^2).
$$

We observe the qualitative agreement of these results with the experimental data (black marks *), and in particular the ability of the numerical model to predict the occurrence of a metastable superheated state with $p < p_{sat}(T)$ (region of the pressure undershoot), followed by vaporization. In Figure 6 we also plot results computed with no mass transfer ($\vartheta \to \infty, \nu = 0$, dashed light blue line) and results computed with instantaneous heat and mass transfer ($\vartheta \to \infty, \nu \to \infty$, solid red line), this corresponding to the solution of the homogeneous equilibrium model (HEM) ($pT_g$-relaxed model [28]). We notice in particular that the activation of instantaneous mass transfer does not allow the description of metastable states.

Table 5: Parameters for the NASG EOS for liquid and vapor water in the temperature range 350-550 K

| phase | γ     | σ  [Pa]  | η [J/kg] | ˜η [J/(Kg · K)] | κv [J/(Kg · K)] | b [m³/kg] |
|-------|-------|----------|----------|-----------------|-----------------|-----------|
| liquid| 1.387 | 8899×10⁵ | -1244191 | 0               | 3202            | 4.78×10⁻⁴ |
| vapor | 1.954 | 0        | 2287484  | 6417            | 462             | 0         |
Figure 5: Dodecane shock tube test. Results at $t = 473 \mu s$. Density $\rho$, velocity $u$, vapor mass fraction $Y_2$, pressure $p$, vapor volume fraction $\alpha_2$, vapor and liquid temperatures $T_k$. The density and pressure plots are in semi-logarithmic scale. $p$-relax (solid violet line): instantaneous mechanical relaxation; $pT_g$-relax (solid blue line): instantaneous mechanical, thermal, and chemical relaxation. Only in the plot of the temperatures $T_k$ the solid line indicates the liquid (l) and the dashed line the vapor (v). Moreover, for the $pT_g$-relaxed case (blue) thinner lines indicates regions where one phase is almost absent. The exact solution of the 5-equation $p$-relaxed model (solid black line) is also plotted.
8.2.4. High-pressure fuel injector

Finally, we simulate a two-dimensional fuel injector. This test is also a variant of a test proposed in [62], which we solved in [53] with the stiffened gas equation of state and instantaneous relaxation processes. We consider a nozzle where liquid fuel (dodecane) is injected from a high-pressure tank to a chamber at atmospheric pressure. The nozzle has the shape shown in the plots of Figures 7-8, and it has a length of 10 cm and a height of 4 cm. The height of the throat is 1.2 cm, and the outer inclination angles of the converging and diverging chambers with respect to the horizontal direction are 45° and 10°, respectively. We set an initial discontinuity at $x = 0.8$ cm between a region of liquid dodecane at a pressure $p = 10^8$ Pa and at temperature $T = 550$ K and a region of dodecane vapor at pressure $p = 10^5$ and with phasic density $p_{\text{vap}} = 5 \text{ kg} \cdot \text{m}^{-3}$. At the initial time, a small amount of vapor is present in the liquid with $\alpha_{\text{vap}} = 10^{-4}$, and a small amount of liquid is present in the vapor with $\alpha_{\text{liq}} = 10^{-6}$. Phases are initially assumed in thermal equilibrium. The dodecane liquid and vapor phases are modeled by the NASG EOS with the parameters in Table 4. In this experiment we activate instantaneous heat and mass transfer at interfaces defined by $\min(\alpha_{\text{vap}}, \alpha_{\text{liq}}) > \epsilon$, with $\epsilon = 0.9 \times 10^{-4}$. We assume instantaneous thermal relaxation ($\theta \to \infty$), while we use different values of the chemical relaxation parameter $\nu$. In Figure 7 we plot results computed with instantaneous heat and mass transfer at a time at which stationary conditions are approximately attained for the mixture density, the vapor volume fraction, the pressure, the vapor mass fraction, the velocity field, and the liquid temperature. For these results we have used $400 \times 160$ grid cells and CFL number = 0.4. In Figure 8 we plot results at three different times for the vapor mass fraction computed by using four different values of the chemical relaxation parameter $\nu$ $[\text{Pa} \cdot \text{kg}^2/(\text{s} \cdot \text{J}^2)]$, $\nu = 0$ (no mass transfer), $\nu = 0.1$, $\nu = 25$, $\nu \to \infty$ (instantaneous mass transfer). For the results in this Figure 8 we have used $200 \times 80$ grid cells and CFL number = 0.4. Note that we can compare results for the vapor mass fraction at $t = 0.0006$ s obtained for the test with instantaneous mass transfer with two different mesh sizes, see Figure 7 plot at the center-right, and Figure 8 plot.
at the center of the bottom row. Overall the results of this numerical test show the capability of the numerical model to simulate mass transfer processes of arbitrary rate, from slow to very fast processes.

9. Conclusions

We have proposed new efficient numerical techniques to treat the mechanical, thermal, and chemical relaxation source terms of the single-velocity two-phase flow model \cite{53} that we have presented in previous work \cite{53}. The new techniques are based on analytical semi-exact exponential solutions of the systems of ordinary differential equations used to model the relaxation processes, and they have two significant features: the applicability to a general equation of state, and the capability to describe arbitrary-rate heat and mass transfer. These relaxation procedures also ensure a mixture-energy-consistent scheme. The procedures are simple, and for equations of state that can be written in the form of the Mie–Grüneisen EOS they do not need iterative methods. In general, for more complex equations of state, only the mixture energy equation \cite{48} that defines implicitly the equilibrium mixture pressure might need
$\nu = 0$

$\nu = 0.1$

$\nu = 25$

$\nu \to \infty$

Figure 8: High-pressure fuel injector experiment. Computed vapor mass fraction $Y_{\text{vap}}$ at times $t = 0.00027, 0.0006, 0.0012$ s (columns from left to right) for $\nu = 0, \nu = 0.1, \nu = 25, \nu \to \infty$ (rows from top to bottom), using a $200 \times 80$ grid.
an iterative solution method. The relaxation techniques for heat and mass transfer can robustly handle both stiff instantaneous processes and non-stiff slow finite-rate relaxation processes. This is an important improvement with respect to our previous work \[17, 18\]. Let us also note that, by construction, the techniques that we have proposed for the six-equation model (1) can be used to treat relaxation terms of the \(p\)-relaxed (11) and \(pT\)-relaxed (21) models, when one solves these models directly (see for instance the application to the \(pT\)-relaxed model in [19]).

Several numerical tests show the effectiveness of the new relaxation techniques. We have first observed the good performance of the numerical model in problems with interfaces and strong shocks and complex equations of state. Then we have shown the ability of the methods to describe finite-rate mass transfer processes, which for instance is essential for predicting the occurrence of metastable superheated liquid in fast depressurization problems. The capability of approximating efficiently solutions to the \(p\)-relaxed and \(pT\)-relaxed models in the limit of instantaneous mechanical and thermal relaxation has been also demonstrated numerically.

Concerning future work, one objective is to couple the new relaxation techniques with a Table Look-up Method similar to the one that we have developed in [16, 18] to employ a very precise equation of state for water, the IAPWS Industrial Formulation 1997 for Water and Steam [73]. Moreover, we plan to extend the proposed relaxation techniques to the three-phase flow model that we have presented in [54], in particular for applications to underwater explosion problems.

A. Derivation of the \(p\)-relaxed model

In this section we derive the \(p\)-relaxed model in (11) from the two-phase model in (1). For simplicity, we shall consider the one-dimensional case \(d = 1\). We follow in particular the technique of Murrone–Guillard [47] to derive the 5-equation model from the seven-equation model (see also [10]). First, we write the system (1) in one dimension in terms of the vector of primitive variables \(w \in \mathbb{R}^6\) as:

\[
\partial_t w + A(w)\partial_x w = \frac{1}{\tau} \Psi(w) + \Phi(w),
\]

(107a)

where \(\tau \equiv \frac{\tilde{\mu}}{\rho}\) (\(\tilde{\mu}\) is an arbitrary reference quantity to non-dimensionalize \(\mu\)), and

\[
w = \begin{bmatrix}
\alpha_1 \\
\rho_1 \\
\rho_2 \\
u \\
p_1 \\
p_2
\end{bmatrix}, \quad A = \begin{bmatrix}
u & 0 & 0 & 0 & 0 \\
0 & u & 0 & \rho_1 & 0 \\
0 & 0 & u & \rho_2 & 0 \\
u & 0 & 0 & \rho_1 c_1^2 & u \\
0 & 0 & 0 & \rho_2 c_2^2 & u
\end{bmatrix},
\]

(107b)
where we look for solutions in the form \( w = \alpha v \). For any \( v \in \Omega \subset \mathbb{R}^L \) the Jacobian matrix \( d\Xi \) is a full rank matrix, moreover, the column vectors of \( d\Xi \) form a basis of \( \ker(\Psi'(\Xi(v))) \). Now let us define the matrix \( C \in \mathbb{R}^{6\times 6} \):

\[
C = [d\Xi^1 \ldots d\Xi^6 \, v^1 \ldots v^{6-L}]
\]

where \( d\Xi^1, \ldots, d\Xi^6 \) are the column vectors of \( d\Xi \), and \( \{v^1, \ldots, v^{6-L}\} \) is a basis of the range of \( \Psi'(\Xi(v)) \). Based on the observations above, the matrix \( C \) is invertible. Let us now denote with \( P \) the \( L \times 6 \) matrix composed of the first \( L \) rows of the inverse \( C^{-1} \). We have also the following results (see [47]):

\[
P \, d\Xi = I_L \quad \text{and} \quad P \, \Psi'(\Xi(v)) = 0,
\]

where \( I_L \) denotes the \( L \times L \) identity matrix. Now to obtain a reduced pressure equilibrium model we look for solutions in the form \( w = \Xi(v) + \tau z \), where \( z \) is a small perturbation around the equilibrium state \( \Xi(v) \). Using this into the system (107) we obtain

\[
\partial_t (\Xi(v)) + A(\Xi(v)) \partial_x (\Xi(v)) - \Psi'(\Xi(v)) z = \Phi(\Xi(v)) + O(\tau).
\]

Multiplying the above equation by \( P \), by using (109), and by neglecting terms of order \( \tau \), we obtain the reduced model system:

\[
\partial_t v + P A(\Xi(v)) d\Xi \partial_x v = P \Phi(\Xi(v)).
\]

In the limit of instantaneous pressure relaxation we have \( p_1 = p_2 \), hence the vector of the variables of the reduced pressure-relaxed model is

\[
v = [\alpha_1, \rho_1, \rho_2, u, p]^T \in \mathbb{R}^5.
\]

Note that here \( L = 5 \). The equilibrium state \( \Xi(v) \) is defined by:

\[
\Xi : v \mapsto \Xi(v) = [\alpha_1, \rho_1, \rho_2, u, p]^T \in \mathbb{R}^6.
\]

The Jacobian \( d\Xi \in \mathbb{R}^{6\times 5} \) of the Maxwellian is:

\[
d\Xi = \begin{bmatrix}
I_4 & 0 \\
0 & \vdots & 0 \\
0 & 0 & 1 \\
0 & 0 & 0 & 1 \\
\end{bmatrix}
\]

\[
(107c)
\]
A basis $V^1 \in \mathbb{R}^6$, for the range of $\Psi'(\Xi(v))$ is found as

$$V^1 = \begin{bmatrix}
1 & -\frac{\rho_1}{a_1} & -\frac{\alpha_1}{a_1} & \rho_2 & 0 & \frac{\alpha_2}{a_2}
\end{bmatrix}.$$  \hspace{1cm} (115)

Hence we can construct the matrix $C \in \mathbb{R}^{6 \times 6}$, compute the inverse $C^{-1}$, and finally obtain the matrix $P \in \mathbb{R}^{5 \times 6}$ by taking the first 5 rows of $C^{-1}$. We find:

$$P = \begin{bmatrix}
I_{4} & \frac{\alpha_1}{D} & \frac{\alpha_2}{D} & \frac{\rho_1}{D} & \frac{\rho_2}{D} & 0
\end{bmatrix},$$  \hspace{1cm} (116)

where $D$ is given in (12). Finally, the reduced $p$-relaxed multiphase flow model in (11) is obtained from (111) by using the above expression of the matrix $P$ and by evaluating the matrix $A$ and the source term $\Phi$ in the equilibrium state $\Xi(v)$ in (113). Let us also note that we use the relations $\chi_k = c_k^2 - \Gamma_k h_k$ in the entries of $\Phi$ in (107c).

**B. Source terms of the $pT$-relaxed model**

We derive here the expressions (27) appearing in the mass transfer source terms of the four-equation $pT$-relaxed model (21) starting from the ordinary differential equations obtained from (21) for the partial densities and the mixture internal energy:

$$\partial_t(\alpha_1\rho_1) = M,$$  \hspace{1cm} (117a)

$$\partial_t(\alpha_2\rho_2) = -M,$$  \hspace{1cm} (117b)

$$\partial_tE = 0.$$  \hspace{1cm} (117c)

Now we determine the source terms corresponding to the equations for the volume fraction $\alpha_1$, the equilibrium temperature $T$, and the equilibrium pressure $p$. To this aim, we write the transformation matrix $\frac{dq}{dw}$, where

$$\tilde{q} = \begin{bmatrix}
\alpha_1\rho_1 & \alpha_2\rho_2 & \alpha_1\rho_1(p, T) & (1 - \alpha_1)\rho_2(p, T) & \alpha_1\epsilon_1(p, T) + (1 - \alpha_1)\epsilon_2(p, T)
\end{bmatrix}, \quad \text{and} \quad w = \begin{bmatrix}
\alpha_1
\end{bmatrix}.$$  \hspace{1cm} (118)

We have:

$$\frac{d\tilde{q}}{dw} = \begin{bmatrix}
\rho_1 & \alpha_1\phi_1 & \alpha_1\zeta_1 & -\rho_2 & \alpha_2\phi_2 & \alpha_2\zeta_2 & \epsilon_1 - \epsilon_2 & C_{\epsilon\rho} & C_{\epsilon T}
\end{bmatrix}.$$  \hspace{1cm} (119)
where $\phi_k$ and $\zeta_k$ are the derivatives defined in (19) (with $T_k = T$, $p_k = p$, $k = 1, 2$) and

$$C_{Ep} = \alpha_1 \left( \frac{\partial E_1}{\partial T} \right)_p + \alpha_2 \left( \frac{\partial E_2}{\partial T} \right)_p,$$

$$C_{ET} = \alpha_1 \left( \frac{\partial E_1}{\partial p} \right)_T + \alpha_2 \left( \frac{\partial E_2}{\partial p} \right)_T.$$  \(_{(120a)}\)

$$C_{Ep} = \alpha_1 \left( \frac{\partial E_1}{\partial T} \right)_p + \alpha_2 \left( \frac{\partial E_2}{\partial T} \right)_p.$$  \(_{(120b)}\)

The system of ordinary equations for $w = [\alpha_1, T, p]^T$ is then obtained as

$$\partial_t w = \left( \frac{d}{dw} \right)^{-1} \begin{bmatrix} M \\ -M \\ 0 \end{bmatrix} = \begin{bmatrix} \frac{M}{S_a} \\ \frac{S_T}{S_p} \end{bmatrix},$$

\(_{(121)}\)

where

$$S_a = \frac{1}{D_T} [C_{ET}(\alpha_1 \phi_1 + \alpha_2 \phi_2) - C_{Ep}(\alpha_1 \zeta_1 + \alpha_2 \zeta_2)],$$

\(_{(122a)}\)

$$S_T = \frac{1}{D_T} [C_{ET}(\rho_2 - \rho_1) + (E_1 - E_2)(\alpha_1 \zeta_1 + \alpha_2 \zeta_2)],$$

\(_{(122b)}\)

$$S_p = \frac{1}{D_T} [C_{Ep}(\rho_1 - \rho_2) - (E_1 - E_2)(\alpha_1 \phi_1 + \alpha_2 \phi_2)],$$

\(_{(122c)}\)

with $D_T$ given in [27d]. Note that we can write the derivatives of $E_k(p_k, T_k)$ appearing in the expressions above as:

$$\left( \frac{\partial E_k}{\partial T} \right)_{p_k} = \frac{\chi_k}{T_k} \phi_k, \quad \left( \frac{\partial E_k}{\partial p} \right)_{T_k} = \frac{1}{T_k} (1 - \chi_k \zeta_k), \quad k = 1, 2.$$  \(_{(123)}\)

Using this, together with $E_1 - E_2 = \rho_1 h_1 - \rho_2 h_2$ and $h_k = \frac{c_k^2 - \chi_k}{T_k}$, we can rewrite the numerators of [122] and we obtain the expressions reported in [27]. Let us remark that the derivation illustrated above can be extended to the case of constant temperature difference $T_2 - T_1 = \Delta T$ by considering the variables associated to the phase $k$ as functions of $p$ and $T_k$ and by taking for instance $w = [\alpha_1, T_1, p]^T$, with the constraint $T_2 = T_1 + \Delta T$, $\Delta T = \text{constant}$. Let us finally note that the derivation of the homogeneous equations for $\alpha_1, p$ and $T$ of the four-equation $pT$-relaxed model [27] from the seven-equation Saurel–Abgrall model [57] in the limit of instantaneous velocity, pressure, and temperature equilibrium has been presented in [19].

**C. Pressure invariance at interfaces**

It is well known that finite volume conservative schemes for compressible flows may produce spurious pressure oscillations at contact interfaces, as first investigated in [1]. This problem can be easily observed for multi-component flow models, however it appears also when computing single-component flows when non-linear equations of state are used. Indeed this issue is a consequence of the cell-based description of the discrete solution, together with the choice of the conserved variables as principal variables, since the pressure derived from the cell-averaged conserved quantities might differ from the uniform pressure value across contact discontinuities.
Following [1], let us consider an isolated material interface moving in a flow with uniform velocity \(\bar{u}\) between the cells \(i\):

\[
p_i(\rho_k, \bar{E}_k) = \bar{G}_k(\bar{E}_k - \rho_k \bar{E}_k) + \bar{p}_k^n.
\]

Omitting here second-order corrections:

\[
p_i(\rho_k, \bar{E}_k) = \bar{G}_k(\bar{E}_k - \rho_k \bar{E}_k) + \bar{p}_k^n.
\]

Therefore, first we easily verify

\[
u_i^{n+1} = \frac{(\alpha_1 \rho_0^n)_{i+1}}{\rho_i^{n+1}} = \bar{u}, \quad \forall i.
\]

Note that this results for the velocity invariance holds in general for any pressure law. Then we compute the phasic pressures of the homogeneous system solution step by using the equation of state above (124):

\[
p_i^{n+1} = \frac{1}{\alpha_1^{n+1}} \left( \bar{G}_k((\alpha_1 \rho_k)_{i+1} - (\alpha_1 \rho_k)_{i} \bar{E}_k) + \bar{p}_k^n = \bar{p}, \quad \forall i, k = 1, 2. \right.
\]

(ii) Pressure relaxation step and pressure update. Since the solution of the homogeneous system gives \((\rho^0_i)_{i} = (\rho^0_i) = \bar{p}\) for each cell \(i\) of the computational domain, the relaxed volume fraction \(\alpha_1^0\) computed in the mechanical relaxation step is \((\alpha_1^0) = (\alpha_1^0) = (1 - \xi_i)\alpha_1^0 + \bar{p} = \alpha_1^0 + \xi_1\alpha_1^{n+1}.

\[
p_i^{n+1} = \frac{\varepsilon_i^0 - (\alpha_1 \rho_0^n)_{i+1} \bar{E}_i + (\alpha_2 \rho_2^n)_{i+1} \bar{E}_i}{\alpha_1^n T_1 + \alpha_2^n T_2} + \frac{\alpha_1^n \rho_1^n + \alpha_2^n \rho_2^n}{T_1 + T_2}
\]

\[
= \frac{1}{T_1} \left( (1 - \xi_i)\alpha_1^n \bar{p} + \bar{p} \right) + \frac{1}{T_2} \left( (1 - \xi_i)\alpha_2^n \bar{p} + \bar{p} \right) = \bar{p}, \quad \forall i.
\]
Although the pressure invariance is proven here only for a linear equation of state, we have observed numerically by performing numerous tests that no oscillations appear around material interfaces for more general nonlinear pressure laws of the form (32).
