We study the dynamics of few interacting bosons in a one-dimensional lattice with dc bias. In the absence of interactions the system displays single particle Bloch oscillations. For strong interaction the Bloch oscillation regime reemerges with fractional Bloch periods which are inversely proportional to the number of bosons clustered into a bound state. The interaction strength is affecting the oscillation amplitude. Excellent agreement is found between numerical data and a composite particle dynamics approach. For specific values of the interaction strength a particle will tunnel from the interacting cloud to a well defined distant lattice location.

PACS numbers: 67.85.-d, 37.10.Jk, 03.65.Ge

Bloch oscillations\textsuperscript{1} in dc biased lattices are due to wave interference and have been observed in a number of quite different physical systems: atomic oscillations in Bose-Einstein Condensates (BEC)\textsuperscript{2}, light intensity oscillations in waveguide arrays\textsuperscript{3}, and acoustic waves in layered and elastic structures\textsuperscript{4}, among others.

Quantum many body interactions can alter the above outcome. A mean field treatment will make the wave equations nonlinear and typically nonintegrable. For instance, for many atoms in a Bose-Einstein condensate, a mean field treatment leads to the Gross-Pitaevsky equation for nonlinear waves. The main effect of nonlinearity is to deteriorate Bloch oscillations, as recently studied experimentally\textsuperscript{5} and theoretically\textsuperscript{6–8}.

In contrast, we will explore the fate of Bloch oscillations for quantum interacting few-body systems. This is motivated by recent experimental advance\textsuperscript{9} in monitoring and manipulating few bosons in optical lattices. Few body quantum systems are expected to have finite eigenvalue spacings, consequent quasiperiodic temporal evolution and phase coherence. In a recent report on interacting electron dynamics spectral evidence for a Bloch frequency doubling was reported\textsuperscript{10}. On the other hand, it has been also recently argued that Bloch oscillations will be effectively destroyed for few interacting bosons\textsuperscript{11}.

In the present paper we show that for strongly interacting bosons a coherent Bloch oscillation regime reemerges. If the bosons are clustered into an interacting cloud at time $t = 0$, the period of Bloch oscillations will be a fraction of the period of the noninteracting case, scaling as the inverse number of interacting particles (Fig.1). The amplitude (spatial extent) of these fractional Bloch oscillations will decrease with increasing interaction strength. For specific values of the interaction, one of the particles will leave the interacting cloud and tunnel to a possibly distant and well defined site of the lattice. For few particles the dynamics is always quasiperiodic, and a decoherence similar to the case of a mean field nonlinear equation\textsuperscript{12} will not take place.

We consider the Bose-Hubbard model with a dc field:

$$\hat{H} = \sum_j \left[ t_1 \left( \hat{b}^+_{j+1} \hat{b}_j + \hat{b}^+_{j} \hat{b}_{j+1} \right) + E \hat{b}^+_{j} \hat{b}_j + \frac{U}{2} \hat{b}^+_{j} \hat{b}^+_{j} \hat{b}_j \hat{b}_{j} \right] \quad (1)$$

where $\hat{b}^+_{j}$ and $\hat{b}_j$ are standard boson creation and annihilation operators at lattice site $j$; the hopping $t_1 = 1$; $U$ and $E$ are the interaction and dc field strengths, respectively. To study the dynamics of $n$ particles we use the orthonormal basis of states $|k\rangle = |k_1, k_2, ..., k_n\rangle = \hat{b}^+_{k_1} \hat{b}^+_{k_2} ... \hat{b}^+_{k_n} |0\rangle$ where $|0\rangle$ is the zero particle vacuum state, and $k_1 \leq k_2, ... \leq k_n$ are lattice site indices (for instance, in the case of two particles the state representation is mapped to the triangle). The eigenvectors $|\nu\rangle$ of Hamiltonian $H$ evolve with time $t$ and can be used to construct the probability density function $P_j(t)$ for the wave function $|\psi(t)\rangle = \sum_j P_j(t) |j\rangle$ (Fig.1).
tonian (1) with eigenvalues \( \lambda_\nu \) are then given by:

\[
| \nu \rangle = \sum_k A^\nu_k |k \rangle , \quad \hat{H} | \nu \rangle = \lambda_\nu | \nu \rangle
\] (2)

where the eigenvectors \( A^\nu_k \equiv \langle k | \nu \rangle \) and the time evolution of a wave function \( | \Psi(t) \rangle \) is given by

\[
| \Psi(t) \rangle = \sum_\nu \Phi_\nu e^{-i \lambda_\nu t} | \nu \rangle , \quad \Phi_\nu \equiv \langle \nu | \Psi(0) \rangle . \] (3)

We monitor the probability density function (PDF) \( P_j(t) = \langle \Psi(t) | b^+_j b_j | \Psi(t) \rangle /n \), which can be also computed using the eigenvectors and eigenvalues:

\[
P_j(t) = \frac{1}{n} \sum_{\nu, \mu} \Phi_\nu \Phi^*_\mu e^{i (\lambda_\nu - \lambda_\mu)t} \langle \mu | b^+_j b_j | \nu \rangle . \] (4)

In Fig.1 we show the evolution of \( P_j(t) \) for \( U = 3 \), \( E = 0.05 \) and \( n = 1, 2, 3, 4 \) with initial state \( k_1 = k_2 = \ldots = k_n \equiv p \), i.e. when all particles are launched on the same lattice site \( p \). For \( n = 1 \) we observe the usual Bloch oscillations with period \( T = 2\pi /E \) (Fig.1a) and below). Due to the small value of \( E \), the amplitudes of oscillations are large. However, with increasing number of particles, we find that the oscillation period is reduced according to \( 2\pi /nE \), and at the same time the amplitude of oscillations is also reduced.

**One particle case:** For \( n = 1 \) the interaction term in (1) does not contribute. The eigenvalues \( \lambda_\nu = E \nu \) (with \( \nu \) being an integer) form an equidistant spectrum which extends over the whole real axis - the Wannier-Stark ladder. The corresponding eigenfunctions obey the generalized translational invariance \( A^\nu_k = A^\nu_{k+p} \) and are given by the Bessel function \( J_k(x) \) of the first kind

\[
A^\nu_k = J_k \equiv J_{k-\nu}(2/E).
\] (5)

All eigenvectors are spatially localized with an asymptotic decay \( | A^\nu_k \rangle \rightarrow (1/E)^k /k! \), giving rise to the well-known localized Bloch oscillations with period \( T_R = 2\pi /E \). The localization volume \( L \) of a single particle eigenstate characterizes its spatial extent. It follows \( L \sim \frac{\xi}{|E|} \sim |\xi| \) for \( E \rightarrow 0 \) and \( L \rightarrow 1 \) for \( E \rightarrow \infty \). For \( E = 0.05 \) the single particle oscillates with amplitude of the order of \( 2L \sim 160 \) (Fig.1a). According to Eqs. (1) and (3) the probability density function is given by:

\[
P_j(t) = \frac{1}{n} \sum_{\nu, \mu} \Phi_\nu \Phi^*_\mu e^{i (\lambda_\nu - \lambda_\mu)t} \langle \mu | b^+_j b_j | \nu \rangle . \] (6)

**Two particle case** \((n=2)\): For \( U = 0 \) the eigenfunctions of the Hamiltonian (1) are given by tensor products of the single particle eigenstates:

\[
| \mu, \nu \rangle = \sqrt{\frac{2 - \delta_{\mu,\nu}}{2}} \sum_{k,j} J^\mu_k J^\nu_j | b^+_k b_j | 0 \rangle , \quad \mu \leq \nu . \] (7)

The corresponding eigenvalues form an equidistant spectrum which is highly degenerate:

\[
\hat{H} | \mu, \nu \rangle = (\mu + \nu)E | \mu, \nu \rangle
\] (8)

For the above initial condition \( k_1 = k_2 \equiv p \) the expression for the PDF \( \ref{pdf} \) is still valid (actually it is for any number of noninteracting particles), with the same period \( 2\pi /E \) of Bloch oscillations as in the single particle case.

For nonvanishing interaction the degeneracy of the spectrum is lifted, and the eigenvalues of overlapping states are not equidistant any more (Fig.2). Therefore we observe quasiperiodic oscillations which however are still localizing the particles. For even larger values of \( U \) the basis states with two particles on the same site will shift their energies by \( U \) exceeding the hopping \( 2t_1 \). Therefore for \( U > 2t_1 \) the spectrum will be decomposed into two nonoverlapping parts - a noninteracting one which excludes double occupancy and has equidistant spacing \( E \), and an interacting part which is characterized by almost complete double occupancy and has corresponding equidistant spacing \( 2E \), which is the cost of moving two particles from a given site to a neighboring site. Some initial state can overlap strongly with eigenstates from one or the other part of the spectrum, and therefore result in different Bloch periods. In particular, when launching both particles on the same site, one strongly overlaps with the interacting part of the spectrum and observes a fractional Bloch period \( 2\pi / (2E) \).
In order to calculate the amplitude of these fractional Bloch oscillations, we note that for \( E = 0 \) there exists a two-particle bound state band of extended states with band width \( \sqrt{U^2 + 16} - U \). For large \( U \) the bound states are again almost completely described by double occupancy. Therefore we can construct an effective Hamiltonian for a composite particle of two bound bosons:

\[
\hat{H} \approx \sum_j \left[ t_2 \left( \hat{R}_{j+1} \hat{R}_j + \hat{R}_j \hat{R}_{j+1} \right) + 2E_j \hat{R}_j^\dagger \hat{R}_j \right]
\]  

(9)

where \( \hat{R}_j^\dagger \) and \( \hat{R}_j \) are creation and annihilation operators at lattice site \( j \) of the composite particle (two bosons on the same site) with the effective hopping

\[
t_2 = \frac{\sqrt{U^2 + 16} - U}{4}.
\]  

(10)

The corresponding PDF is given by

\[
P_j(t) = \sum_{\nu,\mu} A_p^\nu A_p^\mu A_j^\nu A_j^\mu e^{i2E(\mu - \nu)t}.
\]  

(11)

The composite particle eigenvectors \( A_p^\nu = J_{\nu - p}(2t_2/(2E)) \) are again expressed through Bessel functions, but with a modified argument as compared to the single particle case. Bloch oscillations will evolve with fractional period \( 2\pi/(2E) \) as observed in Fig.1(b). The amplitude of the oscillations is reduced with increasing \( U \) since the hopping constant \( t_2 \) is reduced (Fig.2). For \( U = 3 \) it follows \( t_2 = 0.5 \), and together with the doubled Bloch frequency the localization volume should be reduced by a factor of 4 as compared to the single particle case. This is precisely what we find when comparing Fig.1(a,b): for \( n = 1 \) the amplitude is 160 sites, while for \( n = 2 \) it is 40 sites. In the lower plots in Fig.3 we show the probability density of the wave functions \( |\langle \Psi(t)|k \rangle|^2 \) after one half of the respective Bloch period in the space of the two particle coordinates with \( k_1 = k \) and \( k_2 = m \). For \( U = 0 \) both particles are with high probability at a large distance from each other. Therefore the density is large not only for \( k = m \) (the two particles are at the same site), but also for \( k = 5, m = 85 \) (the two particles are at maximum distance). However, for \( U = 4 \) we find that the two particles, which initially occupy the site \( p = 45 \), do not separate, and the density is large only along the diagonal \( k = m \) with \( 35 \leq k \leq 55 \). (For \( U = 4 \), the localization volume is \( \sim 20 \).) Therefore, the two particles indeed form a composite state and travel together.

\textit{n particle case:} We proceed similar to the case \( n = 2 \) and estimate perturbatively the effective hopping constant for a composite particle of \( n \) bosons. For that we use the calculated width of the \( n \)-particle bound state band for \( E = 0 \) \cite{14}. In leading order of \( 1/U \) it reads

\[
t_n \simeq \frac{n}{U^{n-1}(n-1)!}.
\]  

(12)

For \( n = 2 \) the above expression gives \( t_2 \simeq 2/U \), the first expansion term of the exact relation for two bosons \cite{10}. The corresponding composite particle Hamiltonian

\[
\hat{H} \approx \sum_j \left[ t_n \left( \hat{R}_{j+1} \hat{R}_j + \hat{R}_j \hat{R}_{j+1} \right) + nEj \hat{R}_j^\dagger \hat{R}_j \right].
\]  

(13)

The PDF is given by

\[
P_j(t) = \sum_{\nu,\mu} A_p^\nu A_p^\mu A_j^\nu A_j^\mu e^{i2E(\mu - \nu)t},
\]  

(14)

and the composite particle eigenvectors \( A_p^\nu = J_{\nu - p}(2t_2/(2E)) \). Bloch oscillations will evolve with fractional period \( 2\pi/(nE) \) as observed in Fig.1(c,d). The amplitude of the oscillations is reduced with increasing \( U \) since the hopping constant \( t_n \) is reduced. For \( U = 3 \) and \( n = 3 \) it follows \( t_3 = 0.17 \), and for \( n = 4 \) we have \( t_4 = 0.01 \). This leads to a reduction factor 18 and 400 respectively as compared to the single particle amplitude and yields amplitudes of the order of 9 and 0.5 respectively, which is in good agreement with the numerically observed amplitudes (10 and 2 sites respectively) in Fig.1(c,d).
Tunneling oscillations: For \( n = 1 \) the amplitude of Bloch oscillations is less than one site if \( E \geq 10 \). Thus, for \( n \geq 2 \) and increasing values of \( U \), the amplitude of fractional Bloch oscillations will be less than one site if \( EU^{n-1}(n-1)! \geq 10 \). Then, \( n \) particles launched on the same lattice site \( p \) will be localized on that site for all times. The energy of that state will be \( n((n-1)U/2+pE) \). If however one particle will be moved to a different location with site \( q \), then the energy would change to \((n-1)((n-2)U/2+pE)+qE\). For specific values of \( U \) these two energies will be equal:

\[
(n-1)U = dE, \ d = q - p .
\]  

In such a case, one particle will leave the interacting cloud at site \( p \) and tunnel to site \( q \) at distance \( d \) from the cloud, then tunnel back and so on, following effective Rabi oscillation scenario between the states \( p, p \) and \( [p, q] \). This process will appear as an asymmetric oscillation of a fraction of the cloud either up or down the field gradient (depending on the sign of \( U \)). We calculate the tunneling splitting of these two states using higher order perturbation theory, for an example see Ref.\[13\]. The tunneling time is then obtained as

\[
\tau_{\text{tun}} \simeq \frac{\pi}{\sqrt{n}} E^{d-1} (d-1)! .
\]  

In order to observe these tunneling oscillations, we compute the time averaged second moment \( \mathbb{E}^2 = \sum_j j^2 P_j(t) - \left( \sum_j j P_j(t) \right)^2 \) of the PDF \( P \). Then an effective time-averaged volume of the interacting cloud is taken to be \( L = \frac{1}{12} \mathbb{E}^2 + 1 \). We launch \( n = 2 \) particles at site \( p = 40 \) and plot the ratio \( L(U)/L(U = 0) \) in Fig.4 (blue solid line). We find pronounced peaks at \( U = E, 2E, 3E, 4E \) which become sharper and higher with increasing value of \( U \). As a comparison we also compute the same ratio for the initial condition when both particles occupy neighbouring sites (dashed red line), for which the resonant structures are absent. According to the above, the resonant structures correspond to a tunneling of one of the particles to a site at distance \( d = 1, 2, 3, 4 \). The width of the peaks is inversely proportional to the tunneling time \( \tau_{\text{tun}} \), and the height increases linearly with the tunneling distance \( d \). In the inset in Fig.4 we plot the time evolution of the PDF \( P_j \) for \( U = 19.79 \). We observe a clear tunneling process from site \( p = 40 \) to site \( q = 44 \). The numerically observed tunneling time is approximately 1730 time units, while our above prediction \[10\] yields \( \tau_{\text{tun}} \approx 1666 \), in very good agreement with the observations.

Conclusions. The above findings can be useful for control of the dynamics of interacting particles. They can be also used as a testbed of whether experimental studies deal with quantum many body states. One such testbed is the observation of fractional Bloch oscillations, another one is the resonant tunneling of a particle from an interacting cloud. An intriguing question is the way these quantum coherent phenomena will disappear in the limit of many particles, where classical nonlinear and nonintegrable wave mechanics are expected to take over.
