Cluster mean-field approximations with the coherent-anomaly-method analysis for the driven pair contact process with diffusion

(Dated: March 23, 2022)

The cluster mean-field approximations are performed, up to 13 cluster sizes, to study the critical behavior of the driven pair contact process with diffusion (DPCPD) and its precedent, the PCPD in one dimension. Critical points are estimated by extrapolating our data to the infinite cluster size limit, which are in good agreement with recent simulation results. Within the cluster mean-field approximation scheme, the PCPD and the DPCPD share the same mean-field critical behavior. The application of the coherent anomaly method, however, shows that the two models develop different coherent anomalies, which lead to different critical exponents. The values of the critical exponents for the particle density, the pair density, the correlation length, and the relaxation time are fairly well estimated for the DPCPD. These results support and complement our recent simulation results for the DPCPD.

PACS numbers: 05.70.Ln, 02.60.-x, 64.60.Ht

The absorbing phase transition (APT) has been studied extensively to understand many-body cooperative phenomena in nonequilibrium systems [1]. Up to now, two universality classes have been firmly established: directed percolation (DP) and parity conservation (PC) universality classes [2]. A few other candidates for different universality classes have been reported in recent literatures. One is the DP system coupled with a static conserved field [3]. Although the reported values for the critical indices are rather scattered [4, 5, 6], it is widely believed that these systems form a universality class, different from the DP and the PC class. Another candidate is the pair contact process with diffusion (PCPD) that has as yet defied any consensus on the universality issue. Various scenarios have been proposed, including a new single universality class [7, 8], a marginally perturbed DP process with continuously varying exponents [9], and a DP process with a huge crossover time [10, 11], which are summarized in a recent review [12].

Recently, we studied the driven PCPD (DPCPD) which is a variant of the PCPD by introducing biased diffusion [13]. It is shown that the driving is relevant and the DPCPD exhibits a “mean-field-like” critical behavior even in one dimension. Since the DP class is insensitive to the driving, the DP scenario with a huge crossover time should be eliminated. There was a recent attempt to understand the PCPD using the renormalization group (RG) analysis on a single-species Bosonic action derived from the microscopic master equation. However, it turned out to be improper to describe the critical behavior of the PCPD [14]. In our previous work [15], we pointed out a possible reason for this failure and suggested that the PCPD may be described properly by a field theory with two independent fields. Still, the search for the coarse-grained action adequate for the PCPD remains a challenge.

Besides the RG technique on the proper action [15], there are a few other efficient methods to investigate the absorbing critical phenomena. Numerical simulations along with a finite-size-scaling analysis [16] and direct integrations of corresponding Langevin equations [17] are two typical examples. Another frequently used method is the cluster mean-field (CMF) approximation [18] followed by the coherent-anomaly method (CAM) analysis [19]. This method is known to be effective to obtain a quantitative phase diagram and sometimes even explore a true critical scaling behavior [20]. However, the accurate measurement of critical indices is only limited to rather simple DP systems. More complex critical behaviors like in the PC and the PCPD classes could not have been probed with a reasonable accuracy as yet by the CAM analysis [21, 22].

In this paper, motivated by our recent results that the DPCPD exhibits a distinct critical behavior from the PCPD and also a mean-field-like behavior even in one dimension [13], we develop the CMF approximations for the DPCPD and the PCPD, expecting that the CAM analysis would produce a reasonable estimate for the mean-field-like critical indices of the DPCPD. Also, direct comparison of the CMF data for two models may provide an independent support for different scaling behaviors.

We set up dynamic CMF equations up to $n = 13$ cluster size. The steady-state solutions are obtained within machine accuracy using MATHEMATICA. Dynamic information is also extracted from the smallest eigenvalue of the “linearized” transition matrix. Subsequently, through the CAM analysis, we estimate the values of the critical exponents for the particle density, the pair density, the correlation length, and the relaxation time.

The model is defined on a one-dimensional lattice of $L$ sites with periodic boundary conditions. At each site, there is at most one particle and no multiple occupancy is allowed. Hence the configuration is specified by the occupation number which is either 1 or 0 at every site. Each particle hops to the right (left) with transition rate $D_R$ ($D_L$). The total number of particles in the system varies by branching and annihilating events mediated by
a particle pair \((2A \rightarrow 3A\) and \(2A \rightarrow \emptyset)\). The transition rate is \(p(1-p)\) for the annihilating (branching) event with \(0 \leq p \leq 1\). These three dynamics can be described by the master equation which takes the form

\[
\frac{\partial}{\partial t} |P; t \rangle = -\hat{H}|P; t \rangle,
\]

where \(|P; t \rangle\) is the state vector at time \(t\) and the “Hamiltonian” is written as \(\hat{H} = \sum_{i=1}^{L} \hat{H}_i\) with

\[
\hat{H}_i = D_R(\hat{\rho}_i \hat{v}_{i+1} - \hat{a}_i \hat{a}_i^\dagger + 1) + D_L(\hat{v}_i \hat{\rho}_{i+1} - \hat{a}_i \hat{a}_i^\dagger)
- p(\hat{a}_i \hat{a}_i^\dagger + \hat{v}_{i+1} - \hat{v}_i) \hat{\rho}_i \hat{\rho}_{i+1},
\]

where \(\hat{a}_i(\hat{a}_i^\dagger)\) is the annihilation (creation) operator of hard core particles, satisfying \(\{\hat{a}_i, \hat{a}_j^\dagger\} = 1\) and \([\hat{a}_i, \hat{a}_j] = [\hat{a}_i, \hat{a}_j^\dagger] = 0\) for \(i \neq j\), \(\hat{\rho}_i = \hat{a}_i^\dagger \hat{a}_i\) is the number operator, and \(\hat{v}_i = 1 - \hat{\rho}_i\).

Three different cases arise depending on the values of \(D_R\) and \(D_L\). The case of \(D_R = D_L = 0\) represents the pair contact process (PCP) which has infinitely many absorbing states and is known to belong to the DP class at least for static situations. We skip the analysis of the PCP here. The PCPD corresponds to \(D_R = D_L \neq 0\) and the DPCPD corresponds to \(D_R \neq D_L\). In what follows, we set \(D_R + D_L = 1\) for convenience and \(D_R\) is chosen to be \(1/2\) (1) for the PCPD (DPCPD).

We consider an \(n\)-site probability function \(P_n(\rho; t)\). It is defined as the probability at time \(t\) to find an \(n\)-site cluster of the configurational state \(\rho = (\rho_1, \rho_2, \ldots, \rho_n)\), where an occupational state \(\rho_i\) at site \(i\) takes either 0 or 1. Tracing out Eq. 4 over occupational states outside the cluster \((\rho_i)\) for \(i \leq 0\) or \(i \geq n + 1\), one may find a formal exact expression

\[
\frac{dP_n(\rho; t)}{dt} = \hat{F}_p(P_n, P_{n+1}, P_{n+2}),
\]

where the function \(\hat{F}_p\) involves the sets of \(n\)-(\(n+1\))-, and \((n+2)\)-site probability. Notice that \(P_{n+1}\) and \(P_{n+2}\) terms show up due to the boundary dynamics of the \(n\)-site cluster.

As the infinite hierarchy appearing in Eq. 4 is the major obstacle towards analytic treatment, we need an approximation scheme to truncate the hierarchy at finite \(n\). In this paper, we take the so-called \((n+1, n)\) approximations, where \(P_{n+2}\) and \(P_{n+1}\) are expressed in terms of products of \(P_n\)’s. Then, the rate equations for the \(n\)-site cluster probability function become

\[
\frac{dP_n(\rho; t)}{dt} = F_p(P_n),
\]

where \(P_n\) is now the approximate (mean-field) probability function.

The stationary probability distribution function \(P_n^s(\rho)\) can be obtained by solving the set of coupled equations \(F_p = 0\). For given \(n\), the number of equations and the number of variables are both \(2^n\), but not all are independent. The translational invariance and the normalization condition guarantee that all \(P_n(\rho)\) with \(\rho_1 = 0\) can be expressed in a linear combination of \(P_n(\rho)\)’s with \(\rho_1 = 1\). For example, in case of \(n = 4\), one can easily show that \(P_4(0011) = P_4(0111) = P_4(1011) = P_4(1111) = P_4(1101) = P_4(1100) = P_4(1011)\). The absorbing (vacuum) probability \(P_4(0000)\) can be determined by the normalization condition. Hence the DPCPD case has \(2^{n-1}\) independent variables. In case of the PCPD, the left-right symmetry further reduces the number of independent variables, for example, \(P_3(1101) = P_3(1011)\) and so on.

We use MATHEMATICA to find the stationary solutions \(P_n^s(\rho)\) up to \(n = 13\) with machine accuracy \(10^{-20}\) for given values of parameters, \(p\) and \(D_R\). With \(D_R\), we calculate the particle density \(\rho_s\) and the pair density \(\rho_p\) in the steady state as

\[
\rho_s = P_1^s(1) = \text{Tr}_p P_n^s(\rho)\delta_{pk,1},
\rho_p = P_2^s(11) = \text{Tr}_p P_n^s(\rho)\delta_{pk,1}\delta_{pk+1,1},
\]

where \(k\) and \(k + 1\) denotes an arbitrary site inside the cluster. At a fixed value of \(D_R\), the order parameters, \(\rho_s\) and \(\rho_p\), simultaneously vanish for large \(p\) (pair annihilation rate) and the system exhibits an absorbing phase transition into vacuum at \(p = p_c^s\).

Near the transition point \(p_c^s\), the order parameters scale as

\[
\rho_s \simeq A_n(p_{c}^n - p)^{\beta_1^\text{MF}}, \quad \rho_p \simeq B_n(p_{c}^n - p)^{\beta_2^\text{MF}},
\]

where we find the mean-field values for the order parameter exponents: \(\beta_1^\text{MF} = 1\) and \(\beta_2^\text{MF} = 2\). Figure 1 shows
the $n = 12$ cluster approximation results for the DPCPD. We estimate the critical point $p_c^n$ and the critical amplitudes $A_n$ and $B_n$ by fitting five data near the transition ($|p − p_c^n| ≤ 5 \times 10^{-6}$), linearly for $p_c$ and quadratically for $p$. Our results are tabulated in Table I for the PCPD model and in Table II for the DPCPD model. Notice that the relative errors for $p_c^n$ are extremely small ($\sim 10^{-9}$), but the amplitudes $A_n$ and $B_n$ still have a sizable relative error ($\sim 10^{-4}$).

It is interesting to note that, for $n \leq 3$, the diffusion bias does not enter the CMF rate equations at all. The functional form of $F_p$’s is automatically enforced due to the translational invariance, regardless of the details of the dynamics. For example, $P_3(110) = P_3(11) − P_3(111) = P_3(011)$ and so on. However, for $n \geq 4$, the translational invariance does not guarantee the left-right symmetry, which may be broken by the dynamics with a broken left-right symmetry.

In nonequilibrium systems, dynamic relaxation behavior provides one of the key pieces of information on the system. Off criticality, the order parameters are expected to approach their stationary values exponentially with a characteristic relaxation time $\tau$. At criticality, $\tau$ diverges and the order parameters decay algebraically. One may roughly estimate $\tau$ by numerically integrating the rate equations (8) and fitting time-dependent data into an exponential form. However, this method does not produce high-precision data. In this paper, we propose a different method to calculate $\tau$ with machine accuracy in the CMF approximation scheme.

Since the stationary solutions of Eq. (9) were obtained with machine accuracy, we can linearize Eq. (9) near the stationary solutions very accurately. The linearized equation takes the form

$$\frac{d|P_n;t\rangle}{dt} = -M|P_n;t\rangle,$$

where $|P_n;t\rangle$ is the $(n$-cluster) state vector with the components $P_n(p;t)$ and $M$ is a square matrix. It is trivial to show that the eigenvalues of $M$ are equal to the inverse of various characteristic time scales of the dynamics. The most dominant slow mode is determined by the smallest eigenvalue $\Lambda_s$, i.e., the relaxation time $\tau = \Lambda_s^{-1}$.

We analyze the linearized equation up to $n = 12$. Near criticality, we find

$$\tau^{-1} \simeq C_n(p_c^n − p)^\nu_{\|}^{\text{MF}},$$

where we find again the mean-field value for the relaxation exponent, $\nu_{\|}^{\text{MF}} = 2$. We estimate the critical points $p_c^n$ independently, which are found to be consistent with previous estimates from the density data in Tables I and II, where we also tabulate the estimated values for the amplitude $C_n$ for both the PCPD and the DPCPD.

Now, we employ the coherent-anomaly method (CAM) introduced by Suzuki and co-workers (10) and estimate the values of the true critical exponents. Following the CAM analysis, the $n$ dependence of the critical point $p_c^n$ is predicted in the large $n$ limit as

$$\Delta_{n}^{\nu_{\perp}} \sim n^{-1},$$

where $\Delta_n = p_c^n − p_c$ is the distance of $p_c^n$ from the true critical point $p_c = \lim_{n \to \infty} p_c^n$ and $\nu_{\perp}$ is the true correlation length exponent.

---

**TABLE I:** Cluster approximation results for the PCPD model. The errors are in the last digits.

| $n$ | $p_c^n$ | $A_n$ | $B_n$ | $C_n$ |
|-----|--------|-------|-------|-------|
| 4   | 0.216 140 3513 | 4.254 | 44.37 | 16.69 |

We estimate $p_c$ by applying the Bulirsch and Stoer (or BST) algorithm \cite{26} to the series of $\{p^n_c\}$ and find that $p_c = 0.134(2)$ for the PCPD and $p_c = 0.154(3)$ for the DPCPD, which are in good agreement with simulation results of 0.133 522(2) and 0.151 032(1) \cite{13}. Alternatively, we estimate $p_c$ and $\nu_\perp$ simultaneously using Eq. \ref{eq:1}. In Fig. \ref{fig:3} we plot $\Delta_n$ vs $1/n$ in a log-log plot, varying $p_c$ to find the best power-law fit. For the PCPD, the choice of $p_c = 0.1335$ yields the smallest fitting error with $\nu_\perp = 1.04$, where the data from $n = 8$ to 13 are used. For the DPCPD, the best choice is $p_c = 0.153$ with $\nu_\perp = 1.01$. The relative error for $p_c$ is $\sim 2\%$, and the error for $\nu_\perp$ is $\sim 10\%$. The best simulation result of $\nu_\perp = 1.09(2)$ for the PCPD is within the errors, but the accurate measurement seems to be out of reach with data up to $n = 13$. Our estimate of $\nu_\perp = 1.01$ for the DPCPD is in very good agreement with the expected mean-field value $\nu_{\text{MF}} = 1$.

The amplitudes $A_n$ and $B_n$ are expected to scale as

$$A_n \sim \Delta_n^{-(\beta_{1\text{MF}} - \beta_1)}, \quad B_n \sim \Delta_n^{-(\beta_{2\text{MF}} - \beta_2)},$$

where $\beta_1$ and $\beta_2$ are the true critical exponents for the order parameters. In Fig. \ref{fig:4} the log-log plots of $A_n$ and $B_n$ vs $\Delta_n$ for the PCPD are presented. Here we use $p_c = 0.133 522$ (the best estimate from Monte Carlo simulations) \cite{13}. The CAM analysis leads to $\beta_1 \approx 0.92$ and $\beta_2 \approx 0.49$ \cite{27}, both of which are far from the simulation results of $\beta_1 \approx 0.36(2)$ \cite{3} \cite{4}. In particular, there is a huge discrepancy between the estimated values of $\beta_1$ and $\beta_2$ by the CAM analysis, which warns us that the CAM estimates for the order parameter exponents should be interpreted with great caution. This huge discrepancy also implies that the cluster sizes up to $n = 13$ are still too small for the PCPD to reach the asymptotic regime where the system is dominated by long spatial correlations, induced by the long-term memory mediated by solitary particles \cite{3}.

On the other hand, the CAM analysis for the DPCPD looks consistent with the simulation results. In Fig. \ref{fig:4} we use $p_c = 0.151 032$ \cite{13}. First, $A_n$ seems not diverging as $\Delta_n \to 0$ and reaching a nonzero constant, which implies $\beta_1 = \beta_{1\text{MF}} = 1$. Second, $B_n$ behaves very differently from $A_n$ and diverges with the exponent $\sim 0.92$, which implies that $\beta_2 = \beta_{2\text{MF}} - 0.92 \approx 1.08$. Numerical simulation results \cite{13} are in complete agreement with our CAM results. One should notice that $\beta_2$ does not assume the MF value, but seems to be equal to $\beta_1$ except a probable multiplicative logarithmic correction as found in the exponent $\beta/\nu_\parallel$ by numerical simulations \cite{13}. This mean-field-like behavior is expected for the two-dimensional PCPD \cite{28}, of which the upper critical dimension is believed to be 2. Our CAM results independently support the conclusion drawn from our numerical

![Figure 3](image1.png)  
**FIG. 3:** The CAM analysis for the order parameters for the PCPD model. The slope of the straight line is $-1.51$, which leads to $\beta_1 \approx 0.49$. In the inset, the slope of the straight line is $-0.084$, which leads to $\beta_2 \approx 0.92$.

![Figure 4](image2.png)  
**FIG. 4:** The CAM analysis for the order parameters for the DPCPD model. The slope of the straight line is $-0.92$, which leads to $\beta_2 \approx 1.08$. In the inset, $A_n$ vs $\Delta_n$ is drawn without a log scale. $A_n$ remains nearly constant which implies $\beta_1 \approx \beta_{1\text{MF}} = 1$.

![Figure 5](image3.png)  
**FIG. 5:** The CAM analysis for the relaxation time for the PCPD and the DPCPD. The slope of the straight line for the PCPD (DPCPD) is $-0.2 (-0.02)$ which leads to $\nu_\perp = 1.8 (1.98)$. 

simulations results [13] that the DPCPD critical behavior is distinct from the PCPD behavior and the upper critical dimension for the DPCPD is 1 rather than 2.

Finally, we estimate $\nu_{\parallel}$ from the relation
\[
C_n \sim \Delta_n^{-(\nu_{\parallel,\text{MF}} - \nu_{\perp})},
\]
where $\nu_{\parallel}$ is the true critical exponent for the relaxation time. In Fig. 5, the log-log plots of $C_n$ vs $\Delta_n$ are shown.

We estimate that $\nu_{\parallel} \approx 1.8$ for the PCPD and $\nu_{\parallel} \approx 1.98$ for the DPCPD. Rather surprisingly, the PCPD result is consistent with the simulation result of $\nu_{\parallel} \approx 1.85(10)$ [8, 9]. For the DPCPD, the value of $\nu_{\parallel}$ is quite close to the mean-field value of $\nu_{\parallel,\text{MF}} = 2$, consistent with the simulation results.

In summary, we estimated the critical exponents for the PCPD and the DPCPD, using CMF approximations along with the CAM analysis. For the PCPD, the values of the order parameter exponents are poorly estimated, while the estimates for the correlation and the relaxation exponents are consistent with simulation results within error bars. In contrast, the CAM estimates for the DPCPD are in excellent accord with simulation results, supporting our conjecture that the upper critical dimension of the DPCPD is 1.
