W Mass results from Tevatron and LHC

Alex Melnitchouk for ATLAS, CDF, CMS, D0 and LHCb Collaborations

University of Mississippi, University, Mississippi, 38677, USA

Abstract. Most recent results of W boson mass measurements from Tevatron experiments (CDF and D0) in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ GeV are reported, using 0.2 $fb^{-1}$ and 1.0 $fb^{-1}$ data collected at CDF and D0, respectively. The measurements of W boson properties at LHC experiments (ATLAS, CMS, and LHCb) in $pp$ collisions at $\sqrt{s} = 7$ TeV, using data collected before Summer 2011, are presented. These measurements are essential at the preparation stage of the W boson mass measurements at LHC. Challenges for W mass measurement at the LHC in comparison with the Tevatron are outlined. Prospects for W mass precision with upcoming measurements and its implications are discussed.

1 Introduction

Measurement of the W boson mass ($M_W$) provides us with a uniquely powerful key to uncovering the origin of the electroweak symmetry breaking and learning about new physics. At the loop level, W boson is connected with the top quark and the Higgs boson via the radiative corrections to the W mass. Hence precise measurements of the masses of the top quark and W boson allow us to constrain the most probable mass range of the Higgs boson mass. Current world average for W mass is $80.399\pm0.023$ GeV [1]. Current world average for top quark mass is $173.2\pm0.9$ GeV [2]. These measurements combined with other precision measurements tell us that the mass of the Standard-Model Higgs boson is lower than 161 GeV at 95% confidence level [3]. With improved precision of the W boson mass measurement tighter constraints could be placed on the Higgs boson mass. Compatibility of such tighter constraints from precision data with the results from ongoing direct Higgs boson searches or lack thereof would be a critical piece of information for understanding electroweak symmetry breaking mechanism.

2 Identification of Electrons and Muons at CDF and D0

Electrons are identified as an electromagnetic (EM) cluster reconstructed with a simple cone algorithm. To reduce the background of jets faking electrons, electron candidates are required to have a large fraction of their energy deposited in the EM section of the calorimeter and pass energy isolation and shower shape requirements. Electron candidates are classified as tight if a track is matched spatially to EM cluster and if the track transverse momentum is close to the transverse energy of the EM cluster. In CDF [4] electrons are reconstructed both in the central calorimeter and plug calorimeter ($|\eta| < 2.8$) while electrons in D0 [5] are reconstructed in the central and endcap calorimeters ($|\eta| < 1.05$ and $1.5 < |\eta| < 3.2$). Here $\eta = \ln \tan (\theta/2)$, and $\theta$ is the polar angle with respect to the proton direction. Both CDF and D0 require tight electrons in the central calorimeter ($|\eta| < 1.05$) for $W \rightarrow ee$ candidates. Electron energies are measured with the calorimeter, while electron direction is measured with tracking detectors, using tracks that are matched to electron cluster in the calorimeter.

Muons are identified by a track in the muon system matched to a track in the central tracking system. Measurements include the muons reconstructed in the central muon extension sub-detector which extends the coverage from $|\eta| < 0.6$ to $|\eta| < 1$.

3 Overview of W mass measurement

W boson mass is measured using three transverse kinematic variables: the transverse mass

$$m_T = \sqrt{2p_T^e p_T^\nu (1 - \cos \Delta \phi)}$$

the transverse momentum of the lepton ($p_T^e$) and neutrino ($p_T^\nu$) transverse momentum, where $\Delta \phi$ is the opening angle between the electron (muon) and neutrino momenta in the plane transverse to the beam. Neutrino transverse momentum ($p_T^\nu$) is inferred from the imbalance of transverse energy. We also refer to this observable as missing $E_T$ (MET).

A sophisticated parametrized Monte Carlo simulation is used for modeling these variables as a function of $M_W$. $M_W$ is extracted from a binned maximum-likelihood fit between the data and simulation. Fast simulation includes models of electron (muon), recoil system, and backgrounds. Electron efficiencies, resolution and energy scale parametrizations are tuned to $Z \rightarrow ee$ data.

---

1 electron or muon in the context of this usage, D0 uses only electron channel, whereas CDF uses both electron and muon channels for $M_W$ measurement.
Recoil system represents energy deposited in the calorimeter from all sources except the electron(s). Recoil system consists of three major components: hard recoil (particles that collectively balance the $p_T$ of the W of Z boson), underlying event, and additional interactions. Contribution from the third component depends on the instantaneous luminosity. Hard recoil is modeled using the full detector simulation, while the other two components are described by real data events. Full recoil model is tuned to $Z \rightarrow ee$ data, using imbalance between the Z boson momentum measured with electrons(muons) and with recoil system. Sources of backgrounds to $W \rightarrow e, \mu \nu$ events include $W \rightarrow \tau \nu \rightarrow e, \mu \nu$, QCD, and $Z \rightarrow ee, \mu \mu$ processes.

### 4 Lepton Energy Scale Calibration

Dominant uncertainties in $M_W$ measurements come from lepton energy scale measurements. To first order fractional error on the lepton energy scale translates to fractional error on the W mass [6].

D0 determines electron energy scale using high $p_T$ electrons from $Z \rightarrow ee$ decays. Precision of such calibration is limited mostly by the size of the $Z \rightarrow ee$ sample.

CDF relies on tracking detector for both electron and muon energy scale calibration. First tracking detector is calibrated using $J/\psi \rightarrow \mu \mu$ events. $J/\psi$ invariant mass is measured as a function of muon momentum. Fig. 1 shows the correction needed to make measured $J/\psi$ mass to be at its PDG value (overall offset) and independent of muon momentum (slope). This correction was implemented in the simulation by adjusting the energy-loss model. Then tracker calibration is transported to the calorimeter using $W \rightarrow e\nu$ electrons near the peak of the $E/p$ distribution, shown also in Fig. 1.

### 5 Results and Prospects

$M_W$ results from D0 [7] and CDF [8] along with other $M_W$ measurements and combinations are shown in Fig. 2. D0 result $80.401 \pm 0.021^{(\text{stat})} \pm 0.038^{(\text{syst})}$ GeV = $80.401 \pm 0.043$ GeV agrees with the world average and the individual measurements and is more precise than any other $M_W$ measurement from a single experiment. CDF result $80.413 \pm 0.034^{(\text{stat})} \pm 0.034^{(\text{syst})}$ GeV = $80.413 \pm 0.048$ GeV. Fig. 3 shows a comparison of observables between D0 1fb$^{-1}$ $W \rightarrow e\nu$ data and fast simulation. Fig. 4 shows corresponding muon channel plots for CDF 0.2 fb$^{-1}$ measurement. In both CDF and D0 measurements dominant experimental systematic error is due to lepton energy scale, whereas dominant theoretical error is due to PDFs. Currently both CDF and D0 experiments performed W boson mass measurements only on small fraction of their data. These measurement lead to 31 MeV W mass uncertainty from Tevatron and to world average uncertainty of 23 MeV.

Based on electroweak fits most probable Higgs mass value is 92 GeV, mass region above 161 GeV is excluded at 95% confidence level. If world average uncertainty is

**Fig. 1.** Top: fractional muon momentum correction as a function of inverse momentum. Bottom: ratio of electron energy measured in the calorimeter to electron momentum measured by the tracking system in $W \rightarrow e\nu$ events.

**Fig. 2.** Summary of the measurements of the W boson mass and their average. The result from the Tevatron corresponds to the values which includes corrections to the same W boson width and PDFs. The LEP II results are from [9]. An estimate of the world average of the Tevatron and LEP results is made assuming no correlations between the Tevatron and LEP uncertainties.
reduced to 15 MeV then most probable value and exclusion limit would become 71 GeV and 117 GeV respectively [10]. These estimates are made with the assumptions of no change in the central values of W boson mass and top quark mass and with top quark mass uncertainty of 1 GeV.

With the full Tevatron dataset precision of 15 MeV may be possible [6].

6 $W$ boson measurement at the LHC

$W$ mass measurements at the LHC is expected to involve additional challenges in comparison with the corresponding measurements at the Tevatron. First, much higher number of additional interactions, which produce in the detector large energy deposits, uncorrelated with the $W$ boson. Second, specifics of the $W$ boson production mechanisms.

In case of proton-antiproton collisions $W^+ (W^-)$ is produced with valence $u$ and $\bar{d}$ ($d$ and $\bar{u}$) quarks. Total number of produced $W^+$ and $W^-$ is the same. As the $u$ quark tends to carry a higher fraction of the proton’s momentum than the $d$ quark, the $W^+ (W^-)$ is boosted, on average, in the proton(anti-proton) direction. Hence asymmetry in the production rate between $W^+$ and $W^-$ as a function of $W$ rapidity is observed. However, $W$ boson $p_T$ spectrum, integrated over all rapidities is identical for $W^+$ and $W^-$, in case of proton-antiproton collisions.

In case of proton-proton collisions $W^+ (W^-)$ is produced with valence $u$ and sea $\bar{d}$ quarks (valence $d$ and sea $\bar{u}$) quarks. Qualitatively the same type of asymmetry as a function of $W$ boson rapidity is expected as in case of proton-antiproton collisions. However the shape is expected to differ compared to proton-antiproton collisions since valence quarks and sea quarks have different momentum fraction distributions. Besides the total number of produced $W^+$ is expected to exceed that of $W^-$ since proton contains two valence $u$ quarks and one valence $d$ quark. The inclusive ratio of cross sections for $W^+$ and $W^-$ boson production was measured by CMS to be $1.43 \pm 0.05$ [11]. Moreover, the shapes of $W^+$ and $W^-$ $p_T$ spectra are expected to be different. Hence, they need to be measured and modeled separately. Recently ATLAS measured $W$ boson $p_T$ spectrum [15], shown in Fig. 5 which can be considered first step towards understanding this observable at the precision needed for $W$ mass measurement. Another input needed for $W$ mass measurement is precise knowledge of parton distribution functions (PDFs). Since $W$ charge asymmetry as a function of rapidity is driven by parton distributions, by measuring the asymmetry parton distribution functions can be constrained. Asymmetry in the $W$ boson rapidity distribution has traditionally been studied in terms of charged lepton asymmetry, as $W$ boson rapidity cannot be determined on the event-by-event basis, since neutrino escapes the detection. Charged lepton asymmetry, is the convolution of $W^+$ production and V-A (vector-axial vector) decay asymmetries. Asymmetry is defined as a ratio of difference and sum of positively charged and negatively charged leptons. ATLAS [12], CMS [13] and LHCb [14] already per-
formed first measurements of lepton charge asymmetries\cite{16,17,18}

Since sea quarks are involved in $W$ boson production at the LHC, both charm and strange quarks, unlike at the Tevatron, contribute significantly. PDFs of both charm and strange quarks are currently very poorly constrained. Significant improvements in PDF precision would be needed for precise $W$ mass measurement at the LHC.
