Correlations between $< p_T >$ and jet multiplicities 
from the BFKL chain

Abstract

Strong correlations between the number of emitted jets and their average transverse momentum are found for the events resulting from the exchange of a single BFKL pomeron.

As well-known, strong correlations are observed experimentally between the average $p_T$ and multiplicities of particles produced in high-energy hadronic collisions [1]. Average $p_T$ grows with multiplicity. This fact can be interpreted as a consequence of multiple hard collisions, which result in a larger number of particles produced and a broadening of the $p_T$ spectrum [2]. An alternative interpretation can be given in terms of colour strings which are stretched between the colliding hadrons during the collision. Here larger multiplicities correspond to a larger number of strings, which again leads to a broadening of the $p_T$ spectrum either because of the accumulation of more transverse momentum from the parent partons or because of the interaction between strings [3]. In both cases it is tacitly assumed that with only one hard collision or, alternatively, with only one pair of non-interacting strings there are no correlations between $< p_T >$ and multiplicity. Theoretically this assumption can only be tested within the BFKL dynamics, which presents a detailed description of particle (actually jet) production at high energies under certain simplifying assumptions (a fixed small coupling constant). The present calculation is aimed to see whether there exist correlations between $< p_T >$ and the number of produced jets in the hard pomeron described by the BFKL chain of interacting reggeized gluons.

Our study is closely related to the paper by J.Kwiecinski, C.A.M.Lewis and A.D.Martin, who calculated the exclusive probabilities to observe a given number of jets from the exchanged hard pomeron [4]. We shall extensively use both their method of calculations and some of their parametrizations.

The results we present in this letter demonstrate that, in fact, at realistic energies in the BFKL chain there are strong correlations between the number $n$ of produced jets and the average $< p_T >_n$ for these events. We find that $< p_T >_n$ grows roughly linearly with $n$ with a slope independent of $Q^2$ in deep inelastic scattering (DIS) and of the same value for purely hadronic collisions. The slope diminishes with rapidity $y$. So in the limit $y \to \infty$ the correlations are expected to disappear. However, at $y = 15$ ($x \sim 10^{-7}$) the value of the slope is still $\sim 0.8$ GeV/c. These results leave open the question of correlations between $< p_T >_n$ and $n$ in the soft pomeron and in the colour string at the currently available energies.

1On leave of absence from St.Petersburg State University (Russia)
We start by recalling the main points of the formalism employed in [4] to calculate the exclusive probabilities for the production of a given number of jets. To facilitate comparison with [4] we shall borrow their notations. Let the amputated BFKL amplitude be \( f(y, k) \), when \( y \) is the rapidity and \( k \) is the 2-dimensional transverse momentum of the virtual (reggeized) gluon. Function \( f(y, k)/k^2 \) is interpreted as an unintegrated gluon distribution, related to the conventional gluon distribution by

\[
xG(x, Q^2) = \int Q^2 \frac{dk^2}{k^2} f(\ln \frac{1}{x}, k). \tag{1}
\]

The BFKL equation for \( f \) may be written in the form

\[
f(y, k) = f^{(0)}(y, k) + \bar{\alpha}_s \int_0^y dy_1 \int \frac{d^2k_1}{\pi q^2} \left( \frac{k^2}{k_1^2} f(y_1, k_1) - f(y, k)\theta(k^2 - q^2) \right). \tag{2}
\]

Here \( \bar{\alpha}_s = 3\alpha_s/\pi \), \( q = k - k_1 \) is the transverse momentum of the emitted (real) gluon and it was assumed in [4] that the driving term \( f^{(0)} \) (the impact factor of the target) may also depend on rapidity. To suppress the physically unknown infrared domain and make the equation numerically tractable, the integration over \( k_1 \) was constrained in [4] to the interval

\[
Q_0^2 < k_1^2 < Q_f^2, \tag{3}
\]

with \( Q_0 = 1 \) GeV/c and \( Q_f = 100 \) GeV/c. We shall also impose this constraint, implicit in the following equations.

Defining as an observable jet a real gluon with \( q^2 \geq \mu^2 \), one splits the integration over momenta in (2) into two parts by introducing

\[
\theta(q^2 - \mu^2) + \theta(\mu^2 - q^2) = 1 \tag{4}
\]

inside the integral. The whole integration kernel is thus split into two parts: a resolved one, \( K_R \), corresponding to emitted gluons with \( q^2 > \mu^2 \), and an unresolved one, \( K_{UV} \), which combines emission of gluons with \( q^2 < \mu^2 \) and the subtraction term in (2). Explicitly, the action in the momentum space of the two kernels is described by

\[
\left( K_R f \right)(k) = \bar{\alpha}_s k^2 \int \frac{d^2k_1}{\pi q^2 k_1^2} \theta(q^2 - \mu^2) f(k_1), \tag{5}
\]

\[
\left( K_{UV} f \right)(k) = \bar{\alpha}_s k^2 \int \frac{d^2k_1}{\pi q^2 k_1^2} \left( \theta(\mu^2 - q^2) f(k_1) - \frac{k_1^2}{k^2} \theta(k^2 - q^2) f(k) \right). \tag{6}
\]

Exclusive probabilities to produce \( n \) jets are obviously obtained by introducing \( n \) operators \( K_R \) between the Green functions of the BFKL equations with kernel \( K_{UV} \). If one presents the full gluon distribution \( f \) as a sum of contributions \( f_n \) from the production of \( n \) jets

\[
f(y) = \sum_{n=0} f_n(y), \tag{7}
\]

then one gets a recursive relation

\[
f_n(y) = \int_0^y dy_1 K(y - y_1) f_{n-1}(y_1), \tag{8}
\]

where \( K(y) \) is an \( y \)-dependent operator in the transverse momentum space

\[
K(y) = e^{yK_{UV}K_R}. \tag{9}
\]
Eq. (8) allows to successively calculate the relative probabilities to produce \( n = 0, 1, 2, \ldots \) jets starting from the no-jet contribution determined by

\[
f_0(y) = e^{yK_{UV}} f^{(0)}(0) + \int_0^y dy_1 e^{(y-y_1)K_{UV}} \frac{df^{(0)}(y_1)}{dy_1}.
\]  

(10)

In [4] the driving term was chosen to vanish at \( y = 0 \):

\[
f^{(0)}(y, k) = A(1 - e^{-y})^5 e^{-k^2/Q_0^2}
\]

(its normalization factor is irrelevant for our purpose).

Distributions \( f_n(y, k) \) themselves are not observable quantities. Physical probabilities are obtained by convoluting \( f_n \) with the gluon distribution in the projectile (the projectile impact factor). For the perturbative QCD to be applicable, a reasonable choice is to take the virtual photon as a projectile, as done in [4]. Having in mind that the BFKL picture may only be applied to low values of \( x \), in our calculations we used a simplified expression for the virtual photon impact factor, independent of rapidity, which can be found in [5]. To have some qualitative idea of the situation in purely hadronic collisions, we have also made our calculations for a hadronic projectile with an unperturbative impact factor. For collisions of two identical hadrons it should be identical to the target impact factor which appears as an \( y \)-independent driving term \( f^{(0)}(k) \) in (2).

In both cases the exclusive probabilities to observe \( n \) jets are given by

\[
P_n(y) = \frac{\int (d^2k/k^4) h(k) f_n(y, k)}{\int (d^2k/k^4) h(k) f(y, k)},
\]

(12)

where \( h(k) \) is the impact factor of the projectile. Both impact factors, \( f^{(0)}(k) \) of the target and \( h(k) \) of the projectile, should vanish as \( k \to 0 \). This condition is satisfied by the virtual photon impact factor of [5]. As to the hadronic impact factor \( f^{(0)}(k) \), we have chosen it in close similarity with (11): 

\[
f^{(0)}(k) = k^2 e^{-k^2/Q_0^2}.
\]

(13)

As with Eq. (11), the overall normalization is irrelevant.

We are interested in the average values of \( <q>_n \) in the observed jets, provided their number \( n \) is fixed. At this point one has to remember that the momentum \( k \) which serves as an argument of \( f(y, k) \) refers to the virtual gluon, and not to the emitted one, whose momentum \( q \) is hidden inside the kernel \( K_R \). Therefore, to find an average of any quantity \( \phi(q) \) depending on the emitted real jet momentum, one has to introduce the function \( \phi(q) \) into the integral (5), thus changing the kernel \( K_R \) to the kernel \( K_{av} \) defined by

\[
\left(K_{av.f}\right)(k) = \alpha_s k^2 \int \frac{d^2k_1}{\pi q^2 k_1^2} \theta(q^2 - \mu^2) \phi(q) f(k_1).
\]

(14)

With \( n \) jets, one has to substitute one of the \( n \) operators \( K_R \) which generate the jets by \( K_{av} \), take a sum of all such substitutions, and divide by \( n \). One has further to integrate over all momenta of the virtual gluon \( k \) multiplied by the projectile impact factor, and normalize the result to the total probability to have \( n \) jets.

This recipe can be formalized in the following way. Introduce a generalized operator in the virtual gluon momentum space

\[
K_1(y) = e^{yK_{UV}} [K_R + K_{av}].
\]

(15)

Let the function \( F(y, k) \) obey the equation

\[
F(y) = f_0(y) + \int_0^y dy_1 K_1(y - y_1) F(y_1).
\]

(16)
One can split the function $F$ into a sum of contributions $F_{nm}$ corresponding to the action of $n$ operators $K_1$, out of which $m = 0, 1, ...n$, are operators $K_{av}$:

$$F(y) = \sum_{n=0}^{\infty} \sum_{m=0}^{n} F_{nm}(y). \tag{17}$$

Evidently $F_{00} = f_n$. We are interested in the contribution $F_{n1} \equiv g_n$ which contains a single operator $K_{av}$. The average value of interest is determined by

$$\langle \phi(q) \rangle_n = \frac{1}{n} \int (dk^2/k^4) h(k) g_n(y, k) / \int (dk^2/k^4) h(k) f_n(y, k). \tag{18}$$

In analogy with (8), one easily sets up a recursion relation for $g_n$:

$$g_n = \int_0^y dy_1 K(y - y_1) g_{n-1}(y_1) + \int_0^y dy_1 e^{(y - y_1)K_{UV}} K_{av} f_{n-1}(y_1), \tag{19}$$

with the initial condition $g_0(y) = 0$. Together with (8), this relation allows to calculate the function $g_n$ for $n = 1, 2, ..., $ and then to use (18) to find the desired averages.

The concrete choice of $\phi(q)$ is restricted by the condition of convergence at large $q$: $\phi(q) < q^2$, as $q \rightarrow \infty$. For this reason we take $\phi(q) = q$, so that

$$\left( K_{av} f \right)(k) = \bar{\alpha_s} k^2 \int \frac{d^2 k_1}{\pi k_1^2} \theta(q^2 - \mu^2) f(k_1). \tag{20}$$

We defined our jets by taking $\mu = 2$ GeV/c. As for the cutoffs, we used (3). To see the influence of the cutoffs we also repeated our calculations with $Q_0 = 0.5$ GeV/c and $Q_f = 1000$ GeV/c. The results slightly change in their absolute values (by no more than 1-6%) but both the $n$ and $y$ dependences remain the same.

We have calculated the functions $f_n$ and $g_n$ from Eqs. (8) and (19) up to $n = 5$ and $y = 15$. Following [4] we have used the expansion in $N$ Chebyshev polynomials to discretize the kernels in a simple way. The results we present have been obtained with $N = 80$, although, as pointed out in [4], already $N = 20$ gives a reasonable approximation.

In Figs. 1-3 we present the averages $<q>$ for $n = 1-5$ and $x = e^{-y} = 3.10^{-7}$-0.1, for the $J^* \rightarrow$ hadron collisions at $Q^2 = 10, 100$ and $1000$ (GeV/c)$^2$. In Fig 4 we show these averages for the collisions of two identical hadrons with the impact factor (13). As one observes, in all cases $<q>_n$ strongly grows with $n$ at all rapidities. The growth is approximately linear

$$< p_T |_n \simeq a(y, Q^2) + b(y) n, \tag{21}$$

where both $a$ and $b$ depend on rapidity $y$, but, at fixed $y$, $b$ is universal in the sense that it does not depend on $Q^2$ in DIS and has the same value for pure hadronic collisions. The slope $b(y)$ falls with $y$: it is equal 1.25 GeV/c at $y = 7.5$, and 0.8 GeV/c at $y = 15$, so that one may expect that at ultrahigh energies $<q>_n$ will become independent of $n$.

As an interesting byproduct of our study we find that the averages $<q>_n$ go down with rapidity for all $n \geq 2$. This is quite unexpected, since, as well-known, in the BFKL approach an overall average $<q>$ rapidly grows with $y$ ([6] and Eq. (25) below). It seems that this growth is totally explained by the growth of the average number of jets $<n>$. Passing to discussion, we first point out that it is an open question in which kinematical conditions and to what degree the BFKL pomeron may describe realistic hadronic processes. Emissions of high-$p_T$ jets in $J^*$-hadron collisions seem to be a suitable place to see the BFKL signatures. Our results show that in such emissions strong positive correlations are predicted between $< p_T >$ and the number of jets, already for a single pomeron exchange. This indicates that in fact such correlations do not require multiple rescatterings nor pomeronic interactions. We are interested in the contribution $F_{n1} \equiv g_n$ which contains a single operator $K_{av}$. The average value of interest is determined by

$$\langle \phi(q) \rangle_n = \frac{1}{n} \int (dk^2/k^4) h(k) g_n(y, k) / \int (dk^2/k^4) h(k) f_n(y, k). \tag{18}$$

In analogy with (8), one easily sets up a recursion relation for $g_n$:

$$g_n = \int_0^y dy_1 K(y - y_1) g_{n-1}(y_1) + \int_0^y dy_1 e^{(y - y_1)K_{UV}} K_{av} f_{n-1}(y_1), \tag{19}$$

with the initial condition $g_0(y) = 0$. Together with (8), this relation allows to calculate the function $g_n$ for $n = 1, 2, ..., $ and then to use (18) to find the desired averages.

The concrete choice of $\phi(q)$ is restricted by the condition of convergence at large $q$: $\phi(q) < q^2$, as $q \rightarrow \infty$. For this reason we take $\phi(q) = q$, so that

$$\left( K_{av} f \right)(k) = \bar{\alpha_s} k^2 \int \frac{d^2 k_1}{\pi k_1^2} \theta(q^2 - \mu^2) f(k_1). \tag{20}$$

We defined our jets by taking $\mu = 2$ GeV/c. As for the cutoffs, we used (3). To see the influence of the cutoffs we also repeated our calculations with $Q_0 = 0.5$ GeV/c and $Q_f = 1000$ GeV/c. The results slightly change in their absolute values (by no more than 1-6%) but both the $n$ and $y$ dependences remain the same.

We have calculated the functions $f_n$ and $g_n$ from Eqs. (8) and (19) up to $n = 5$ and $y = 15$. Following [4] we have used the expansion in $N$ Chebyshev polynomials to discretize the kernels in a simple way. The results we present have been obtained with $N = 80$, although, as pointed out in [4], already $N = 20$ gives a reasonable approximation.

In Figs. 1-3 we present the averages $<q>$ for $n = 1-5$ and $x = e^{-y} = 3.10^{-7}$-0.1, for the $J^* \rightarrow$ hadron collisions at $Q^2 = 10, 100$ and $1000$ (GeV/c)$^2$. In Fig 4 we show these averages for the collisions of two identical hadrons with the impact factor (13). As one observes, in all cases $<q>_n$ strongly grows with $n$ at all rapidities. The growth is approximately linear

$$< p_T |_n \simeq a(y, Q^2) + b(y) n, \tag{21}$$

where both $a$ and $b$ depend on rapidity $y$, but, at fixed $y$, $b$ is universal in the sense that it does not depend on $Q^2$ in DIS and has the same value for pure hadronic collisions. The slope $b(y)$ falls with $y$: it is equal 1.25 GeV/c at $y = 7.5$, and 0.8 GeV/c at $y = 15$, so that one may expect that at ultrahigh energies $<q>_n$ will become independent of $n$.

As an interesting byproduct of our study we find that the averages $<q>_n$ go down with rapidity for all $n \geq 2$. This is quite unexpected, since, as well-known, in the BFKL approach an overall average $<q>$ rapidly grows with $y$ ([6] and Eq. (25) below). It seems that this growth is totally explained by the growth of the average number of jets $<n>$. Passing to discussion, we first point out that it is an open question in which kinematical conditions and to what degree the BFKL pomeron may describe realistic hadronic processes. Emissions of high-$p_T$ jets in $J^*$-hadron collisions seem to be a suitable place to see the BFKL signatures. Our results show that in such emissions strong positive correlations are predicted between $< p_T >$ and the number of jets, already for a single pomeron exchange. This indicates that in fact such correlations do not require multiple rescatterings nor pomeronic interactions.
interactions, but they are already present in the basic mechanism of jet production. Obviously, this conclusion cannot be directly applied to particle production in the soft region, and so the empirically invoked absence of such correlations for particle production from the colour string does not really contradict our results. It can only be tested in its own framework by confronting colour string predictions with the experimental data.

Our result (21) has been obtained for relatively small number of jets and at energies corresponding to \( y \leq 15 \). If extrapolated to all \( n \) and energies it would lead to a relation between the overall averages

\[
< p_T > \propto < n > .
\]

However, it is well-known that this relation does not hold in the BFKL model at asymptotic energies, when \( < p_T > \) grows much faster than \( < n > \). This more or less known fact can be demonstrated by a simple calculation. Indeed the inclusive cross-section \( I(y, y_1, q) \) to produce a jet at rapidity \( y_1 \) and with a transverse momentum \( q \), in a collision with an overall rapidity \( y >> 1 \) is given by \([7]\)

\[
I(y, y_1, q) = \frac{\alpha_s}{4\pi} \sigma(y) \frac{1}{q^2} (1 - \Phi(z)),
\]

where

\[
z = b \ln q, \quad b = \sqrt{\frac{y}{ay_1(y - y_1)}}, \quad a = 14\bar{\alpha}_s(3).
\]

Here \( \Phi \) is the error function and \( \sigma(y) \) is the total cross-section. Since \( b \sim 1/\sqrt{y} \ll 1 \), the term with \( \Phi \) is actually important only at large \( \ln q \) when it cuts the distribution in \( q \) at \( \ln q \sim \sqrt{y} \). For this reason the scale of \( q \) is unimportant, so that one may safely fix it by setting \( \mu = 1 \). The average value of any positive power \( \beta \) of the transverse momentum is easily found to be

\[
< p_T^\beta > = \frac{\int_0^y dy_1 \int d^2q q^\beta I(y, y_1, q)}{\int_0^y dy_1 \int d^2q I(y, y_1, q)} = \frac{1}{\lambda^2} e^{\lambda^2 \Phi(\lambda)}, \quad \lambda = (1/2)\beta \sqrt{ay}.
\]

Evidently \( < p_T^\beta > \) grows exponentially with \( y \) for any \( \beta > 0 \).

Thus our results cannot be valid for all \( n \) and energies and refer precisely to the values of \( n \) and energies for which the calculations were done. It is interesting to note that relations similar to (22), with \( < p_T > \) substituted by \( < p_T^2 > \), were earlier obtained from gluon saturation \([8]\), and in the percolation approach \([9]\).

As mentioned, an unexpected result obtained in our calculation is that \( < p_T >_n \) at fixed \( n \geq 2 \) fall with energy. As seen in Figs. 1-4 this fall is not dramatic at energies at which we can expect the BFKL pomeron to be relevant \((y > 10)\). Still, it is quite appreciable, especially in view of the naive belief that the average transverse momentum should grow with energy. This prediction can easily be tested experimentally as a possible signature of the BFKL pomeron.

It is a pleasure to thank C. Pajares for interesting discussions and for pointing out to us some relevant references. We also thank J. Castro and G. Parente for their useful comments. This work was supported by the Secretaría de Estado de Educación y Universidades of Spain and by the RFFI grant 01-02-17137 (Russia).
