ABSTRACT

We present $V$ and $I$ photometry of the resolved stars in the most metal-deficient blue compact dwarf galaxy known, I Zw 18 ($z = 50$), using Hubble Space Telescope/ACS images, the deepest ones ever obtained for this galaxy. The resulting $I$ versus $V − I$ color-magnitude diagram (CMD) reaches limiting magnitudes $V = I = 29$ mag. It reveals a young stellar population of blue main-sequence (MS) stars (age $\lesssim 30$ Myr) and blue and red supergiants (10 Myr $\lesssim$ age $\lesssim 100$ Myr), but also an older evolved population of asymptotic giant branch (AGB) stars (100 Myr $\lesssim$ age $\lesssim 500$ Myr). We derive a distance to I Zw 18 in the range 12.6–15 Mpc from the brightness of its AGB stars, with preferred values in the higher range. Red giant branch (RGB) stars are conspicuous by their absence, although, for a distance of I Zw 18 $\leq 15$ Mpc, our imaging data go $\sim 1$–2 mag below the tip of the RGB. Thus, the most evolved stars in the galaxy are not older than 500 Myr and I Zw 18 is a bona fide young galaxy. Several star formation episodes can be inferred from the CMDs of the main body and the C component. There have been, respectively, three and two episodes in these two parts, separated by periods of $\sim 100$–200 Myr. In the main body, the younger MS and massive post-MS stars are distributed over a larger area than the older AGB stars, suggesting that I Zw 18 is still forming from the inside out. In the C component, different star formation episodes are spatially distinct, with stellar population ages decreasing from the northwest to the southeast, also suggesting the ongoing buildup of a young galaxy.

Subject headings: galaxies: dwarf — galaxies: individual (I Zw 18) — galaxies: ISM — galaxies: photometry — galaxies: starburst — galaxies: stellar content

1. INTRODUCTION

The question of whether there are young galaxies in the local universe forming stars for the first time is of considerable interest for galaxy formation and cosmological studies. There are several reasons for this. First, cold dark matter models predict that low-mass dwarf galaxies could still be forming at the present epoch because they originate from density fluctuations considerably smaller than those giving rise to giant galaxies. Thus, the existence of young dwarf galaxies in the local universe would put strong constraints on the primordial density fluctuation spectrum. Second, while much progress has been made in finding large populations of galaxies at high ($z > 3$) redshifts (e.g., Steidel et al. 1996), truly young galaxies in the process of forming remain elusive in the distant universe. The spectra of those faraway galaxies generally indicate the presence of a substantial amount of heavy elements, implying previous star formation and metal enrichment. Thus, it is important to have examples of bona fide young galaxies in the local universe because they can be used as laboratories to study star formation and chemical enrichment processes in environments that are sometimes much more pristine than those in known high-redshift galaxies. Moreover, their proximity allows studies of their structure, metal content, and stellar populations with a sensitivity, precision, and spatial resolution that faint distant high-redshift galaxies do not allow. Finally, in the hierarchical model of galaxy formation large galaxies result from the merging of smaller structures. These building-block galaxies are too faint and small to be studied at high redshifts, while we stand a much better chance of understanding them if we can find local examples.

The blue compact dwarf (BCD) galaxy I Zw 18 is one of the best candidates for being a truly young galaxy. Zwicky (1966) described it as a double system of compact galaxies, which are in fact two bright knots of star formation with an angular separation of 57′. These two star-forming regions are referred to as the brighter northwest (NW) and fainter southeast (SE) components. They form what we refer to as the main body (Fig. 1). The presence of ionized gas emission (e.g., Hunter & Thronson 1995) and of Wolf-Rayet stars in the NW component (Izotov et al. 1997; Legrand et al. 1997; Brown et al. 2002) suggest active ongoing star formation in the main body. Later studies by Davidson et al. (1989) and Dufour & Hester (1990) have revealed a more complex optical morphology. They pointed out the existence of a prominent diffuse feature $\sim 22''$ NW of the main body, hereafter called the C component (Fig. 1), which contains a blue irregular star-forming region. Dufour et al. (1996a), Izotov & Thuan (1998), and van Zee et al. (1998) have shown the C component to have a systemic radial velocity equal to that of the ionized gas in the main body, thus establishing its physical association to I Zw 18. Furthermore, the interferometric H I map of I Zw 18 by van Zee et al. (1998) has shown
that the C component is embedded in a common H\textsc{ii} envelope with the main body.

I Zw 18 remains the most metal-poor BCD and the lowest metallicity star-forming galaxy known since its discovery by Sargent & Searle (1970). Later spectroscopic observations by Searle & Sargent (1972), Lequeux et al. (1979), French (1980), Kinman & Davidson (1981), Pagel et al. (1992), Skillman & Kennicutt (1993), Izotov & Thuan (1998), and Izotov et al. (1999) have confirmed its low metallicity, with an oxygen abundance of only $\frac{1}{50}$ the solar value.

Many studies have focused on the evolutionary state of I Zw 18. Searle & Sargent (1972) and Hunter & Thronson (1995) have suggested that it may be a young galaxy, recently undergoing its first burst of star formation. The latter authors concluded from Hubble Space Telescope (HST) Wide Field and Planetary Camera 2 (WFPC2) images that the colors of the diffuse unresolved component surrounding the SE and NW regions are consistent with a population of B and early A stars, with no evidence for older stars. From color-magnitude diagram (CMD) studies of the main body based on other HST WFPC2 images, Dufour et al. (1996b) have found that star formation in I Zw 18 began at least 30–50 Myr ago and is still continuing to the present. Aloisi et al. (1999) have estimated an age for the C component not exceeding 200 Myr.

Using integrated optical and NIR photometric colors derived from ground-based and archival HST images, Papaderos et al. (2002) and Hunt et al. (2003) have shown that the age of I Zw 18 as a whole, including both the main body and the C component, does not exceed 500 Myr. This is in agreement with the upper age limits obtained by Hunter & Thronson (1995), Aloisi et al. (1999), and Dufour et al. (1996b), but in contradiction with the large upper age limit of 5 Gyr obtained by Östlin (2000).

Legrand (2000) and Legrand et al. (2000) have proposed an extreme scenario in which star formation in I Zw 18 proceeds not only in recent short episodic bursts but also in a continuous fashion at a low level over a long period of many Gyr. This would result in an extended underlying low surface brightness (LSB) red stellar component in I Zw 18. However, Izotov et al. (2001) and Papaderos et al. (2002) have shown that the

![Fig. 1.—(a): $V$ and (b) $I$ ACS images of I Zw 18. North is up and east is to the left. The contrast has been adjusted to show the features with lowest surface brightnesses. Large supershells of ionized gas can be seen delineating supernova cavities in both the main body and the C component. However, no extended low surface brightness underlying component of red old stars is present. The scale is shown in (a).](image-url)
existence of such a component is supported neither by spectroscopic nor photometric measurements of the extended emission around I Zw 18.

It is evident that, despite considerable work, the debate on the age of I Zw 18 is still not settled. The evolutionary status of I Zw 18 remains elusive because of several limitations in the preceding work. Previous studies of stellar populations in I Zw 18 based on integrated photometric colors or on spectral synthesis do not provide a unique star formation history. CMD studies constrain better the star formation history, but until now the available HST WFPC2 images on which these studies are based did not go deep enough below the tip of the red giant branch (TRGB) to reveal whether a faint old (≥1–2 Gyr) stellar population of red giant branch (RGB) stars exists in I Zw 18 or not. Evidently, deeper HST observations were needed. The installation of the Advanced Camera for Surveys (ACS) on HST in 2003 made those deeper observations possible.

Here we use new deep HST/ACS imaging of I Zw 18 in F and I to go ~1–2 mag below the TRGB and put more stringent constraints on the state of evolution of the BCD. The observations and data reduction are described in § 2. The lack of a RGB population in the CMD of I Zw 18 is examined in § 3. The distance determination to I Zw 18 is discussed in § 4. CMDs of the stellar populations are studied in § 5. We find that I Zw 18 does not contain stars older than ~500 Myr, making it a truly young galaxy. Our results are summarized in § 6.

2 OBSERVATIONS AND DATA REDUCTION

We have obtained HST images of I Zw 18 during the 2003 May 26–June 6 period, in the course of eight visits totaling 25 orbits, with the ACS Wide Field Camera (WFC) detector through filters F555W and F814W, which we refer to hereafter as V and I. The V exposure was obtained during five visits totaling 16 orbits and the I exposure during three visits with a total of nine orbits. All observations were obtained with the same orientation of the field of view, with one exposure per orbit, split into two subexposures to permit cosmic ray removal. Drizzling was applied so that separate exposures obtained during one visit were slightly offset with respect to one another to permit better spatial sampling. The total exposure time was 43520 s (~12.1 hr) in V and 24300 s (~6.8 hr) in I. The galaxy was positioned on the WFC1 frame, with the scale being 0.051 pixel⁻¹.

Preliminary processing of the raw images was done at the Space Telescope Science Institute through the standard pipeline. This resulted in distortion-corrected and drizzled images, six in the V band and three in the I band, which we used in our subsequent reductions with IRAF.² The separate V and I images were then combined with a coregistration better than 0.1 pixel and cosmic rays removed.

The ACS V and I images of I Zw 18 are shown in Figures 1a and 1b, rotated so that north is up and east is to the left. The main body and the C component are labeled in Figure 1b. Their enlarged V and V − I views are displayed in Figures 2a and 2b, and 2c and 2d, respectively. The dark regions in the V − I images correspond to blue colors and the white regions correspond to red colors. The extended and filamentary dark regions in the main body (Fig. 2b) represent ionized gas emission from supernova shells, while extended white sources are background red galaxies. Note the presence of several blue stars at large distances from the main body, suggesting recent or ongoing star formation in the halo. However, the extended halo of red stars, which is a common feature of many dwarf galaxies observed with HST (e.g., in NGC 2366, Thuan & Izotov 2004), is conspicuous by its absence in I Zw 18. No appreciable ionized gas emission is seen in the C component (Figs. 2c and 2d), despite the presence of many blue stars.

The superior spatial resolution of the HST/ACS images permits us to resolve individual stars and study stellar populations in I Zw 18 by means of CMDs. Thanks to the higher sensitivity of the ACS and longer exposure times, our data is considerably deeper than previous HST observations of I Zw 18 with the WFPC2. We used the DAOPHOT package in IRAF to perform point-spread function (PSF) fitting photometry in the sky area shown in Figure 1. Thanks to the drizzling procedure, the several bright and relatively isolated stars around the main body and the C component (Figs. 2a and 2c) allow us to derive reliable and well-sampled stellar PSFs. We obtain full widths at half maximum (FWHM) of the stellar profiles of 2.5 pixels (0.′125) and 2.8 pixels (0.′140) for the V and I images, respectively. As for the aperture radius to use for stellar photometry, we experimented with radii between 2 and 4 pixels to search for the best value giving at the same time a high recovery rate of point sources and small aperture corrections to the derived magnitudes. We find that the best compromise is an aperture radius of 3 pixels (0.′15). With smaller radii, the aperture corrections are too large (the calibrating aperture radius is 0.′5) and introduce unwanted uncertainties in the photometry. With larger radii the number of recovered stars is sharply reduced because of the crowding effect, which is especially important in the main body. The background level was measured in an annulus with radii 4 and 6 pixels (0.′2 and 0.′3) around each source and subtracted. The zero points of the photometry are defined as the magnitude of a star that produces a count rate of 1 electron s⁻¹ in a given filter and are set so that the star Vega has magnitude 0 at all wavelengths. This gives zero points of 25.711 and 25.487 mag for V (F555W filter) and I (F814W filter), respectively.³

Photometric aperture corrections were obtained by a comparison of PSF-fitted magnitudes of 12 bright isolated stars with the magnitudes of the same stars measured with the aperture photometry technique within a 10 pixel (0.′5) aperture. We obtained the corrections VAp(0.′5) − Vfit = −0.18 mag and IAp(0.′5) − Ifit = −0.23 mag. Correction for charge transfer efficiency loss has been carried out according to the prescriptions of Rieess (2003). We find, however, that this effect is negligible (less than 0.01 mag for sources brighter than 29 mag) given the high level of the night sky in our long-exposure images.

To check our photometry, we compare the magnitudes of several bright isolated stars in the main body, measured through a large aperture of 10 pixel radius, with those measured using the same aperture in the WFPC2 images of Hunter & Thronson (1995). We find that our magnitudes are fainter by 0.05 mag in V and I. To put our results on the same scale as the WFPC2 data, we have applied that small correction to our data. Since no photometric correction to infinite aperture is yet available for the ACS data, we have not considered it. In total, taking into account the aperture corrections and the slight shift between the ACS and WFPC2 magnitude scales, the corrections to our

² IRAF is the Image Reduction and Analysis Facility distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy (AURA) under cooperative agreement with the National Science Foundation (NSF).

³ See the Web page at http://www.stsci.edu/hst/acs/analysis/zeropoints.
PSF photometry amount to −0.23 mag in $V$ and −0.28 mag in $I$.

To minimize the number of false detections, we have adopted the minimum detection level to be 3 σ above the sky noise and a sharpness in the −1.0 to +1.0 range. Figure 3 shows the distribution of photometric errors as a function of $V$ and $I$ magnitudes as determined by DAOPHOT. It is seen that errors are ∼0.2 mag at $V = 29$ mag and $I = 28.5$ mag. They increase to ∼0.4 mag at $V = 30$ mag and $I = 29.5$ mag. Note that at bright magnitudes ($V, I \lesssim 27$ mag), the error distribution is very broad at a given brightness because of the effects of crowding, ionized gas emission and a high background level of the unresolved stellar component in the brightest regions of the main body.
The total numbers of recovered stars are 1599, 3555, and 671, respectively, in the $V$ image, the $I$ image, and in both of these images at the same time. We have adopted a matching radius of 1 pixel, although changing that radius within the range 0.5–2 pixels does not appreciably change the number of stars in both $V$ and $I$ frames. That more than half the stars are not matched is likely caused by incompleteness effects and an increasing number of false detections at faint magnitudes. Indeed, the number of the stars with $V = 26–27$ mag recovered in both $V$ and $I$ images is ~74% that recovered in the $V$ image alone, while the number of the stars with $V = 29–30$ mag recovered in both $V$ and $I$ images is only ~5% that recovered in the $V$ image alone.

The transformation of instrumental magnitudes to the Johnson-Cousins $UBVRI$ photometric system as defined by Landolt (1992) was performed according to the prescriptions of Holtzman et al. (1995). The magnitudes and colors of point sources were corrected for Galactic interstellar extinction, adopting $A_V = 0.106$ mag (Schlegel et al. 1998).

We have carried out a completeness analysis using the DAOPHOT routine ADDSTAR. Since the crowding level is more important in the main body than in the C component, the analysis was done for each component separately, in the regions determined by the rectangles in Figure 4. For each frame we have added artificial stars amounting to ~5% of the number of real stars detected inside each rectangle. We then performed a new photometric reduction using the same procedure as that applied to the original frame and checked how many added stars were recovered. This operation was repeated 10 times for each frame and each magnitude bin and the results were averaged. The completeness factor in each magnitude bin, defined as the percentage of recovered artificial stars, is shown in Table 1. It can be seen that the completeness is better for the C component because of its lesser crowding: it is ~69% in $V$ and 44% in $I$ in the 28–29 mag range but drops to ~17% and ~10% in the 29–30 mag range. For the main body, the completeness is ~55% in $V$ and 39% in $I$ in the 28–29 mag range but drops to ~10% and ~5% in the 29–30 mag range.

3. THE LACK OF A RGB STELLAR POPULATION

3.1. The Color-Magnitude Diagram of I Zw 18

Figure 5 displays the combined $I$ versus $V$ CMD for the main body and the C component. The 50% detection limit in both $V$ and $I$ filters is shown by a dashed straight line. Our CMD is more than 2 mag deeper than the CMDs obtained earlier for I Zw 18 (Hunter & Thronson 1995; Dufour et al. 1996b; Aloisi et al. 1999; Oštíl 2000). A well-populated MS can be seen at $V - I \approx 0$ mag, which begins with the brightest stars ($I \approx 23.5$ mag) and goes all the way down to 28.5 mag. Many bright blue loop (BL) and RSG stars with $V - I \gtrsim 0$ mag

| MAGNITUDE | F555W | F814W | F555W | F814W |

are present in the upper part of the diagram. Two clumps of AGB stars with $I_{C24}/C25$ and $I_{C24}/C26$ mag and with $V_{C0}/C0$ redder than 1.0 mag are detected. There is, however, a conspicuous lack of a RGB stellar population, despite the fact that our data, depending on the adopted distance to I Zw 18, goes 1–2 mag fainter than the TRGB. Only a few faint red ($V_{C0}/C0 > 1.3$ mag) sources close to the detectability limit ($I_{C24}/C24 > 26.6$ mag) are present in the combined CMD. They may be false detections because of their faintness in $V$ ($k_{28.5}$ mag). They may also be real stars with erroneous colors due to the large photometric uncertainties (see their error bars in Fig. 5) and/or with colors reddened by dust. Their possible nature is discussed in § 5.2.3.

We have indicated the expected location of the RGB in the CMD by superposing on the data points the isochrone of the very metal-deficient and old globular cluster M15. Its metallicity [Fe/H] = $-2.17$ (Da Costa & Armandroff 1990), lower than the metallicity of the ionized gas in I Zw 18. We have used M15 because it has the lowest metallicity in the Da Costa & Armandroff (1990) globular cluster sample and because its isochrone fits well the RGB of the very metal-deficient BCD UGC 4483 ($Z_{C12}/C12 = -2.3$; Izotov & Thuan 2002). Isochrones of globular clusters with higher metallicities are too red as compared to the data. The dotted, dashed, and solid lines show, from left to right, respectively, the location of the M15 isochrone for three distances of I Zw 18: 10, 12.6, and 15 Mpc, corresponding to distance moduli $m - M = 30.88$, 30.5, and 30.0 mag, corresponding to distances 15, 12.6, and 10 Mpc. Mean error bars as a function of $I$ magnitude are given on the left for MS stars. Error bars for faint ($I > 26.6$ mag) and very red ($V - I > 1.3$ mag) individual sources are also indicated. Also shown is the extinction vector for $A_V = 1$ mag.
The distance-dependent effects of incompleteness due to star fading and crowding have been taken into account. The left and right ordinates in each panel are apparent and absolute magnitudes, respectively. In each panel, the thick line shows the isochrone of the globular cluster M15 ([Fe/H] = −2.17), adjusted for the respective distances. The two parallel lines in (b) and (c) show the CMD region used to construct the histograms of number of stars vs. magnitude in Fig. 8.

First, we consider how the fading of a star affects the detection probability of a star in the CMD of Figure 9. Assuming that UGC 4483 is at the distance of I Zw 18 and that it is observed with ACS, we have to take into account the fading of stars, the increasing errors of the stellar apparent magnitudes, and the incompleteness factors of the ACS observations (Table 1), and 

$$p_{\text{in}}(V + \Delta m, I + \Delta m) = p_{\text{ACS}}(V + \Delta m) \times p_{\text{ACS}}(I + \Delta m),$$

where $p_{\text{ACS}}(V + \Delta m)$ and $p_{\text{ACS}}(I + \Delta m)$ denote the incompleteness factors for the ACS observations (Table 1), and $V + \Delta m$ and $I + \Delta m$ are the magnitudes of a star when moved to the distance of I Zw 18. Although the incompleteness factors are different for the main body and the C component, we have used only the incompleteness factors for the latter in our modeling. This is because the contamination by ionized gas emission in UGC 4483 is more similar to that in the C component than in the main body of I Zw 18, where it is considerably higher.

Next we consider the crowding effect: not all stars that are resolved in UGC 4483 at its distance of 3.4 Mpc will be resolved at the distance of I Zw 18. We assume that this effect is independent of apparent magnitude. In Figure 6 we show the distribution of distances to the nearest companion of each star in I Zw 18 (Fig. 6a) and in UGC 4483 (Figs. 6b and 6c for the parts of the galaxy imaged, respectively, by the PC and by the WF2 + WF3 + WF4 frames, hereafter WF frames). All distances are expressed in ACS pixels. It is seen from Figures 6a and 6b that both stars in a pair are resolved by the ACS and the PC only if their separation is more than 3 ACS pixels. The lower separation limits of the ACS and the PC are similar because their resolutions are nearly the same. On the other hand, in the WFPC2/WF frames, because of their twice as worse angular resolution, both stars in a pair are recovered only if their separation is more than ~6 ACS pixels. Because the linear resolution at a distance of 15 Mpc as compared to one of 3.4 Mpc is 15/3.4 = 4.4 times worse, of the detected stars in UGC 4483 only those in pairs with separations $\geq 3 \times 4.4 \approx 13$ ACS will be resolved at the distance of 15 Mpc. The parts of the distributions occupied by the resolved pairs of stars are shown by shaded regions in Figures 6b and 6c. They correspond to a fraction of stars of ~0.06 for the PC frame and of ~0.51 for the WF frames. The remaining pairs with smaller separations are not resolved. We assume that for those, only one of the two stars in a pair is recovered. This corresponds to a fraction of stars in unresolved pairs of 0.94/2 = 0.47 for the PC frame and of 0.49/2 = 0.25 for the WF frames.

However, these fractions can be even smaller if there are stars close to the unresolved pairs. To estimate this effect, we consider the distribution of separations between the unresolved...
I Zw 18 is a pure Hubble flow velocity.

The redshift distance of I Zw 18 without correction for Virgocentric infall is 10 Mpc. If this distance is correct, then the I magnitude of the TRGB would be ~26 mag, corresponding to the upper extremity of the dotted line in Figure 5; i.e., it would appear brighter than some AGB stars. This seems unlikely, since AGB stars are usually brighter than the TRGB. For example, the AGB stars in the BCD VII Zw 403 that contains numerous RGB stars are ~0.5 mag brighter than the TRGB (Lynds et al. 1998; Schulte-Ladbeck et al. 1998). In another BCD, UGC 4483, the AGB stars are brighter than the TRGB by ~0.7 mag (Izotov & Thuan 2002). Thus, we conclude that a distance of 10 Mpc to I Zw 18 is too small.

There is other evidence that goes in the same sense. Östlin (2000), by correcting the radial velocity of I Zw 18 for Virgocentric infall, obtained $D = 12.6$ Mpc. Izotov et al. (2001)
and Izotov & Thuan (2002) suggested that I Zw 18 should be as distant as 15 Mpc. Thus, Izotov et al. (2001) found that the ionized gas emission seen in the southeastern and central parts of the C component can only be produced by stars with ages less than \( \sim 15 \) Myr or with masses \( \gtrsim 10–15 \, M_\odot \). At a distance of 10 Mpc, the absolute luminosities of the brightest stars in the CMD of the C component would not be large enough for such massive stars (e.g., Aloisi et al. 1999). Furthermore, Izotov & Thuan (2002) have compared the CMDs of 11 galaxies (five BCD and irregular galaxies outside the Local Group and six Local Group irregular galaxies) observed with the HST and found that the absolute magnitudes of the brightest stars in the main body of I Zw 18 would be systematically fainter than those in these galaxies if I Zw 18 is at 10 Mpc, which is not plausible. Increasing the distance of I Zw 18 to 12.6 Mpc still does not match the observations. The youngest bright stars in the CMD of the C component would still have too low absolute luminosities and too large ages (\( \gtrsim 25–30 \) Myr) to account for the ionized gas in the C component.

We estimate the distance to I Zw 18 by comparing the absolute magnitudes of the AGB stars in I Zw 18 with those in other BCDs. In Figure 9 we compare the CMDs of I Zw 18 (Figs. 9a and 9b) and the BCD UGC 4483 (Fig. 9c). We consider two distances for I Zw 18: 12.6 Mpc (Fig. 9a) as proposed by Östlin (2000) and 15 Mpc as proposed by Izotov et al. (2001) and Izotov & Thuan (2002; Fig 9b). As in Figure 7, the scales of apparent magnitudes (left ordinate in each panel) are adjusted so that the absolute magnitude scale (right ordinate in each panel) is the same in all panels. The thick solid line is the isochrone of the globular cluster M15; the dashed line in Figures 9a–9b shows the 50% completeness limit. Two clumps of AGB stars with \( I \sim 25 \) and 26 mag are seen in the CMD of I Zw 18. For each CMD, we have derived the mean magnitudes of the AGB stars in the shaded regions. In the case of I Zw 18, this corresponds to the fainter clump. The short horizontal lines in Figure 9 indicate the mean absolute magnitude of AGB stars thus obtained.

The absence of RGB stars implies that the AGB stars of the fainter clump in I Zw 18 should be at least as bright in absolute magnitude as those in UGC 4483, since they are descendants of more massive stars. However, at the distance of 12.6 Mpc (Fig. 9a), the AGB stars in I Zw 18 are fainter by 0.25 mag than those in UGC 4483 (Fig. 9c). Their absolute magnitudes are similar to those of older AGB stars in the BCD UGC 4483 (Lynds et al. 1998; Schulte-Ladbeck et al. 1998). If we increase the distance of I Zw 18 to 15 Mpc, then the AGB stars in I Zw 18 are 0.13 mag brighter, a much more satisfactory state of affair (Figs. 9b and 9c). In fact, the AGB stars in I Zw 18 and in UGC 4483 have the same absolute magnitudes if the distance to I Zw 18 is 14.1 Mpc, corresponding to a distance modulus of 30.75 mag. Poor statistics of the AGB stars in the CMD of I Zw 18 and uncertainties in their real absolute magnitudes preclude a more precise determination of the distance to the BCD. All we can say is that it is somewhere between 12.6 Mpc and 15 Mpc, with the most likely value being in the upper range.

5. STELLAR POPULATIONS

5.1. Color-Magnitude Diagrams

Our ACS data are considerably deeper than all previous imaging of I Zw 18, obtained with the WFPC2 or NICMOS. For comparison, the faintest red stars with \( I \sim 25 \) mag and \( V – I \gtrsim 1 \) mag in the CMD of Aloisi et al. (1999, their Fig. 7b) correspond to the brightest AGB stars in our CMD (Fig. 5). Likewise, the faintest red stars with \( M_{I \text{F}} \sim -7.5 \) mag (at the distance of 12.6 Mpc) detected by Östlin (2000) correspond to the same brightest AGB stars in our data. These AGB stars are
Fig. 10.—$V-I$ vs. $I$ CMDs for (a) the main body and (b) the C component of I Zw 18, with an adopted distance of 15 Mpc. Left and right ordinates in each panel are the $I$ apparent and absolute magnitudes, respectively. The two stellar clusters in the C component are shown by large filled circles and labeled “C” and “NW” in (b). Superposed are Geneva theoretical isochrones for a heavy-element mass fraction $Z = 0.0004$ (Lejeune & Schaerer 2001). The logarithms of the ages in years for each isochrone are shown in each panel. The dashed line represents the 50% completeness limit of stars in both $V$ and $I$ images.

$\sim 2.5$ mag brighter than the TRGB absolute magnitude of approximately $-5$ mag in the $H$ band (Ferraro et al. 2000; Valenti et al. 2004). Furthermore, the ACS observations of the C component have 2 times better spatial resolution as compared with the previous WFPC2 observations ($0'05$ instead of $0'1$). Thus, there is no doubt that our deep images allow us to study much fainter stellar populations and put more stringent constraints on the evolutionary state of I Zw 18.

We have already discussed in § 3 the absence of a RGB stellar population in I Zw 18. We now examine the stellar populations that are present. The CMDs for the main body and C component are shown in Figures 10a and 10b, respectively. The distance of 15 Mpc to I Zw 18 is adopted hereafter. Overplotted on the data are Geneva theoretical isochrones (solid lines) of single stellar populations for a heavy-element mass fraction $Z = 0.0004$ (Lejeune & Schaerer 2001), which corresponds to the metallicity of the ionized gas in I Zw 18. Each isochrone is labeled by the logarithm of the age in years. We choose to use Geneva instead of Padova isochrones (Girardi et al. 2000) because the latter are not able to reproduce the isochrone of the globular cluster M2 with a similar metallicity, $[[Fe/H]] = -1.58$ (Izotov & Thuan 2002), while the agreement is better with Geneva isochrones.

5.1.1. The Main Body

Several star formation episodes in the main body can be inferred from the CMD in Figure 10a and from other observational data. The ongoing star formation with age $\sim 4$ Myr is evidenced by the ionized gas emission (Figs. 2a and 2b) and the presence of WR stars in the NW component (Izotov et al. 1997; Legrand et al. 1997), located in two compact clusters (Brown et al. 2002). The brightest post-MS star in the CMD with an absolute magnitude $M_I \sim -9.7$ mag and an age of $\sim 5$–6 Myr is also part of the present burst. Numerous supergiants with $M_I \sim -8$ mag indicate that intense star formation occurred $\sim 10$–15 Myr ago. There is evidence for two older star formation events in the CMD. A first star formation episode occurred $\sim 200$ Myr ago, as indicated by the bright AGB stars with $M_I \sim -6$ mag. A second star formation happened $\sim 300$–500 Myr ago, which is responsible for the oldest stars in the main body, the AGB stars with $M_I \sim -5$ mag. These age estimates are in agreement with the previous CMD analyses by Hunter & Thronson (1995), Dufour et al. (1996b), and Aloisi et al. (1999), although those authors discussed only one previous star formation episode because their data did not go as deep as ours and the 300–500 Myr old AGB stars were not seen. Most importantly, no old AGB stars with ages $\geq 1$ Gyr are seen, contrary to the assertion of Östlin (2000) on the basis of his HST NICMOS CMD. The presence of such old AGB stars would have required numerous RGB stars that are not present in our CMD.

5.1.2. The C Component

We turn next to the stellar populations in the C component. Here there is no substantial ongoing massive star formation, since intense ionized gas emission is not seen. This is corroborated by the upper part of the CMD, which is nearly devoid of bright stars (Fig. 10b). The lone bright source and the brightest one in the CMD, at $I \sim 22$ mag (shown by a large filled circle in Fig. 10b and labeled “C” in Figs. 2c and 10b), is in fact not a single star but represents the central cluster discussed by Dufour et al. (1996b). It is partially resolved in our images with a FWHM $\sim 0'15$, corresponding to a linear size of $\sim 10$ pc. There is a second resolved cluster (also shown in Fig. 10b by a large filled circle and labeled “NW” in Figs. 2c and 10b) with a FWHM $\sim 0'21$, corresponding to a linear size of $\sim 15$ pc. It was also noted by Dufour et al. (1996b).
Two star formation episodes can be deduced from the CMD. The most recent one happened \( \sim 15–20 \) Myr ago, while the older one took place \( \sim 200–300 \) Myr ago. There is an indication that the C component is slightly younger than the main body because its oldest AGB stars are slightly brighter on average (by \( \sim 0.2 \) \( \text{mag} \)). Our age estimates for the C component are also in agreement with those of Dufour et al. (1996b) and Aloisi et al. (1999) based on the HST WFPC2 data.

### 5.1.3. Individual Regions

In Figure 11 we show CMDs for the different regions in the main body and in the C component as delimited in Figure 4. Ongoing and recent past star formation in the main body is mainly localized in the MII region associated with the SE component and in the MIII region associated with the NW component. This is evidenced by the presence of numerous bright MS (age \( \lesssim 10 \text{ Myr} \)) and BL + RSG (10 Myr \( \lesssim \text{age} \lesssim 100 \text{ Myr} \)) stars in both CMDs (Figs. 11b–11c). Some AGB stars are also present in region MII. On the other hand, only a few RSG stars are seen in the CMD of the southernmost region MI. The population of AGB stars is more numerous there, indicating older star formation (age \( \gtrsim 100 \text{ Myr} \); Fig. 11a).

In the CMD of the southernmost region Cl of the C component (Fig. 11d) only stellar populations with ages \( \lesssim 100 \text{ Myr} \) are present. The age of the youngest stars in this region is \( \sim 15–20 \) Myr, as evidenced by the brightest post-MS stars (\( M_I \sim -8 \text{ mag} \)) in the CMD and the presence of weak H\( \beta \) and H\( \alpha \) emission lines in its spectrum (e.g., Izotov et al. 2001). In the central region CII (Fig. 11e), older stars with ages \( \sim 200–300 \) Myr are present. There is a population of younger stars, with ages \( \sim 30 \text{ Myr} \) as deduced from the \( M_I \sim -6.4 \text{ mag} \) of the brightest post-MS stars. Although they are not resolved, the youngest stars (age \( \sim 15 \text{ Myr} \)) are likely present in the central cluster, as evidenced by the presence of ionized gas emission there (Dufour et al. 1996b; Izotov et al. 2001). Region CIII is the oldest (age \( \gtrsim 300 \text{ Myr} \)) region in the C component (Fig. 11f). There is no recent star formation here, since no bright MS star is seen. The AGB stars are fainter than those in region CII, also suggesting a larger age. Probably, the youngest object in region CIII is the NW stellar cluster. However, the absence of ionized gas emission around this cluster (Dufour et al. 1996b) and its relatively red \( V - I \) \( \gtrsim 0.35 \text{ mag} \) (Fig. 11f) implies that its age is \( \gtrsim 100 \text{ Myr} \).

### 5.1.4. The Age of I Zw 18

All previous CMD studies of I Zw 18 did not go deep enough to allow the setting of an upper limit to its age. Our new deep ACS images permit us to do so. For the distance of I Zw 18 in the range between 12.6 and 15 Mpc, no RGB stars are seen in our CMDs and the age upper limit can be set to \( 1–2 \) Gyr. However, the real age for I Zw 18 is likely smaller, since only stars with ages \( \lesssim 500 \text{ Myr} \) are present (Figs. 10 and 11). This age upper limit of \( \sim 500 \text{ Myr} \) is in excellent agreement with the age estimates obtained by Papaderos et al. (2002) and Hunt et al. (2003) by examining the integrated optical and NIR colors of I Zw 18.
While we favor a distance of 1 ZW 18 in the upper range of the 12.6–15 Mpc interval, our conclusions will be re-enforced if the smaller distance of 12.6 Mpc is adopted for the BCD. In this case, it would be easier to detect faint RGB stars, since the apparent magnitude of the TRGB would be up to 0.38 mag brighter (compare Figs. 9 and 10 with the simulated CMDs for UGC 4483 in Figs. 7 and 8). The ages of the oldest stellar populations will increase at most by a few hundred Myr. However, we have argued in § 4 that such a small distance would not be in agreement with photometric and spectroscopic observations of 1 ZW 18.

5.2. Spatial Distributions

The spatial distributions of stars with different ages in 1 ZW 18 can give useful information on its star formation history. To carry out the study, we divide the stars in the CMD in Figure 5 into three categories: (1) MS stars with $V - I < -0.05$ mag, (2) BL stars with $-0.05 \text{ mag} \leq V - I < 0.4 \text{ mag}$ and RSG stars with $I < 24 \text{ mag}$ and $V - I \geq 0.4 \text{ mag}$, and (3) AGB stars with $26.4 \text{ mag} \leq I \leq 24 \text{ mag}$ and $V - I \geq 0.8 \text{ mag}$. We have also included in the last category the progenitors of the AGB stars located in the lower right corner of the CMD with $26.4 \text{ mag} \leq I \leq 27.5 \text{ mag}$ and $0.6 \text{ mag} \leq V - I \leq 1.2 \text{ mag}$. The boundaries of the regions in the CMD of 1 ZW 18 where these stars are located are shown in Figure 5.

The spatial distributions of different types of stars are displayed by in Figures 12a–12d. The open circles indicate the locations of the NW and SE components in the main body and of the central cluster in the C component. In the main body, the younger MS and BL + RSG stars are distributed in larger areas as compared to the older AGB stars (compare b and c with d), suggesting that 1 ZW 18 is building up from the inside out. In the C component, stars of different ages are located in different regions, reflecting the stochastic mode of star formation in BCDs and also suggesting the ongoing formation of 1 ZW 18. The scale is shown in (a). North is up and east is to the left.

![Spatial distributions of stars](image)

Fig. 12.—Spatial distributions of (a) stars of all types, (b) MS stars, (c) BL and RSG stars, and (d) AGB stars in 1 ZW 18 (date). Crosses in (d) show faint red stars with $I > 26.6 \text{ mag}$ and $V - I > 1.3 \text{ mag}$ (see the points with error bars in Fig. 5). Open circles show the locations of the NW and SE components in the main body and of the central cluster in the C component. In the main body, the younger MS and BL + RSG stars are distributed in larger areas as compared to the older AGB stars (compare b and c with d), suggesting that 1 ZW 18 is building up from the inside out. In the C component, stars of different ages are located in different regions, reflecting the stochastic mode of star formation in BCDs and also suggesting the ongoing formation of 1 ZW 18. The scale is shown in (a). North is up and east is to the left.

5.2.1. The Main Body

In the main body, the MS and BL + RSG stars (Figs. 12b and 12c) are distributed uniformly, suggesting that ongoing and recent past star formation took place over the whole body.
On the other hand, the AGB stars are mainly located in the southeastern part (Fig. 12d). This was noted earlier by Aloisi et al. (1999) and Izotov & Thuan (2002) on the basis of WFPC2 images. The absence of AGB stars in the northwestern region may be caused in part by a more severe crowding and a larger contribution of ionized gas emission in the V image (Figs. 2a and 2b). This may make DAOPHOT miss more of the AGB stars, since they are fainter in V than the MS and BL + RSG stars. However, we believe that some of the effect is real. The most striking feature is that the older AGB stars are not more spread out spatially than the younger stars, a fact already noted by Izotov & Thuan (2002). Such a distribution is drastically different from the situation in other galaxies, where the old AGB and RGB stars are distributed over a considerably larger area as compared to younger stars because of diffusion and relaxation processes of stellar ensembles. If anything, the reverse appears to be true here: the MS and BL + RSG stars are distributed over a larger area around the main body as compared to the AGB stars. This suggests that the star formation in the past responsible for the AGB stars was more concentrated in the main body, while recent star formation responsible for the MS and BL + RSG stars is more spread out. Evidently, I Zw 18 is a galaxy in the process of forming from the inside out.

The absence of a halo of AGB stars and of their progenitors around I Zw 18, despite easier detectability at large distances because of less crowding, is in direct contradiction to the scenario of Legrand (2000) and Legrand et al. (2000). These authors have proposed that continuous low-mass star formation has proceeded in I Zw 18 on cosmological timescales in a large area around the main body. They predict the existence of a red extended underlying stellar component that Kunth & Östlin (2000) claim to have detected from their optical and NIR surface photometry but which was not confirmed by independent photometry by Papaderos et al. (2002) and Hunt et al. (2003). In fact, the spatial distributions in Figure 12 suggest that the AGB stars in the main body are relatively young and have had no time to migrate to large distances (cf. Izotov & Thuan 2002).

5.2.2. The C Component

In the C component, the spatial distributions of the different types of stars are very different from those in the main body. The MS stars are seen primarily in the southeastern part and are nearly absent in the northwestern part (Fig. 12b). The BL + RSG stars are also mainly distributed in the southeastern part; however, their location is offset as compared to the MS stars: the MS stars are mostly aligned in the east-west direction while the BL + RSG stars are mainly distributed in the southeast-northwest direction. On the other hand, AGB stars are located principally in the northwestern part. Some of these stars are also present to the south of the central cluster. It appears that the two major episodes of star formation in the C component have occurred in spatially different regions. This is characteristic of the mode of star formation in BCDs, where the centers of star formation move about in a stochastic manner. This also implies that, as for the main body, the formation of the C component is still proceeding. It started in the northwestern part ~200–300 Myr ago, lasting for a relatively short period, and continues now in the southeastern part. That MS stars are not seen in the northwestern part does not mean that such stars are not present there. They are simply too faint to be detected because the MS turnover for a 200–300 Myr old stellar population is $M_V \sim -1$ mag (e.g., Girardi et al. 2000) or $I \sim 30$ mag, below the detectability limit. The absence of MS stars also means that no detectable star formation has occurred during the last ~200 Myr in the northwestern part. One possible exception is the NW cluster with the age $\gtrsim 100$ Myr. On the other hand, the absence of AGB stars in the southeastern region, where MS stars reside, suggests that this region is younger, with an age $\lesssim 100$ Myr. A similar age estimate was made by Izotov et al. (2001) from a spectroscopic study.

5.2.3. Faint Red Stars

Finally, we consider the spatial distribution and nature of the few faintest ($I > 26.6$ mag) and reddest ($V - I > 1.3$ mag) sources in the CMD of Figure 5. They are shown by crosses in Figure 12d. A few of these sources are scattered in the field and are likely false detections. Two others are in the C component, while the remaining six are in the southeastern part of the main body. Their $V - I$ colors are redder than those of globular cluster stars in M15. The location of some of these sources in the CMD of the main body to the right of the 10 Gyr Geneva theoretical isochrone with $Z = 0.0004$ (Fig. 10a) implies that they are older than the universe, which is absurd. The situation is worse when Padova isochrones are used. Thus, we conclude that the red colors of the faint sources are not due to their large ages but to some other reason. Their very red $V - I$ colors may be explained in part by large photometric uncertainties, which at these faint magnitudes can reach $\pm 0.5$ mag (see the error bars in Fig. 5). Furthermore, these sources may be reddened by dust known to be present in the main body, with a maximum extinction $A_V \sim 0.5$ mag in the southeastern part (Cannon et al. 2002). However, this value is derived over large areas, and the extinction can be clumpy and significantly higher on small scales. It is seen from Figure 5 that correction for interstellar reddening with $A_V \gtrsim 1$ mag will move all red faint sources in the CMD region where stars with ages $\lesssim 500$ Myr reside. In any case, the faintness of these sources and the unknown distribution of extinction on small scales in the main body and in the C component precludes a more reliable explanation of their nature.

5.3. Surface Brightness and Color Distributions

Another way to study the properties of stellar populations is to consider their integrated characteristics as given by the surface brightness and color profiles in different regions of the galaxy. The advantage of this approach is that it includes both resolved and unresolved stars. The disadvantage is that populations with different ages contribute to the integrated light and assumptions have to be made on the star formation history to derive the age distribution of stars.

In Figure 13, we show the $V$ (Fig. 13a) and $I$ (Fig. 13b) surface brightness and $V - I$ (Fig. 13c) color distributions averaged over a $7''$ wide strip along the position angle $-47^\circ$ connecting the main body and the C component. The origin is taken to be at the center of the NW component of the main body. Surface brightnesses and colors have been transformed to the standard $VI$ photometric system according to the prescriptions of Holtzman et al. (1995) and have been corrected for Galactic extinction with $A_V = 0.106$ mag (Schlegel et al. 1998). The NW and SE components of the main body and the central cluster in the C component are labeled in each panel. The bluest color, approximately $-0.5$ mag, is in a region $\sim 3''$ northwest of the NW component. The equivalent width of the He I emission line in this region exceeds 1000 $\AA$ (Izotov et al. 2001) and hence the blue color is due to ionized gas emission. Other regions in the main body with $V - I$ as blue as $\sim -0.3$ to $-0.4$ mag are also strongly contaminated by ionized gas emission. The only region in the main body free of ionized gas
emission is the southernmost one (region MI), which, with \( V - I \approx 0.3 - 0.4 \) mag, is the reddest part in I Zw 18. In the C component, the contribution of ionized gas emission is negligible (Izotov et al. 2001) and the bluest color \( V - I \approx 0 \) mag in the southeastern part (region CI) really reflects that of a young stellar population. The reddest color \( V - I \approx 0.2 - 0.3 \) mag is in the northernmost part of the C component. It is slightly bluer than the color of the reddest region in the main body, suggesting that the C component may be slightly younger than the main body. The surface brightness profiles also show the absence of an extended LSB component, with a precipitous drop of 6 mag from the NW component to the edge of the galaxy over a distance \( \sim 10^6 \) or 750 pc.

To model the colors of the reddest regions in I Zw 18, we use spectral energy distributions of single stellar populations with a heavy-element mass fraction \( Z = 0.0004 \), calculated with the PEGASE.2 code of Fioc & Rocca-Volmerange (1997). Because Geneva stellar evolutionary models (Lejeune & Schaerer 2001) do not include AGB stars, the Padova models (Girardi et al. 2000)\(^4\)\footnote{See http://pleiadi.pd.astro.it.} are used. The Salpeter initial mass function (IMF) with a slope \( \alpha = -2.35 \) and lower and upper stellar mass limits of 0.1 and 120 \( M_\odot \), respectively, are adopted. The models predict that the \( V - I \) color of an instantaneous burst with age between 200 and 500 Myr is \( \sim 0.5 \) mag, or \( \sim 0.1 - 0.2 \) mag redder than the observed reddest color. Only for an instantaneous burst with age \( \lesssim 150 \) Myr, several 100 Myr smaller than the CMD-derived ages, are the modeled colors consistent with the observed ones. We have also considered the case of continuous star formation. If star formation has occurred at a constant rate continuously during the period 50–160 Myr ago, then the \( V - I \) color is \( \sim 0.35 \) mag, in agreement with the observed value. But the upper age limit is again significantly lower than the CMD-derived ages. We can increase the upper age limit for continuous star formation to make it consistent with the CMD-derived value of \( \sim 500 \) Myr, but to reproduce \( V - I \approx 0.35 \) mag we must at the same time decrease the lower age limit to \( \sim 10 \) Myr. In this case young massive stars should be present in the reddest regions of I Zw 18, and they are not seen.

A possible cause for the color discrepancy may be that the metallicity of stars in I Zw 18 is not equal to the metallicity of the ionized gas as assumed, but lower. We have checked this possibility with models that are 4 times as metal-poor (\( Z = 0.0001 \)). The \( V - I \) does become bluer, but the bluing is not sufficient. For instantaneous bursts with ages in the range 200–500 Myr, \( V - I \approx 0.46 \) mag, still too red when compared to the observed value. We have also varied the parameters of the IMF for a single stellar population with a heavy element mass fraction \( Z = 0.0004 \). Making the slope flatter or steeper with \( \alpha \) in the range \(-2 - 3\) and increasing the lower mass limit from 0.1 to 1 \( M_\odot \) does not result in a significantly bluer \( V - I \) color. The \( V - I \) colors are in the range 0.45–0.50 mag for instantaneous bursts with ages in the range 200–500 Myr. We conclude from the previous considerations that, despite the uncertainties of the models and the fact that they cannot reproduce precisely the observed reddest colors in I Zw 18, they do predict young ages that are in the ballpark of CMD-derived ages.

6. SUMMARY

We present a photometric study of the resolved stellar populations in I Zw 18, the most metal-deficient blue compact dwarf (BCD) galaxy known. The analysis of the color-magnitude diagram (CMD) of I Zw 18, based on Hubble Space Telescope/Advanced Camera for Surveys \( V \) and \( I \) images, the deepest ever obtained for the BCD, have led us to the following conclusions:

1. The CMD of I Zw 18 is populated by stars with different ages, including the youngest hydrogen core burning main-sequence (MS) stars (age \( \lesssim 30 \) Myr), evolved massive stars with helium core burning (blue loop [BL] stars and red supergiants [RSG]) with ages between 10 and 100 Myr, and asymptotic giant branch (AGB) helium shell–burning stars with ages between 100 and 500 Myr. However, I Zw 18 is the first galaxy with resolved stellar populations where no red giant branch (RGB) stars are seen, although our data go 1–2 mag deeper than the tip of the RGB for a distance of I Zw 18 in the range 12.6–15 Mpc (see conclusion 2). The oldest stars, located mainly in the southeastern part of the main body and the northeastern part of the C component, have an age not exceeding \( \sim 500 \) Myr. Thus, I Zw 18 is a bona fide young galaxy.

2. Since no RGB stars are seen, we cannot use the brightness of the tip of the RGB to derive the distance to I Zw 18. Instead, we compare the brightness of the AGB stars in I Zw 18 with those in the very metal-deficient BCD UGC 4483 with a heavy-element abundance of \( Z/23 \) to derive a distance in the range 12.6–15 Mpc, with the most likely value in the upper range.
3. Several star formation episodes in I Zw 18 can be inferred from its CMD. However, star formation proceeds differently in the main body and in the C component. In the main body, three star formation episodes are indicated, separated by periods of 100–200 Myr. Examination of the spatial distribution of the stellar populations suggests that the star formation process is still gradually building up the main body from the inside out as the young MS and BL + RSG stars occupy larger areas as compared with the older AGB stars. In the C component, two star formation episodes are inferred, separated by a period of 200 Myr. These separate star formation episodes occurred in spatially different regions, reflecting the stochastic mode of star formation in BCDs. The southeastern region of the C component is a few hundred Myr younger than the northwestern region. Both in the main body and in the C component, the spatial distributions of the stellar populations in I Zw 18 strongly suggest that the galaxy is still in the process of forming.
