Oliveira, and Marciano V. Paes

Dengue is a mild flu-like arboviral illness caused by dengue virus (DENV) that occurs in tropical and subtropical countries. An increasing number of reports have been indicating that dengue is also associated to neurological manifestations, however, little is known regarding the neuropathogenesis of the disease. Here, using BALB/c mice intravenously infected with DENV-2 strain 66985, we demonstrated that the virus is capable of invading and damaging the host’s central nervous system (CNS). Brain and cerebellum of infected animals revealed histological alterations such as the presence of inflammatory infiltrates, thickening of pia matter and disorganization of white matter. Additionally, it was also seen that infection lead to altered morphology of neuroglial cells and apoptotic cell death. Such observations highlighted possible alterations that DENV may promote in the host’s CNS during a natural infection, hence, helping us to better understand the neuropathological component of the disease.

Dengue is a mosquito-borne disease that represents a major health problem especially in tropical and subtropical regions worldwide. The disease is caused by dengue virus (DENV), which comprises four antigenically different serotypes (DENV-1 to DENV-4) belonging to the Flaviviridae family. Dengue burden has been expanding since 1960s as it grew side by side with the world’s population. Nowadays, around 390 million people are infected every year, of which about 25% are of clinical relevance. Symptoms of dengue are usually similar to the regular flu, however, a small fraction of cases may evolve to a severe hemorrhagic form that is eventually responsible for about 20,000 deaths in an annual basis.

An intriguing fact that has drawn attention in dengue is the involvement of the host’s central nervous system (CNS) in the course of infection. CNS-related symptoms of dengue were first reported as an acute encephalopathy in 1976 and, classically, these manifestations have been treated as rare phenomena in humans. Back in 1998,
Results

DENV infection in BALB/c mice induces TCD8-mediated cellular immunity. In the experiments considered here, BALB/c mice were infected with patient-isolated DENV-2 by the intravenous (i.v.) route. It was previously demonstrated that although the infection is not capable of producing symptoms, it can induce hepatic injury in the subjects and virus can be detected in different cell types such as hepatocytes, Kupffer cells and endothelium. Given the influence that the cellular immunity may have towards the neurological involvement in dengue, our initial step here was to address the immunological status of these mice upon the i.v. infection.

Spleen and blood samples of infected animals were evaluated by flow cytometry two and seven days post infection (d.p.i.). When analyzing the spleen of infected mice, we observed relevant increments in the percentages of CD86+CD11c+ cells (which we considered as the antigen presenting cell subset - APC) on the 2nd and on the 7th d.p.i., in comparison to controls. Of note, on the 7th d.p.i. the percentage of CD86+CD11c+ cells reached approximately 2 times higher than the observed in the mock-infected group (Fig. 1A). This finding suggested that the i.v. infection induced activation and migration of APCs to the lymphoid organ in order to trigger specific immunity. Electron microscopy analyses of brain and cerebellum from DENV-infected mice revealed cellular impairments that suggested apoptotic induction. We also found that DENV was able to reach the host’s CNS upon i.v. inoculation, as detected by DENV-NS3 staining, supporting the natural neurotropic behavior of the virus and suggesting that the observed effects were due to direct viral infection in the CNS. Such findings highlighted possible brain alterations that could yield CNS-related symptoms in dengue and helped us to better understand the neuropathological component of the disease.

BALB/c mice present damage in the CNS after DENV infection by the i.v route. In the previous evaluation, the occurrence of activated lymphocytes in the circulation of infected mice draw our attention for a possible targeting of T-cell migration to host’s tissues. To address the involvement of infection and a possible impact of the cellular immunity in the CNS we proceeded with histological studies considering the brain and the cerebellum tissues. Four major areas were took into account for investigation: (i) the cerebral cortex, which comprises the sensory and motor areas of the brain; (ii) the hippocampus, which consists of an internal area of the brain related to memory; (iii) the cerebral white matter, a region of myelinated nerve fibers that is critical for the axonal signaling and flux; and (iv) the cerebellum, a structure that plays a crucial role in motor control.

Considering the samples from infected mice, histopathological analyses showed damage in the brain and cerebellum tissues. On the 2nd d.p.i., the cerebral cortex showed thickening of the pia mater with an increased cellularity (Fig. 2B) and focal perivascular inflammatory infiltrate consisting mainly of lymphocytes and glial cells (Fig. 2C). On the 7th d.p.i., the inflammatory infiltrates were more diffuse by the parenchyma with predominance of microglial cells (Fig. 2D). As expected, brain of non-infected mice showed pia mater, molecular layer, granular layer, pyramidal neurons layer and white matter with regular structures (Fig. 2A). When analyzing the white matter from infected mice we found that this region was structurally disorganized. On the 2nd d.p.i. this area was marked by microglial cell infiltrates within the parenchyma (Fig. 2F), while later on the 7th d.p.i. the cell infiltrates were more characterized around blood vessels (Fig. 2G). Regarding the hippocampus area, while non-infected mice exhibited regular structures (Fig. 2H), infected animals showed presence of neuronal cells infiltrates within this region. In this case, on the 2nd d.p.i. infiltrates were seen in the CA1 (Cornu Ammonis 1) region (Fig. 2I), while on the 7th d.p.i. this manifestation occurred mainly in the CA3 (Cornu Ammonis 3) (Fig. 2K).

Analyses of the cerebellum tissue collected from infected animals revealed inflammatory infiltrates in the pia mater. Purkinje neurons were also characterized by altered morphology on the 2nd d.p.i. (Fig. 2M). On the 7th d.p.i., it was observed an extensive area of demyelination with presence of microglial cells in the white matter.
(Fig. 2N) and circulatory damage such as hemorrhage in the cerebellar parenchyma (Fig. 2O). Control mice showed cerebellum structures with regular aspects (Fig. 2L).

In order to identify the extent of brain damage caused by DENV-2 strain 66985, three histopathological parameters were quantified: (i) hemorrhage; (ii) perivascular infiltrate; and (iii) pia mater infiltrate. Although the infection could lead to brain hemorrhage, this morphological change was mostly focal and limited to small areas. In average, on the 2nd d.p.i. there were only 2 positive fields out of 30, while on the 7th d.p.i. this damage was found in a more spread fashion (in average 4 positive fields out of 30) but still rarely observed (Fig. 3 left). Perivascular and pia mater infiltrates behaved similarly, however at different magnitudes, being more evident on the 7th d.p.i., when compared to the 2nd d.p.i. In average, considering perivascular infiltrates, on the 2nd d.p.i. there were approximately 6 positive fields out of 30, while on the 7th d.p.i. this margin was increased up to 11 positive fields out of 30 (Fig. 3 center). Infiltrates in the pia mater were averaged as 4 positive fields out of 30 on the 2nd d.p.i. and 7 positive fields out of 30 towards the 7th d.p.i. (Fig. 3 right). No histological alterations were observed in the controls.

Infected animals reveal morphological alterations of microglial cells and astrocytes. After characterizing tissue alterations in the brain and cerebellum of DENV-infected animals, we considered investigating the brain cellular components responsible for tissue homeostasis. For this, we analyzed in more detail the neuroglial cells, in particular microglial cells and astrocytes, since they are known to play critical roles in maintaining CNS’ homeostasis, supporting and protecting neurons from injury.

In samples collected from non-infected mice, microglial cells (IBA-1+ cells) were detected in the cortex and white matter. This cell population was found exhibiting scarce cytoplasm, long/thin extensions (Fig. 4A) and assuming a ramified morphology, which is known to be typical of their surveillant and homeostatic state. In the samples from infected animals, these cells were characterized by ameboid morphology with retracted extensions and increased cytoplasm located in the cortex (Fig. 4B) as well as in the white matter close to the capillaries (Fig. 4C). This morphological characterization, which is typical from their activated state, was observed mainly on the 2nd d.p.i. Based on morphology, later at the 7th d.p.i. these cells seemed to return to their regular activity/processes (as seen by their ramified appearance) both in the cortex (Fig. 4D) and in the white matter (Fig. 4E). Astrocytes (GFAP+ cells) in non-infected mice showed thin appearance in the cortex (Fig. 4F) and in the white matter (Fig. 4G). In the samples from infected mice, GFAP+ cells were found under a degenerative process with atrophy of their cytoplasmic extensions on the 2nd d.p.i. (Fig. 4H). On the 7th d.p.i., astrocytes assumed large and thick shapes with thicker cytoplasmic extensions either in the cerebral cortex or in the white matter (Fig. 4I).
In order to identify whether the CNS was committed by reactive microgliosis or astrogliosis, we proceeded with the quantification of both IBA-1⁺ and GFAP⁺ cells within the cerebral cortex and white matter. As shown in the Fig. 4 panels k and l, both cell types statistically increased in number on the 7th d.p.i., when compared to controls. This finding confirmed the occurrence of reactive microgliosis and astrogliosis upon infection with DENV by the i.v. route.

Ultrastructural aspects of brain and cerebellum from DENV-infected mice. To obtain a better description of the cellular changes in the CNS originated upon infection with DENV, ultrastructural evaluations were performed using electron microscopy. Brain and cerebellum tissues from infected mice showed degenerated pyramidal and Purkinje neurons with irregular nuclear membrane and mitochondria swelling (Figs 5B and 6B). In the same analyzed sites, microglial cells exhibited increased nucleus and loss of integrity of mitochondrial ridges (Figs 5D and 6D). Brain astrocytes showed a deposition of heterochromatin in a cell pole (Fig. 5F). In the cerebellum, there was disorganization of the myelin fiber pattern suggesting a process of demyelinating neuropathy (Fig. 6F), which corroborated with the findings from the histopathological analyses. Samples collected from control mice exhibited regular structures of pyramidal and Purkinje neurons (Fig. 5A and 6A), microglial cells (Fig. 5C and 6C), astrocytes (Fig. 5E) and myelin fibers (Fig. 6E).

Viral detection in the SNC of DENV-infected mice. To address the viral presence and its ongoing replicative process in the CNS we performed immunostaining of DENV-NS3 protein, since this viral antigen is only
expressed upon viral replication. DENV-NS3 protein was found in endothelial cells of the cerebral cortex and hippocampus (Fig. 7B,F), microglial cells of the hippocampus and cerebellum (Fig. 7E,J) and in Purkinje neurons on the 2nd d.p.i. (Fig. 7I). On the 7th d.p.i., DENV-NS3 was present in microglial cells of the cerebral cortex (Fig. 7C), granular cells of the hippocampus (Fig. 7G), neurons and endothelial cells in the cerebellum (Fig. 7K,L).

Figure 3. Quantification and qualification of damage in the brain of infected mice. Groups of BALB/c mice (n = 4 each), mock, 2nd and 7th d.p.i. were considered for quantification and qualification of damage in their brains. Three types of tissue damage were taken into account: (i) hemorrhage; (ii) perivascular infiltrate; and (iii) pia mater infiltrate. 30 fields of HE-stained histological cuts at magnification of 400× were evaluated according to an arbitrary scale as follows: 0 - absent; 1 - light and focal; 2 - light; 3 - moderate; and 4 - diffuse. Raw data is available in the Supplementary Information, Table 1. d.p.i. - days post infection; ID - identification number of animal.
Measurement of viral titers in the infected brains. Brain cuts from infected mice showed clear expression of DENV-NS3 in several cell types. In order to strengthen this observation a new round of experiment was performed in which brains from infected animals were collected on the 2nd (10 mice) and on the 7th d.p.i (9 mice). Mock-infected controls (4 animals per group) were also taken into account on the 2nd and on the 7th day after inoculation. While all controls were negative, four animals out of ten had their brain tissue positive for DENV-RNA on the 2nd d.p.i. with titers of $3.72 \times 10^4$, $5.68 \times 10^4$, $6.02 \times 10^3$ or $9.19 \times 10^2$ RNA copies/mL. Two animals out of nine were positive for DENV-RNA in their brains on the 7th d.p.i. with titers of $3.80 \times 10^4$ or $2.26 \times 10^3$ RNA copies/mL.

Discussion
In this work, using BALB/c animals inoculated with DENV-2 strain 66985 by the i.v. route, we characterized several alterations in the CNS of infected mice which could be correlated with the neurological component of the disease. We identified that brain and cerebellum tissues extracted from DENV-infected animals presented cellular damage, tissue disorganization, morphological alterations of microglia and astrocytes (cells that provide support and homeostatic balance to neurons) and ultrastructural cellular impairments that suggested apoptotic induction. We also found that DENV was able to reach the brain and cerebellum tissues of mice upon i.v. inoculation, an observation that supported the natural neurotropic behavior of the considered viral strain.

Although the infected animals presented these CNS alterations, an intriguing observation that must be taken into account is that the animals were not phenotypically influenced after virus inoculation. Survival rates were not affected by the infection. Additionally, previous observations showed that animals remained apparently asymptomatic for at least 50 days after viral inoculation. We consider that the absence of clinical effects in infected mice,
such as altered motor coordination for example, did not exclude the possibility of other existing effects affecting the CNS. A study that corroborates with this line of thinking is from Huy and colleagues that by means of a meta-analytical study identified that clinical manifestations, such as, restlessness, irritability, dizziness, drowsiness and stupor have been associated to the disease. Given the empirical nature in assessing these clinical parameters in animal models, it becomes difficult to categorically affirm whether infected mice were experiencing neurological symptoms at this peculiar level or not. Another fact that may have contributed to the absence of apparent CNS-related effects in infected mice is that immunocompetent animals are naturally resistant to DENV infection. It was seen that DENV is not able to subvert the IFN-α/β antiviral response in mice as it happens in humans. Despite this resistance, immunocompetent mice can still be infected as evidenced in other mouse models of dengue. In our experimental approach, even considering this phenotypic peculiarity, we could observe signs of host response to the infection, such as APC induction and TCD8 cell activation. Additionally, by an unrecognized mechanism, viruses were able to cause blood-brain barrier dysfunction and infect brain and cerebellum cells. One hypothesis to explain this scenario is that the immune-privileged characteristic of the brain may be related to increased permissiveness of viral replication in this site. Our data also showed that the infection leads

Figure 5. Ultrastructural aspects of the brain tissue of BALB/c mice infected with DENV-2. (A) Pyramidal neurons, (C) microglial cells and (D) astrocyte of non-infected mice showing regular aspects. (B) Pyramidal neuron exhibiting increased nucleus, swollen mitochondria and irregular nuclear membrane. (D) Microglial cell with increased nucleus and swollen mitochondria. (F) Astrocyte with heterochromatin deposition. Samples from infected mice were considered on the 7th d.p.i. Het - heterochromatin; (Red asterisk) - mitochondria; MF - myelin fibers; N - nucleus; NM - nuclear membrane; d.p.i. - days post infection.
to circulatory disturbances (hemorrhage), which on its own infers changes in the permeability of the blood-brain barrier. Although hemorrhagic events were scarce, they would have been sufficient to cause an early outbreak of the virus (on the 2nd d.p.i.) from the circulation to the brain.

Among the tissue alterations found in the infected mice, we observed inflammatory infiltrates, thickening of pia matter, increased number of activated neuroglial cells and DENV-NS3 expression in brain and cerebellum cells. Such alterations were in accordance with the study from Amaral and coworkers, in which after infecting C57BL/6 mice intracerebrally with DENV-3, the following changes were observed: (i) increased leukocyte rolling and adhesion in brain microvasculature; (ii) tissue evidences of meningoencephalitis, such as perivascular hemorrhages and infiltration of mononuclear cells in brain and cerebellum; (iii) reactive gliosis; and (iv) immunoreactive cells for anti-NS3 in several brain areas. While these observations were essentially in congruence to our study, the phenotype of infected C57BL/6 mice diverged from our infected mice. In Amaral and coworkers’ model, animals showed symptoms of apathy, stereotyped behavior, seizures and died at the 8th d.p.i., suggesting the induction of an intense encephalitis by the viral infection. The effectiveness of this referred model in promoting such a drastic neurological manifestation may be involved with the following reasons: (i) infection was administered by the intracranial route that obviously resulted in a massive viral load in the host’s CNS; (ii) animals were infected with DENV-3 genotype I and its level of virulence in comparison to the strain we

Figure 6. Ultrastructural aspects of the cerebellum tissue of BALB/c mice infected with DENV-2. (A) Pyramidal neurons, (C) microglial cells and (D) organized myelin fibers in samples from non-infected mice. Samples from infected mice showing (B) Purkinje neuron with increased nucleus and swollen mitochondria, (D) microglial cell with swollen mitochondria and (F) disorganized myelin fibers. Samples from infected mice were considered on the 7th d.p.i. M - mitochondria; MF - myelin fibers; N - nucleus; d.p.i. - days post infection.
used is unknown; and (iii) divergences of mouse strain susceptibility to DENV (C57BL/6 versus BALB/c) is also unknown. Based on the above reasons, we consider that the histological alterations found in our infected mice resembles the scenario of encephalitis, however in a much more limited fashion that is not able to yield detectable motor alterations or death. Yet, this controlled and relatively slow process by which the virus invades the CNS, spread and promote the specific changes found in our experimental approach can provide us hints about how the neurological manifestations of dengue take place.

Infected animals responded to virus with induction of TCD8-mediated immunity. However, this host response was still unable to clear the virus, as within two d.p.i. the pathogen could able to reach the brain and to promote alteration in the tissue organization. In the normal pathway of infection, infected mosquitoes deliver the virus to the subcutaneous space. What is generally expected when the infection bypasses the innate immunity, is an initial activation of APCs, migration of these activated cells to lymphoid organs and further expansion and distribution of the virus to the circulation. In our approach, the virus could have reached the brain relatively fast (on the 2nd d.p.i.) because it was administered directly by the i.v. route. Also, if we look at the TCD8 activation kinetic, a relevant specific clone expansion was not seen at the 2nd d.p.i., instead, it was detected by the 7th d.p.i. Consistent to this, major perivascular and pia mater infiltrates were detected by the 7th d.p.i. and not by the 2nd d.p.i. Taking together, in this peculiar case, the virus may have took advantage during the initial days of infection to reach and infect the brain while the TCD8 response was still starting to develop.

Neurogliosis found in the brain of infected animals may represent a key finding in dengue neuropathogenesis. Due to morphological changes and increased cell numbers, it became clear that microglial cells (IBA-1+) and astrocytes (GFAP+) were involved in activation processes. Microglial cells are the resident macrophages of the brain and are known to be susceptible to flavivirus infection. Once activated, microglial cells are thought to act as the first line of defense in the brain tissue as these cells promote antiviral responses to prevent the progression of encephalitis. In their non-activated physiological state, microglial cells display a ramified surface that is suitable for the constant surveillance of the local environment. On the other hand, in pathological conditions these cells become activated and proliferate, assuming an ameboid form that is usually characterized as a spherical-shaped cell that carries several phagocytic vacuoles into its cytoplasm. Activated microglia release many factors that contribute to inflammation and tissue repair, however, exacerbated reactions of these cells are implicated.
with massive production and release of IFN-γ, TNF-α and nitric oxide, which can be toxic to neurons. In fact, it represents a mechanistic arm that influences several CNS pathologies, such as multiple sclerosis34,35, Alzheimer’s disease36 and Parkinson’s disease37. In our experimental approach, it is also likely that microglial cells can function as a “double-edged sword” either by acting protectively when promoting the initial antiviral response, or by mediating local damage or dysfunction in cases of signaling exacerbation. Reactive gliosis was also characterized in our experimental approach of infection by the presence of clusters of astrocytes (GFAP⁺ cells). Astrocytes are the most abundant cells in the CNS and act cooperatively with microglia to stimulate T-cell responses58. Divergences in controversial behavior typical of astrocytes in promoting/inhibiting inflammation60, more investigation is needed to better characterize the contribution of these cells in the considered scenario.

Other findings that were implicated with the establishment of neuropathological processes were resultant from the ultrastructural analyses. We observed that neurons, microglia and astrocytes in the brain/cerebellum areas of infected mice exhibited cellular alterations (mainly mitochondria swelling) that indicated processes of apoptotic cell death. The induction of apoptosis by DENV in susceptible cells is well reported in the literature61-64. Particularly, mitochondria swelling in response to DENV was previously characterized under other circumstances such as in peripheral organs of dengue fatal cases65 and in human hepatoma cell line (Hep-G2)66. Similarly to other viral diseases, DENV proteins could also interact with mitochondrias and somehow result in the modulation of apoptotic processes67,68. Given the central role of the brain in receiving information from the body, interpreting and then guiding the body's response to it, the elimination of brain cells by apoptotic processes could be critical depending on the affected areas. As these target cells, neurons and neuroglial cells, are located within the cerebral cortex and white matter, respectively, it is reasonable to suggest that DENV infection could potentially impact the host's sensory and/or motor functions. An additional effect that could also potentially commit the motor functions is the demyelination found in the cerebellar tissue. Previous studies suggested that there is a connection between the disruption of the myelin sheath and the activation of microglia69, nonetheless, in dengu this phenomenon is still unknown.

In conclusion, we observed that DENV-2 strain 66985 isolated from the patient and subsequently adminis-
tered by the i.v. route in mice was able to cause dysfunction in the blood-brain barrier and to replicate in endothelial cells of the brain. This occurred in association with tissue damage/disorganization of CNS structures, reactive gliosis and induction of apoptotic cell death. It is important to note that not all dengue infections lead to neu-
rological manifestations, hence, the phenomena observed in this work could be influenced by the viral strain or even by the applied dose. The experimental approach of infection presented in this work reaffirmed the neuro-
tropic nature of the considered DENV strain in mice and shed light into possible existing CNS changes that may justify neurological manifestations in dengue disease.

Methods

Virus. The virus used in our experiments was the DENV-2 strain BR/RJ66985/2000 representing the linage I isolated from human serum samples at Laboratório de Flavivús/Instituto Oswaldo Cruz (IOC)/Fiocruz/Rio de janeiro/Brazil. The BR/RJ66985/2000 strain (GenBank register number: #HQ012518) was isolated in 05/05/2000 from a 39-year-old male patient that presented classic dengue70. Viruses were propagated in Aedes albopictus mosquito cell line (C6/36) using L-15 medium (Sigma, USA) supplemented with 1% non-essential amino acids, 10% tryptose phosphate broth solution and 10% fetal bovine serum. Infected cells were cultured at 28 °C for 15 days.

Flow cytometry. For flow cytometry analysis, leukocytes were isolated from blood and spleen. Spleens were dissociated in wire mesh screens using RPMI medium. Spleen macerates and total blood samples were treated with BD FACS Lysing for red blood cell lysis and fixation according to manufacturer's instructions (BD Biosciences, USA). Cells were spun down, washed and suspended in PBS/BSA 1%. Approximately 10⁶ cells were stained on ice for 20 min in the dark with the following mab combinations: (i) CD11c-PE and CD86-FITC; or (ii) CD4-PE, CD8-PerCP and CD45RB-FITC. All mabs used in this work were obtained from BD Biosciences and background-staining controls were performed using isotypes recommended by the manufacturer. Samples were read in a BD Accuri C6 flow cytometer and analyzed offline with C6 software (BD Biosciences).

Histopathological analysis. Staining protocol. Histological analyses were carried out based as previously described by Paes and colleagues72. Briefly, fragments of brain and cerebellum collected from mice were fixed in 10% buffered formalin, cleaved into smaller fragments, dehydrated in ethanol, clarified in xylene and blocked in
paraffin resin. In sequence, samples were sectioned in 5-μm thick units, deparaffinized in xylene and rehydrated with alcohol. Samples were stained with hematoxylin and eosin (H.E.) and visualized under a light microscopy (Olympus BX 53 F, Japan). Digital images were rendered using Image Pro Plus software version 4.5.

Quantification of damage. Three types of damage were considered for quantification: hemorrhage, perivascular infiltrate and pia mater infiltrate. Histological brain cuts of animals belonging to each analyzed group (mock, 2nd d.p.i. or 7th d.p.i. -4 animals per group) had 30 images randomly captured at 400× magnification using Image Pro software version 4.5. Tissue damages were quantified and qualified in each of the 30 images as: 0 - absent; 1 - light and focal; 2 - light; 3 - moderate; and 4 - diffuse. Infected animals considered in this analysis were positive for DENV-NS3 immunohistochemical reaction in the brain (see “Immunohistochemistry” section in “Methods”).

Ultrastructural analysis. For electron microscopy, fragments of brain and cerebellum were post fixed with 2.5% glutaraldehyde in sodium cacodylate buffer (0.2 M, pH 7.2), dehydrated in acetone, post fixed with 1% buffered osmium tetroxide, embedded in Epon and polymerized at 60 °C for three days. Semi-thin sections (0.5 μm thick) were obtained using a diamond knife (Diatome, Switzerland) adapted to a Reichert-Jung Ultracut E microtome (Markham, Canada) and stained with methylene blue. Ultra-thin sections (60–90 nm) were contrasted with uranyl acetate and lead citrate and observed under a JEOL-JEM-1011 transmission electron microscope.

Immunohistochemistry. Staining protocol. For immunohistochemical studies, the paraffin-embedded tissues were cut (5 μm thick), incubated at 60 °C for one hour, deparaffinized in xylene and rehydrated with alcohol. Antigen retrieval was performed by heating the tissue in the presence of citrate buffer. Next, tissues were blocked for endogenous peroxidase with 3% hydrogen peroxidase in methanol for 10 minutes and rinsed in tris-HCl (pH 7.4). To reduce non-specific binding, sections were incubated in Protein Blocker solution (Spring Bioscience, USA) for 10 min at room temperature. Afterwards, samples were incubated overnight at 4 °C with primary antibodies: (i) anti-IBA1 antibody (1:200, Wako) to recognize microglia cells; or (ii) anti-GFAP antibody (1:300, Sigma) to astrocyte staining; or (iii) anti-NS3 antibody (diluted 1:100, to detect the DENV-infected cells. In the next day, sections were incubated with secondary complement (REVEAL complement - Spring Bioscience) for 10 minutes and with a rabbit anti-mouse IgG-HRP conjugate (REVEAL polyclonal HRP - Spring Bioscience) for one hour, deparaffinized in xylene and rehydrated with alcohol. Antigen retrieval was performed by heating the tissue in the presence of citrate buffer. The sections were permeabilized for 10 minutes with 0.5% Triton X-100, and incubated for 30 minutes with 2% bovine serum albumin (BSA) and 5% normal goat serum (NGS) for blocking, at room temperature. In sequence, slides were co-stained overnight at 4 °C with anti-F4/80 (eBioscience) and anti-NS3 (in-house produced antibody) antibodies diluted at 1:200 and 1:100, respectively. Sections were washed in PBS and incubated with Alexa 488-conjugated rabbit anti-mouse IgG (Thermo Scientific) or with Alexa 555-conjugated goat anti-rabbit IgG (Thermo Scientific, USA). Samples were analyzed under an Olympus BX 53 microscope and frames were acquired using a coupled Olympus DP72 camera.

Quantification of positive cells. For each specific staining (IBA-1 and GFAP) 50 images were randomly captured at 1000× magnification using Image Pro software version 4.5. Positive cells were quantified in each of the 50 images and the median of positive cell number was determined. All analyzes were accomplished in a blind test without prior knowledge of the studied groups. After quantification, frames exhibited in figures were selected as to be more informative according to specific areas in the analyzed tissues.

Immunofluorescence assay. The paraffin-embedded tissues were cut (5 μm thick), incubated at 60 °C for one hour, deparaffinized in xylene and rehydrated with alcohol. Antigen retrieval was performed by heating the tissue in the presence of citrate buffer. The sections were permeabilized for 10 minutes with 0.5% Triton X-100, and incubated for 30 minutes with 2% bovine serum albumin (BSA) and 5% normal goat serum (NGS) for blocking, at room temperature. In sequence, slides were co-stained overnight at 4 °C with anti-F4/80 (eBioscience) and anti-NS3 (in-house produced antibody) antibodies diluted at 1:200 and 1:100, respectively. Sections were washed in PBS and incubated with Alexa 488-conjugated rabbit anti-mouse IgG (Thermo Scientific) or with Alexa 555-conjugated goat anti-rabbit IgG (Thermo Scientific, USA). Samples were analyzed under a Zeiss LSM 510 Meta confocal microscope (Zeiss, Germany).

Quantitative polimerase chain reaction (qPCR). DENV viral titers in the brain of mice were estimated by using the quantitative qPCR system Taqman (PE Applied Biosystems, Foster City, CA, USA) according to the protocol described by Johnson and coworkers. For the analysis by molecular techniques, the viral RNA was extracted from samples using the QIAamp Viral RNA Mini Kit (Qiagen, Hilden, Germany) following the manufacturer’s instructions. The estimated limit of detection for the technique was 1.0 × 10⁻⁵ DENV2-RNA copies per mL.

Statistical Analysis. Data obtained from the quantification of positive cells in the immunohistochemistry were analyzed with GraphPad prism software v5.1 (La Jolla, USA) using non-parametric statistical tests. Significant differences between analyzed groups (mock, 2nd d.p.i. and 7th d.p.i.) were determined using Mann-Whitney test with *p < 0.05.

Data Availability. All data generated or analyzed during this study are included in this published article.

**Acknowledgements**

We thank the Brazilian foundation FAPERJ (grant number: E-26/110.511/2014 and E-26/202.003/2016) and CNPq (grant number: 30382202015-5) for the financial support and Geraldo C. Wagner from Universidade Federal do Estado do Rio de Janeiro (UNIRIO) for the help with slides production. We also acknowledge the Laboratory of Flaviviruses, Fiocruz, Rio de Janeiro, Brazil, for kindly providing us the DENV-2 samples isolated from patient.

**Author Contributions**

M.V.P., E.R.A.O., and N.G.S. conceptualized the work; M.V.P., E.R.A.O. and N.G.S. performed the formal analyses; N.G.S., M.V.P. and E.R.A.O. participated directly in the investigation; N.G.S., K.R., M.V.P., T.F.P., E.R.A.O., A.M.B.A., S.M.C., A.J.S.G., J.F.A., A.S.A., P.C.G.N., C.A.B., R.P.B., C.G.F. and L.H.M.G. performed the experiments; M.V.P., R.M.B., E.M.S., C.A.B., R.P.B., F.B.S. and P.C.G.N. provided resources; N.G.S., M.V.P. and E.R.A.O. supervised the results; M.V.P. provided funding acquisition and administrated the project; N.G.S. and E.R.A.O. wrote the original draft of the paper; M.V.P., E.R.A.O., L.H.M.G., F.R.S.L., and K.R. reviewed and edited the paper.
