A Modified Janus Cassette (Sweet Janus) to Improve Allelic Replacement Efficiency by High-Stringency Negative Selection in *Streptococcus pneumoniae*

Yuan Li*, Claudette M. Thompson, Marc Lipsitch

Department of Epidemiology and Department of Immunology & Infectious Diseases, Harvard School of Public Health, Boston, Massachusetts, United States of America

**Abstract**

The Janus cassette permits marker-free allelic replacement or knockout in streptomycin-resistant *Streptococcus pneumoniae* (pneumococcus) through sequential positive and negative selection. Spontaneous revertants of Janus can lead to high level of false-positives during negative selection, which necessitate a time-consuming post-selection screening process. We hypothesized that an additional counter-selectable marker in Janus would decrease the revertant frequency and reduce false-positives, since simultaneous reversion of both counter-selectable makers is much less likely. Here we report a modified cassette, Sweet Janus (SJ), in which the *sacB* gene from *Bacillus subtilis* conferring sucrose sensitivity is added to Janus. By using streptomycin and sucrose simultaneously as selective agents, the frequency of SJ double revertants was about $10^{-3}$-fold lower than the frequency of Janus revertants. Accordingly, the frequency of false-positives in the SJ-mediated negative selection was about 100-fold lower than what was seen for Janus. Thus, SJ enhances negative selection stringency and can accelerate allelic replacement in pneumococcus, especially when transformation frequency is low due to strain background or suboptimal transformation conditions. Results also suggested the *sacB* gene alone can function as a counter-selectable marker in the Gram-positive pneumococcus, which will have the advantage of not requiring a streptomycin-resistant strain for allelic replacement.

**Introduction**

Genetic manipulations of *Streptococcus pneumoniae* (pneumococcus) have been a powerful approach to understand virulence factors and drug targets in this important human pathogen. In particular, the Janus cassette [1] permits marker-free allelic replacement or knockout in *Streptococcus pneumoniae* through sequential positive and negative selection [2–4]. The Janus comprises a kanamycin-resistance (Km*) marker and a counter-selectable *rpsL+* marker that confers dominant streptomycin-sensitivity (Sm*) in a streptomycin-resistant (Sm*) background [1]. Allelic replacement is accomplished in a Sm* parental strain by a 2-step transformation procedure. The first transformation tags the locus of interest with the Janus cassette by homologous recombination while conferring a Km* phenotype that can be selected (positive selection) and Sm*. The resulting Janus-carrying strain (Km*Sm*) is then transformed by donor DNA to replace Janus with an allele of interest. The loss of Janus and acquisition of the allele of interest after the second transformation result in a Sm* phenotype that can be selected (negative selection) and Km*. However, Sm* can also result from spontaneous conversion of the *rpsL*+ marker in Janus into a Sm* *rpsL* allele (spontaneous revertants), which occurs at a frequency of $10^{-5}$ to $10^{-7}$ and leads to false-positives during the negative selection [1]. Unlike true Janus replacement transformants (Km*Sm*), spontaneous revertants are Km*Sm* since Janus is not replaced. To identify true allelic replacement, Sm* clones resulted from the negative selection need to be duplicated on Km and Sm plates to screen for Km* ones. When the transformation frequency is around $10^{-7}$, as reported for several pneumococcal strains [5,6], more than 99% of the Sm* clones would be false-positives, making the post-selection screening a time-consuming process.

To improve the efficiency of negative selection, we hypothesized that adding another counter-selectable marker, especially one not subject to gene conversion, to Janus would decrease the revertant frequency and reduce false-positives. Here we show that the *sacB* gene from *Bacillus subtilis* can be used in pneumococcus as an additional counter-selectable marker in Janus. The *sacB* gene encodes the enzyme levansucrase that converts sucrose to high molecular-weight fructose polymers (levans) [7,8]. *sacB* is commonly used to mediate negative selection in gram-negative bacteria [9] because expression of *sacB* leads to cell death in the presence of sucrose (Su) [7]. In a few gram-positive bacteria, *sacB* was also shown to confer sucrose sensitivity (Su*) and function as a counter-selectable marker [10–12]. Because simultaneous reversion of both counter-selectable makers is much less likely, the addition of *sacB* in Janus reduces the revertant frequency to around $10^{-9}$ and greatly enhances negative selection efficiency.
Materials and Methods

Bacterial strains, DNA, and growth conditions

*Streptococcus pneumoniae* strains used in this study are described in Table 1. All strains were maintained in Todd-Hewitt broth supplemented with 0.5% yeast extract (THY) or on blood agar base no. 2 medium (Becton Dickinson, Sparks, MD) supplemented with 5% defibrinated sheep blood (Northeast Laboratory, Waterville, ME) (SBA). Antibiotic concentrations in SBA selective media were 500 μg/mL for kanamycin and 200 mg/mL for streptomycin. Genomic DNA was prepared by DNeasy Blood & Tissue Kit (Qiagen, Valencia, CA). Growth media and culture methods for genetic transformations have been described by Pozzi et al. [13]. The transformation of TIGR4 derivatives was induced by competence-stimulating peptide variant 2 (CSP-2) and the transformation of SpnYL002 was induced by CSP-1. The concentrations of donor DNA used in transformation steps were 200 ng/mL for chromosomal DNA and 100 ng/mL for PCR products.

Construction of the SJ cassette

The *sacB* coding region was amplified from the SacB plasmid (pCre-SacB-Zeo, kindly provided by Kenan Murphy of University of Massachusetts Medical School) by PCR using the primer pair (pCre-SacB-Zeo, kindly provided by Kenan Murphy of University of Massachusetts Medical School) by PCR using the primer pair (pCre-SacB-Zeo, kindly provided by Kenan Murphy of University of Massachusetts Medical School) by PCR using the primer pair (pCre-SacB-Zeo, kindly provided by Kenan Murphy of University of Massachusetts Medical School) by PCR using the primer pair (pCre-SacB-Zeo, kindly provided by Kenan Murphy of University of Massachusetts Medical School) by PCR using primers (pCre-SacB-Zeo). DNA fragments YL229-YL264, YL265-YL266 and YL257-YL236, were prepared by PCR using genomic DNA from a serotype 6B strain (603) or no DNA (None) was used to transform recipient strains TIGR4J and SpnYL001. Cultures of transformation were subjected to titer determination on SBA plates supplemented with Km, Sm, Su, or Sm+Su. The false-positive frequency was calculated as (T S/T K) Non/(T S/TKm) 603, where TS and TKm are the concentrations of colony-forming units on a selection plate (Sm, Su, or Sm+ Su) and on the Km plate, respectively. If the observed ratio was greater than 1 then the false-positive frequency was denoted as 0.99. To calculate the screen size (number of colonies on the selection plate to be examined after transformation) that would allow 95% probability of finding at least one true transformant (Km+) among revertants (Kms), the observed revertant frequency during transformation was used (3.34×10⁻⁻ for TIGR4J selection by Sm and 2.06×10⁻⁻ for SpnYL001 selection by Sm+Su). For a given transformation frequency, the screen size was calculated as maximum of (1, log(1-0.95)/log(1-f)), where f = transformation frequency/(transformation frequency + revertant frequency).

Results

SJ was constructed by inserting the sacB coding sequence between the promoter region and the start codon of the Km resistance gene in the Janus cassette (Figure 1). The SJ was used to replace the cps loci in the TIGR4S and SpnYL002 strains to construct the SpnYL001 and SpnYL004 strains, respectively (Table 1). The SJ-carrying strains (Km’Sms’Su’) were subjected to titer determination on SBA plates supplemented with Km, Sm, Su, or a mix of Sm and Su (Sm+Su) to determine sensitivity to selective agents. Two Janus-carrying strains (Km’Sms’Su’), TIGR4J and SpnYL003, were also subjected to titer determination on the same set of SBA plates for comparison. Both SJ- and Janus-carrying strains showed spontaneous Sm’ revertant frequencies ranging from $10^{-6}$ to $10^{-5}$ (Table 2). For Janus-carrying strains, the Su' titer was similar to the Km’ titer. In contrast, the Su’ titer was approximately $10^{3}$-fold lower than the Km’ titer for the SJ-carrying strains (Table 2). Moreover, growth of SJ-carrying strains on plates containing both Sm and Su (Sm+Su) was about $10^{2}$-fold lower than the growth on Km plate (Table 2), which represented about $10^{4}$-fold additional growth reduction compared to when Sm or Su alone was used as selective agent. The results indicated that SacB in the SJ conferred Su' in pneumococcus and functioned in synergy with rpsL* to reduce the spontaneous revertant frequency.

To test whether the low revertant frequency of SJ could enhance negative selection stringency, the TIGR4J and SpnYL001 strains were transformed with genomic DNA from a type 6B strain (603). The transformation cultures were subjected to titer determination on SBA plates with different selective agents (Table 3). Control transformations with no DNA added (None) were also performed. The false-positive frequency of negative selection was calculated as the ratio between the frequency of selected clones in the control transformation and frequency of selected clones in the DNA transformation. As shown in Table 3, when Sm alone was used as the selective agent, both Janus and SJ showed a high false-positive frequency close to 1. When Su alone was used as the selection agent, the false-positive frequency for SJ was also high (0.50, Table 3). However, when Sm and Su were used together (Sm+Su), the false-positive frequency for SJ decreased to 0.01 (Table 3). Further examination of 10 Sm’Su’ clones in the DNA transformation of SpnYL001 showed that all were Km’ and typed as serotype 6B. Thus, nearly all Sm’Su’ clones after DNA transformation of SpnYL001 resulted from replacement of SJ by the cps operon of the donor DNA. In fact, the frequency of the true transformants (Sm’Su’) was only $5.24 \times 10^{-7}$, which was much lower than the spontaneous revertant frequency for either Sm or Su. The low transformation frequency could explain the high false-positive frequency observed when Sm or Su alone was used as the selective agent.

For both Janus- and SJ-mediated allelic exchange, an additional screening step is usually needed after the negative selection in order to identify true transformants (Km’ Su’) among spontaneous revertants (Km’). The screen size (number of clones to be examined) is determined by transformation frequency and spontaneous-revertant frequency. Using the observed revertant frequency in the presence of CSP-2, we estimated the screen size required to ensure 95% probability of finding at least one true transformant (Figure 2). The screen size required by SJ would be more than 100-fold lower than the screen size required by Janus when the transformation frequency is below $10^{-6}$ (Figure 2).

We observed that growing the SJ-carrying strains on a Su plate resulted in very small colonies. To test whether these colonies are true Su’ revertants, we duplicated 21 clones of SpnYL004 found on Su plate to another Su plate and a plate with no selective agent. 20 of these clones showed no growth on either plates, and 1 clone showed growth on both plates. For the one stable Su’ revertant of SpnYL004, we sequenced the SacB coding region and found a C to

### Table 3. Comparison of false positive frequency in the Janus- and SJ-mediated negative selection.

| Recipient Strain | Donor DNA | Growth (CFU/ml) with selection on | False positive frequency |  
|------------------|-----------|----------------------------------|--------------------------|
|                  |           | Km                               | Sm | Su | Sm+Su | Selection by Sm only | Selection by Su only | Selection by Sm+Su |
| TIGR4J           | None      | $1.98 \times 10^7$               | $6.61 \times 10^2$ | NA | NA    | 0.99               | NA               | NA               |
|                  | 603(Sm^3) | $2.28 \times 10^7$               | $7.21 \times 10^2$ | NA | NA    | NA                | NA               | NA               |
| SpnY001          | None      | $4.85 \times 10^7$               | $1.80 \times 10^2$ | $2.70 \times 10^2$ | $0.3^e$ | 0.99               | 0.50             | 0.01             |
|                  | 603(Sm^3) | $5.15 \times 10^7$               | $1.83 \times 10^2$ | $5.71 \times 10^2$ | 27      | NA                | NA               | NA               |

$^e$ Titer below the limit of detection was denoted as one-half the detection limit.
NA: No data was collected for the TIGR4J strain when Su was used in selection because TIGR4J showed no Su sensitivity.

[doi:10.1371/journal.pone.0100510.t003](https://doi.org/10.1371/journal.pone.0100510.t003)
T substitution at position 1078, which will cause an arginine-to-cysteine change in the encoded protein.

**Discussion**

In this study we constructed a modified Janus cassette, SJ, by adding an additional counter selectable marker, sacB, to Janus. Introduction of SJ to pneumococcus resulted in sensitivity to both Sm and Su. The frequency of SJ spontaneous double revertants (Sm'Su') was about 10^4-fold lower than the frequency of Janus spontaneous revertants (Sm'). Accordingly, the frequency of false-positives in the SJ-mediated negative selection was about 100-fold lower than what was seen for the Janus-mediated negative selection. We propose that the SJ cassette can greatly accelerate constructing marker-free allelic replacement or knockout in Streptococcus pneumoniae by reducing the amount of work required for post-selection screening.

The false-positive frequency during negative selection is determined by the relative frequency between transformation and spontaneous reversion since both events generate the selectable Sm' phenotype. Transformation frequency was reported to vary among pneumococcal strains and a frequency below 10^-6 was not unusual [5,6]. Transformation conditions, including the choice of competence-stimulating peptide variants [13], can also influence transformation frequency. When transformation frequency is lower than 10^-6 due to, for example, strain background or suboptimal transformation conditions, a Janus-mediated negative selection would require screening hundreds of Sm' clones after selection (Figure 2) in order to identify a true transformant because vast majorities of the Sm' clones would be spontaneous revertants. In contrast, a screen size less than 10 would usually be sufficient for the SJ-mediate negative selection (Figure 2) due to its extremely low double revertant frequency.

Growing the SJ-carrying strains, and not the Janus-carrying strains, was severely inhibited in the presence of sucrose (Table 2). The results suggested the sacB gene can confer sucrose-sensitivity, making it possible to use sacB alone as a counter-selectable marker in the Gram-positive pneumococcus. Compared to using rpsL+, using sacB alone to mediate negative selection in pneumococcus will have the advantage of not requiring a Sm' background to perform allelic replacement, such that the strain after allelic replacement would not remain Sm' and be truly maker-free. Use of SacB alone would work best when transformation frequency is high relative to the frequency of Su' revertants; otherwise high false-negative frequency may result similar to the situation when rpsL+ is used alone. In addition, the sucrose sensitivity resulting from expression of sacB has been shown in many Gram-negative bacteria but only in a few Gram-positive bacteria [9]. The basis of the toxicity is still unclear. It will be interesting to understand the mechanism by which sacB expression causes cell death of the Gram-positive pneumococcus in the presence of sucrose.

Growing the SJ-carrying strains on a Su plate resulted in very small colonies and most of these small colonies could not be cultured on either a Su plate or a plate with no selective agents. These observations suggested that many of the apparent Su' revertants on the Su plate are phenotypic variants that did not acquire stable resistance to Su. It is possible that the small colony observed is composed of dead or dying bacteria accumulated during a slowing killing kinetics mediated by expression of the SacB gene in pneumococcus. Further investigation is needed to understand the source of the small colonies.

**Acknowledgments**

The sequence of the SJ cassette, including the sacB sequence, is deposited in GeneBank (Accession number: KJ845726).
