Abstract

Face detection, as a fundamental technology for various applications, is always deployed on edge devices. Therefore, face detectors are supposed to have limited model size and fast inference speed. This paper introduces a Light and Fast Face Detector (LFFD) for edge devices. We rethink the receptive field (RF) in the context of face detection and find that RFs can be used as inherent anchors instead of manually construction. Combining RF anchors and appropriate strides, the proposed method can cover a large range of continuous face scales with nearly 100% hit rate, rather than discrete scales. The insightful understanding of relations between effective receptive field (ERF) and face scales motivates an efficient backbone for one-stage detection. The backbone is characterized by eight detection branches and common building blocks, resulting in efficient computation. Comprehensive and extensive experiments on popular benchmarks: WIDER FACE and FDDB are conducted. A new evaluation schema is proposed for practical applications. Under the new schema, the proposed method can achieve superior accuracy (WIDER FACE Val/Test – Easy: 0.910/0.896, Medium: 0.880/0.865, Hard: 0.780/0.770; FDDB – discontinuous: 0.965, continuous: 0.719). Multiple hardware platforms are introduced to evaluate the running efficiency. The proposed methods can obtain fast inference speed (NVIDIA TITAN Xp: 131.45 FPS at 640x480; NVIDIA TX2: 136.99 FPS at 160x120; Raspberry Pi 3 Model B+: 8.44 FPS at 160x120) with model size of 9 MB.

1. Introduction

Face detection is a long-standing problem in computer vision. In practice, it is the prerequisite to some face-related applications, such as face alignment [14] and face recognition [31]. Besides, face detectors are always deployed on edge devices, such as mobile phones, IP cameras and IoT (Internet of Things) sensors. These devices have limited memory storage and low computing power. Under such condition, face detectors that have high accuracy and fast running speed are in demand.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
\textbf{Method} & \textbf{Easy} & \textbf{Medium} & \textbf{Hard} \\

\caption{Accuracy of the top-5 methods on validation set of WIDER FACE.}
\end{table}

Current state of the art face detectors have achieved fairly high accuracy on convective benchmark WIDER FACE [33] by leveraging heavy backbones like VGG16 [27], Resnet50/152 [7] and Densenet121 [10]. We investigate the top-5 methods on WIDER FACE and present their accuracy in Table 1. It can be observed that these methods have similar performance with marginal gaps which are hardly perceived in practical applications. It is difficult and unpractical to further boost the accuracy by using more complex and heavier backbones. In our view, to better balance accuracy and running efficiency is crucial for applying face detection to more applicable areas.

Face detection is a fast-growing branch of general object detection in the past decade. The early work of Viola-Jones face detector [29] proposes a classic detection framework–cascade classifiers with hand-crafted features. One of its well-known followers is aggregate channel features (ACF) [4, 32] which can take advantages of channel features effectively. Although the methods mentioned above can achieve fast running speed, they rely on hand-crafted features and are not trained end-to-end, resulting in not robust detection accuracy.

Recently, convolutional neural network (CNN) based face detectors [35, 38, 16, 3, 28, 13, 30, 34, 9, 37, 39, 20, 36] show great progress partially owing to the success of WIDER FACE benchmark. These methods can be roughly divided into two categories: two-stage methods and one-stage methods. Two-stage methods [13, 30] consist of proposal selection and localization regression, which are

*Authors contributed equally
mainly originated from R-CNN series [6, 5, 26]. Whereas, one-stage methods [9, 37, 20, 36, 28, 3, 16, 35] coherently combine classification and bounding box (bbox) regression, always achieving anchor-based and multi-scale detection simultaneously. For most one-stage methods, anchor design and matching strategy is one of the essential components. In order to improve the performance, these methods propose more complex modules based on heavy backbones. Although the above methods can achieve state of the art results, they may not properly balance accuracy and running speed. Complex models with manually pre-defined anchors prevent their running speed from being further boosted.

In this paper, we propose a Light and Fast Face Detector (LFFD) for edge devices, considerably balancing both accuracy and running efficiency. The proposed method is inspired by the one-stage and multi-scale object detection method SSD [17] which also enlightens some other face detectors [16, 28, 37]. One of the characteristics of SSD is that pre-defined anchor boxes are manually designed for each detection branch. These boxes always have different sizes and aspect ratios to cover objects with different scales and shapes. Therefore, anchors play an important role in most one-stage detection methods. For some face detectors [37, 39, 28, 16], sophisticated anchor strategies are crucial parts of the contributions. However, anchor-based methods may face three challenges: 1) anchor matching is unable to sufficiently cover all face scales. Although this can be relieved, it remains a problem; 2) matching anchors to ground-truth boxes is determined by thresholding IOU (Intersection over Union). The threshold is set empirically and it is difficult to make a solid investigation of its impact; 3) setting the number of anchors for different scales depends on experiences, which may induce sample imbalance and redundant computation.

In our point of view, receptive fields (RF) of neurons in feature maps are inherent anchors. RF anchors can naturally handle above challenges. Firstly, neurons with RF of the same size can predict continuous scales of faces rather than discrete scales. Secondly, matching strategy is clear, namely a RF anchor is matched to a ground-truth bbox if and only if its center falls in the ground-truth bbox. Thirdly, the number of RF anchors is naturally fixed and equals to the number of neurons. What’s more, we make a qualitative analysis on pairing face scales and RF sizes by understanding the insights of ERF, resulting in an efficient backbone with eight detection branches. The backbone only consists of common building blocks (conv3x3, conv1x1, ReLU and residual connection), which is much lighter than VGG16 [27], Resnet50 [7] and Densenet121 [10]. Consequently, the final model has only 2.1M parameters (versus VGG16 138.3M and Resnet50 25.5M ) and achieves superior accuracy and running speed, which makes it appropriate for edge devices.

In summary, the main contributions of this paper include:

- We study the relations between ERFs and face scales. The relevant understanding motivates the network design.
- We introduce the concept of RF anchor to overcome the drawbacks of the previous anchor strategies.
- We proposed a new backbone with common building blocks for accurate and fast face detection.
- Extensive and comprehensive experiments on multiple hardware platforms are conducted on benchmarks WIDER FACE and FDDB to firmly demonstrate the superiority of the proposed method for edge devices.

2. Related Work

Face detection has attracted a lot of attention since a decade ago.

Early works Early face detectors leverage hand-crafted features and cascade classifiers to detect faces in forms of sliding window. Viola-Jones face detector [29] uses Ad-boost with Haar-like features to train face classifiers discriminatively. Subsequently, utilizing more effective handcrafted features [21, 40, 32] and more powerful classifiers [1, 22] becomes the mainstream. These methods are not trained end-to-end, treating feature learning and classifier training separately. Although achieving fast running speed, they can not obtain satisfied accuracy.

CNN-based methods Current CNN-based face detectors benefit from two-stage [6, 5, 26] and one-stage [17, 23, 24, 25] general object detection. Both [13] and [30] are based on faster R-CNN [26], adapting the original faster R-CNN to face detection. Recently, one-stage face detectors are dominant. MTCNN [34] performs face detection in a sliding window manner and relies on image pyramid. HR [9] is an advanced version of MTCNN to some extent, also requiring image pyramid. Image pyramid has some drawbacks like slow speed and high memory cost. S3FD [37] takes RF into consideration for detection branch design and proposes an anchor matching strategy to improve hit rate. In [39], Zhu et al. focuses on detecting small faces by proposing a robust anchor generating and matching strategy. It can be concluded that anchor related strategies are crucial for face detection. Following S3FD [37], Pyramid-Box [28] enhances the backbone with low-level feature pyramid layers (LFPN) for better multi-scale detection. SSH [20] constructs three detection modules cooperating with context modules for scale-invariant face detection. DSFD [16] is characterized by feature enhance modules, early layer supervision and an improved anchor matching strategy for better initialization. S3FD, Pyramid-Box, SSH and DSFD use VGG16 as backbones, leading to big model size and inefficient computation. Face-Boxes [36] aims to make the face detector run in real-time by rapidly reducing the size of input images. In detail, it reaches a large stride size 32 after four layers: two convolution layers and two
pooling layers. Although the running speed of Face-Boxes is fast, it abandons the detection of small faces, resulting in relatively low accuracy on WIDER FACE. Different from Face-Boxes, our method handles the detection of small faces delicately, achieving fast running speed and large scale coverage in the meantime. It can be observed that the networks used by recent state of the art methods tend to become more complex and heavier. In our view, to gain marginal improvement in accuracy at the cost of running speed is not appropriate for practical applications.

3. Light and Fast Face Detector

In this section, we first revisit the concept of RF and its relation to face detection in Sec. 3.1. Then Sec. 3.2 describes the rationality and advantages of using RFs as anchor boxes. Subsequently, the details of the proposed network is depicted in Sec. 3.3. Finally, we present the specifications of network training in Sec. 3.4.

3.1. Type-style and fonts

In the beginning, we make a brief description of RF and its properties. The RF of a certain neuron can be straightly defined as an area of the input that affects the activation of the neuron. RF determines the range that a neuron can see in the original input. For detection tasks, RFs roughly restrict areas that contain object candidates with high probabilities. In general, the neurons in shallow layers have small RFs and those in deep layers have large RFs. One of the important properties of RF is that each input pixel contributes differently for the neuron’s activation [18]. Specifically, the pixels locating around the center have larger impact. And the impact decreases gradually when the pixels are far away from the center. This phenomenon is named as effective receptive field (ERF). ERFs inherently exist in neural networks and present a Gaussian-like distribution. Especially for one-stage detectors, ERF is helpful to anchor design and backbone refactoring. The proposed LFFD benefits from these important observations.

Face detection is a well-known branch of general object detection and it has some characteristics. First, big faces are approximately rigid due to their unmovable components. Although there are facial expression changes, hair occlusion and other unconstrained situations, big faces are still distinguishable. Second, tiny or small faces have to be treated differently compared to big faces. Tiny faces always have unrecognizable appearances (an example is shown in Fig. 1). It is difficult for humans to make a face/non-face decision by only seeing the facial area of a tiny face, and the same goes for CNN based classifiers [9]. With more context information about necks and shoulders, tiny faces become easier to recognize as shown in Fig. 1.

Based on above understandings, we apply different RF strategies for faces with different sizes: 1) for tiny/small faces, ERFs have to cover the faces as well as sufficient context information; 2) for medium faces, ERFs only have to contain the faces with little context information; 3) for large faces, only keeping them in RFs is enough.

3.2. RFs as Inherent Anchors

One-stage detectors are mostly characterized by predefined bbox anchors. In order to detect different objects, anchors are in multiple aspect ratios and sizes. These anchors are always redundantly defined. In terms of face detection, it is rational to use 1:1 aspect ratio anchors since faces are approximately square, which is also mentioned in [37, 36]. The shapes of RFs are also square if widths and heights of the kernels are equal. The proposed method adopts RFs as inherent anchors. For the neurons in the same layer, their RFs are regularly tiled in the original image with the same size. Consequently, the proposed method does not need to consider both aspect ratios and sizes compared to the previous anchor-based detectors [16, 28, 39, 37, 36].

As for anchor matching, the proposed method uses a straight and concise strategy—the RF anchor is matched to a ground-truth bbox if and only if its center falls in the ground-truth bbox, other than thresholding IOU. In the typical anchor-based method S3FD [37], Zhang et al. also analyses the influence from ERFs and designs anchor augmentation for tiny faces in particular. In spite of improving the anchor hit rate, S3FD induces the anchor
imbalance problem (too many anchors for tiny faces) which has to be addressed by additional means. However, the proposed method can achieve nearly 100% anchor hit rate in theory by controlling the RF stride. Besides, RF anchors with our matching strategy can naturally handle continuous face scales. For an instance, RFs with the size of 100 pixels are able to predict faces between 20 pixels to 40 pixels. In this way, anchor imbalance problem is greatly relieved and faces from each scale are equally treated. In fact, the proposed method is anchor-free since we do not really match anchors to ground-truth bboxes.

3.3. Network Architecture

According to above analyses, we can design a specialized backbone for face detection. There are two factors that determine the placement of loss branches—the size and stride of RFs. The size of RFs guarantees that the learned features of faces are robust and distinguishable, whereas the stride ensures the 100% hit rate. The overall architecture of the proposed network is illustrated in Fig. 2. The proposed method can detect faces that are larger than 10 pixels (the size of a face is indicated by the longer side), since WIDER FACE benchmark dataset requires faces more than 10 pixels to be detected. It can be observed that the proposed backbone is one-stage with four parts. The concrete information about loss branches can be found in Table 2.

The tiny part has 10 convolution layers. The first two layers down-sample the input with stride 4, stride 2 from each. Therefore, RFs of other convolution layers in this part are in stride 4. The advantages of this operation are two-fold: 1) rapidly reducing the size of the input in shallow layers can speed up the network; 2) the stride of 4 can guarantee 100% hit rate for tiny faces. This part has two loss branches. The loss branch 1 stems from c8 whose RF size is 55 for continuous face scale 10-15. Similarly, the loss branch 2 is from c10 with RF size 71 for continuous face scale 15-20. Obviously, we can make sure that centers of at least two RFs can fall in the smallest face, thus achieving 100% hit rate. There is a special case that one center may fall in two faces at the same time, in which the corresponding RF is ignored directly. As we have discussed in Sec. 3.1, tiny faces need more context information and ERFs are smaller than RFs. To this end, we use much larger RFs than average face scales. The ratios of RFs and average face scales are 4.4 and 4.0 for branch 1 and branch 2, respectively. In Table 2, such ratios are gradually decreased from 4.4 to 1.3, because larger faces need less context information. In the backbone, all convolution layers have the kernel size of 3x3. Nevertheless, the kernel size of convolution layers in branches is 1x1 which does not change the size of RFs. In each branch, there are two sub-branches, one for face classification and the other one for bbox regression.

The small part is in charge of two continuous face scales 20-40 and 40-70. The first convolution layer c11 in this part...
down-samples the feature maps by 2X. For the subsequent parts, their first convolution layers accomplish the same function. In small part, the RF increasing speed becomes 16 compared to that of tiny part 8. So it takes less convolution layers to reach the targeted RF sizes. The medium part is similar to the small part, having only one branch.

At the end of the backbone, the large part has seven convolution layers. These layers easily enlarge the detection scale without too much computation gain due to small feature maps. Three branches are from this part. Since big faces are much easier to detect, the ratios of RFs and average face scales are relatively small.

The proposed method can detect a large range of faces from 10 pixels to 560 pixels within one inference. The overall backbone only consists of conv 3x3, conv 1x1, ReLU and residual connection. The main reason is that conv 3x3 and conv 1x1 are highly optimized by inference libraries, such as cuDNN\(^1\), ncnn\(^2\), mace\(^3\) and paddle-mobile\(^4\), since they are most widely used. We do not adopt BN [11] as components due to slow inference speed, although it has become the standard configuration of many networks. We compare the speed between the original backbone and the one with BN: the original one can achieve 7.6 ms and the one with BN only has 8.9 ms, resulting in 17% slower (resolution: 640x480, hardware: TITAN X (Pascal)). In stead of using BN, we train much more iterations for better convergence. As shown in Fig. 2, in each part, residual connections are placed side by side for easily training the deep backbone. The number of filters of all convolution layers in the first two parts is 64. We do not increase the filters, since the first two parts have relatively large feature maps which are computationally expensive. However, the number of filters in the last two parts can be increased to 128 without too much additional computation. More details can be found in Table 2.

### 3.4. Training Details

In this subsection, we describe the training related details in several aspects.

**Dataset and data augmentation.** The proposed method is trained on the training set of WIDER FACE benchmark [33], including 12,880 images with more than 150,000 valid faces. Faces less than 10 pixels are discarded directly. Data augmentation is important for improving the robustness. The detailed strategies are listed as follows:

- **Color distort**, such as random lighting noise, random contrast, random brightness, et al. More information can refer to [8, 15].
- **Random sampling for each scale.** In the proposed network, there are eight loss branches, each in charge of a certain continuous scale. Thus, we have to guarantee that: 1) the number of faces for each branch is approximately the same; 2) each face can be sampled for each branch with the same probability. To this end, we first randomly select an image, and then randomly select a face in the image. Second, a continuous face scale is selected and the face is randomly resized within the scale as well as the entire image and other face bboxes. Finally, we crop a sub-image of 640x640 at the center of the selected face, filling the outer space with black pixels.

- **Randomly horizontal flip.** We flip the cropped image with probability of 0.5.

**Loss function.** In each loss branch, there are two sub-branches for face classification and bbox regression. For face classification, we use softmax with cross-entropy loss over two classes. The matched RF anchors are positive and the others are negative. Those RF anchors with more than one matched faces are ignored. Besides, gray scale is set for each continuous scale. Let \([S_L^i]\) be lower bounds of continuous scales and \([S_U^i]\) for upper bounds. The lower and upper gray bounds are calculated as \([S_L^i \ast 0.9]\) and \([S_U^i \ast 1.1]\). For each continuous scale \(i\), the relevant gray scales are \([S_L^i \ast 0.9], S_L^i\) and \([S_U^i, S_U^i \ast 1.1]\). For example, branch 3 is for face scale 20-40, the corresponding gray scales are [18, 20] and [40, 44]. Faces that fall in gray scales are also ignored by the corresponding branch. For bbox regression, we adopt L2 loss directly. The regression ground-truth is defined as:

\[
\frac{RF_x - b_x^l}{RF_x/2}, \frac{RF_y - b_y^l}{RF_y/2}, \frac{RF_x - b_x^u}{RF_x/2}, \frac{RF_y - b_y^u}{RF_y/2}, \]

where \(RF_x\) and \(RF_y\) are center coordinates of the RF, \(b_x^l\) and \(b_y^l\) are coordinates of top-left corner of the bbox, \(b_x^u\) and \(b_y^u\) are coordinates of bottom-right corner of the bbox and the normalization constant is \(RF_x/2, RF_y\) is the RF size. The \(L_2\) loss is only activated for positive RF anchors without being ignored. In the final loss function, the two losses have the same weight.

**Hard negative mining.** For each branch, negative RF anchors are usually more than positive ones. For stable and better training, only a fractional negative RF anchors are used for back-propagation: we sort the loss values of all negative anchors and only select the top ones for learning. The ratio between the positive and negative anchors is at most 1:10. Empirically, hard negative mining can bring faster and stable convergence.

**Training parameters.** We initialize all parameters with xavier method and train the network from scratch. The inputs first minus 127.5, and then divided by 127.5. The optimization method is SGD with 0.9 momentum, zero weight decay and batch size 32. The reason for zero weight decay is that the number of parameters in the proposed
network is much less than that of VGG16. Thus, there is no need to punish. The initial learning rate is 0.1. We train 1,500,000 iterations and reduce the learning rate by multiplying 0.1 at iteration 600,000, 1,000,000, 1,200,000 and 1,400,000. The training time is about 5 days with two NVIDIA GTX1080ti. Our method5 is implemented using MXNet [2].

4. Experiments
In this section, comprehensive and extensive experiments are conducted. Firstly, a new evaluation schema is proposed and the evaluation results on benchmarks are presented. Secondly, we analyse the running efficiency on multiple platforms. Thirdly, we further investigate the amount of computation and storage memory cost, introducing the computation efficiency rate.

4.1. Evaluation on Benchmarks
In this subsection, a new evaluation schema is described at the beginning. The new schema is named as Single Inference on the Original (SIO). SIO emphasizes two things: 1) evaluation results are based on only one inference; 2) the input image size is kept originally without rescaling. On the one hand, it is a shortcut to improve the accuracy by running multiple inferences with different configurations. However, the time cost is not acceptable by doing this. To evaluate via a single inference is rational for practical applications. On the other hand, the sizes of faces from various applications are unpredictable. One of the proper ways to tackle this problem is to keep the original sizes. As far as we know, current evaluation in most methods involves multiple inferences mainly including horizontal flips and image pyramid. We remove these tricks and apply SIO for evaluation.

In the experiments, we have to reproduce the results according to SIO schema. Therefore, we collect the compared methods which have released codes and models. Finally, the following methods are taken for comparison: DSFD [16] (Resnet152 backbone ), Pyramid-Box [28] ( VGG16 backbone ), S3FD [37] ( VGG16 backbone ), SSH [20] ( VGG16 backbone ) and Face-Boxes [36]. DSFD and Pyramid-Box are state of the art methods. The proposed method is named as LFFD. LFFD and Face-Boxes do not rely on existing pretrained backbones and are trained from scratch. We evaluate all methods on two benchmarks: FDDB [12] and WIDER FACE [33].

FDDB dataset. FDDB contains 2845 images with 5171 unconstrained faces. There are two types of scoring: discrete score and continuous score. The first scoring criterion is obtained by thresholding IOU. And the second criterion directly uses IOU ratios. We show final evaluation results of LFFD on FDDB against above five methods in Fig. 3. The overall performance on both scoring types shows the similar trends. DSFD, Pyramid-Box, S3FD and SSH can achieve high accuracy with marginal gaps. The proposed LFFD gains slightly lower accuracy than the first four methods, but outperforms Face-Boxes evidently. The results indicate that LFFD is superior for detecting unconstrained faces.

WIDER FACE dataset. In WIDER FACE, there are 32,203 images and 393,703 labelled faces. These faces are in a high degree of variability in scale, pose and occlusion. Until now, WIDER FACE is the most widely used benchmark for face detection. All images are randomly divided into three subsets: training set (40%), validation set (10%) and testing set (50%). Furthermore, images in each subset are graded to three levels (Easy, Medium and Hard) according to the difficulties for detection. Roughly speaking, a large number of tiny/small faces are in Medium and Hard parts. The ground-truth annotations are available.

---

Figure 3. Evaluation results on FDDB. Many other published methods are not displayed here for clarity.

5Our trained model will be released upon publication
only for training and validation sets. All the compared methods are trained on training set. We report the results on the validation and testing sets in Table 3 and 4, respectively.

Some observations can be made. Firstly, performance drop is evident for DSFD, Pyramid-Box, S3FD and SSH compared to their original results. On the one hand, achieving high accuracy through only one inference is relatively difficult. On the other hand, the tricks can indeed improve the accuracy impressively. Secondly, Pyramid-Box obtains the best results on Hard parts, whereas the performance of SSH on Hard parts is decreased dramatically mainly due to the neglect of some tiny faces. Thirdly, Face-Boxes does not get desirable results on Medium and Hard parts. Since Face-Boxes produces large stride 32 rapidly, which means that faces smaller than 32 pixels are hardly detected. To make it clearer, we conduct additional experiments for Face-Boxes, named as FaceBoxes3.2X, in which the both sides of input images are enlarged 3.2X. We can see that the results on Medium and Hard parts are improved remarkably. The performance drop on Easy parts is attributed to that some faces are resized too large to be detected. To some extent, the results of Face-Boxes and FaceBoxes3.2X indicate that Face-Boxes can not cover faces with large range. Fourthly, the proposed method LFFD consistently outperforms Face-Boxes, although having gaps with state-of-the-art methods. Additionally, LFFD is better than SSH that uses VGG16 as the backbone on Hard parts.

### 4.2. Running Efficiency

In this subsection, we analyze the running speed of all methods on three different platforms. The information of each platform and related libraries are listed in Table 5. We use batch size 1 and a few common resolutions for testing. For fair comparison, FaceBoxes3.2X is used here instead of Face-Boxes. The running speed is measured in ms and the corresponding FPS. The final results are presented in Table 6, 7 and 8.

In Table 6, we also add VGG16 and Resnet50 for sufficient comparison. SSH and S3FD are based on VGG16, having similar speed with VGG16. Whereas, Pyramid-Box is much slower due to additional complex modules, although based on VGG16 as well. DSFD can achieve state of the art accuracy, but it has the slowest running speed. The proposed LFFD runs the fastest at 3840 2160, and FaceBoxes3.2X obtains the highest speed at other three resolutions. Both LFFD and FaceBoxes3.2X can reach or even exceed the real-time running speed (> 30 FPS) at the first three resolutions. The aforementioned trend that state of the art methods pursue higher accuracy at the cost of running speed is clearly verified.

TX2 and Raspberry Pi 3 are edge devices with low computation power. DSFD, Pyramid-Box, S3FD and SSH are either too slow or failed to run on these two platforms. Thus, we only evaluate the proposed LFFD and FaceBoxes3.2X at lower resolutions in Table 7 and 8. The overall results show that LFFD is faster than FaceBoxes3.2X except for the case at 640x480 on Raspberry Pi 3. LFFD can better benefit from optimizations of ncnn than FaceBoxes3.2X at low resolutions 160 120 and 320x240.

### 4.3. Parameter, Computation and Model Size

We investigate the compared methods from the perspective of parameter, computation and model size in this subsection. The edge devices always have constrained storage memories. It is necessary to consider the memory usage of face detectors. The number of parameters is highly related to the model size. However, less parameters do not mean less computation. Following [19], we use FLOPs to measure the computation at resolution 640x480. All the information is presented in Table 9.

For state-of-the-art methods DSFD and Pyramid-Box,

| Method | Easy     | Medium   | Hard     |
|--------|----------|----------|----------|
| DSFD   | 0.947 (0.960) | 0.934 (0.953) | 0.845 (0.900) |
| PyramidBox | 0.926 (0.956) | 0.920 (0.946) | 0.862 (0.887) |
| S3FD   | 0.917 (0.928) | 0.904 (0.913) | 0.821 (0.840) |
| SSH    | 0.919 (0.927) | 0.903 (0.915) | 0.705 (0.844) |
| FaceBoxes | 0.839 | 0.763 | 0.396 |
| FaceBoxes3.2X | 0.791 | 0.794 | 0.715 |
| LFFD   | 0.896 | 0.865 | 0.770 |

Table 3. Performance results on the validation set of WIDER FACE. The values in () are results from the original papers.

| Method | Easy     | Medium   | Hard     |
|--------|----------|----------|----------|
| DSFD   | 0.947 (0.960) | 0.934 (0.953) | 0.845 (0.900) |
| PyramidBox | 0.926 (0.956) | 0.920 (0.946) | 0.862 (0.887) |

Table 4. Performance results on the testing set of WIDER FACE. The values in () are results from the original papers.
they have large amounts of parameters and FLOPs. The proposed LFFD and FaceBoxes3.2X have light networks which are appropriate to deploy on edge devices. To further demonstrate the efficiency of the proposed network, we developed a new metric:

$$E_{\text{net}} = \frac{\text{FLOPs}}{t} \quad (2)$$

where $t$ indicates the running time. $E_{\text{net}}$ reflects the computation efficiency of networks (the larger, the more efficient) and can be calculated at a certain resolution on a specific platform. We compute this metric for LFFD and FaceBoxes3.2X at 640x480 on three platforms (LFFD vs. FaceBoxes3.2X):

- 1.22G/ms vs. 0.42G/ms on TITAN Xp;
- 0.14G/ms vs. 0.04G/ms on TX2;
- 0.0022G/ms vs. 0.00088G/ms on Raspberry Pi 3;

Evidently, the proposed network has much more efficient computation, which demonstrates the superiority of the concise network design.

5. Conclusion

This paper introduces a light and fast face detector that properly balances accuracy and running efficiency. By deeply rethinking the RF in context of face detection, we propose to use RFs as inherent anchors which can cover continuous face scales and reach nearly 100% hit rate. After investigating the essential relations between ERFs and face scales, we delicately design an efficient network with eight detecting branches. Comprehensive and extensive experiments are conducted to fully analyse the proposed method. The final results show that the proposed method can achieve superior accuracy with small model size and efficient computation, which makes it an excellent candidate for edge devices.
