Water model experiments were performed to measure the mixing time and to investigate the effect of nozzle depth in a ladle-refining process. The depth of the submergence nozzle was varied by 6.0, 7.2, and 8.4 cm, which correspond to fractional depths of 0.5, 0.6, and 0.7, respectively. A new technique was proposed in the present study to measure the mixing time using optical image processing. The mixing time for fractional depths of 0.5, 0.6, and 0.7 determined is 26, 19, and 20 sec, respectively. The gas dispersions in the plume zone are distributed asymmetrically. An increase in the nozzle depth, which enhances recirculation speeds, leads to a decrease in mixing time.

KEY WORDS: mixing time; water model; optical image processing.

1. Introduction

An improvement in steel quality plays an important role in the production of clean steel. Clean steel has a very low content of impure elements and inclusions. Inclusions are known to have an adverse effect on steel quality and properties. Gas injection is one of methods developed to remove inclusions from liquid steel. It is usually employed in secondary metallurgy processes and continuous casting to achieve a homogeneous distribution of temperature and composition, and to eliminate second phases and dissolved impurities. Earlier studies on the water model reported particle removal using gas bubble flotation. To analyze phenomena associated with the agitation of liquid baths, the determination of the mixing time is very important. A number of studies have reported that the value of the mixing time obtained experimentally is dependent on the location of the measuring probe and the tracer injection. Murthy has shown that the degree of mixing in the bath changes as the operating conditions is varied.

Gas injection operation is conducted to obtain chemical and thermal homogenization. It plays a significant role in achieving the minimum mixing time at the optimum process parameters. The mixing time refers to the time required for homogeneity to be achieved in all parts of the bath. Therefore, the mixing time can be considered as a representative parameter of the mixing phenomena of the bath in chemical and metallurgical processes. The electrical conductivity technique is usually applied for the determination of mixing time by measuring the concentration changes of an added tracer (for example, NaCl solution) in a liquid bath as a function of time.

Therefore, we propose a new technique in the current study using optical image processing to determine the mixing time for the injection of gas in ladle.

2. Experimental Set-up

The fluid-flow phenomena in a ladle-refining process were simulated physically in the current study using a water-modeling technique. The refining ladle was represented by a transparent, plexi-glass vessel. During the experiment, a series of photographs was taken to examine the flow pattern in the refining process.

The experimental set-up for the determination of mixing time is schematically shown in Fig. 1. The system of the water model consists of a cylindrical plexi-glass vessel containing tap water at room temperature. The vessel is 100 mm wide, 270 mm high, and 2 mm thick. Before injection, 300,000 spherical particles of low-density polyethylene (with a density of 0.92 g/cm³) were on the top surface. Air was injected into the bath through a centric top nozzle using a compressor, and the flow rate is 4 L/min. The nozzle which has an inner diameter of 1.2 mm was located 36, 48, and 58 mm above the bottom part, respectively. The nozzle depths at 36, 48, and 58 mm correspond to 0.5, 0.6, and 0.7 fractional depths of nozzle submergence, respectively.

In the experiments, fluid-flow phenomena were simulated by recording the trajectories of the particles in the quasi-2D area. To simulate a quasi-2D projected area, light is limited to pass through two narrow parallel planes as shown in Fig 1. A CCD camera, Canon EOS D40 with a 2592 × 3888 pixel resolution, was used to record photos every 0.5 sec during the measurement time of 200 sec. The aperture of 2.8 is employed due to a very low illumination on the particles during taking photos. Thus, the aperture is set to a small number, that is, a lot of light get into the camera. It enhances the brightness and contrast of images which is of importance for later image processing.
3. Results and Discussion

3.1. Determination of Mixing Time

In the current study, we proposed a new technique to measure the mixing time using optical image processing. The concept of the application of this technique is based on the distribution of tracer particles in a bath as shown in Fig. 2(g). Chemical homogenization is obtained as the distribution of particles is steady, which means that the flow patterns do not change. Therefore, recording images of the particle distribution every 5 sec and summing up the gray scale value of each pixel in the digital image as a function of time are possible. In the case of 6.0 cm depth, the histograms of the digital image at 10, 20, 30, and 40 sec are shown in Fig. 3(a). Except for that at 10 sec, the distribution of the gray scale from 0 to 4 is almost the same and can be considered as noise. Figure 4(a) shows the filtered image in which each pixel is in black as the value of the gray scale falls below 4, which is called “noise.” In the following calculation, the sum of the gray scale of the “noise” points is abstracted from that of each point in the image.

The sum of the gray scale as a function of time is shown in Fig. 5(a) in which the dashed line refers to experiment data. A Gauss function is used to fit the experiment data, which is represented as a solid line. As time increases, the value approaches a constant value. Therefore, the mixing time is defined when the fitting curve arrives at a constant value. The mixing time for depths of 6.0, 7.2, and 8.4 cm is 26, 19, and 20 sec, respectively.

3.2. Flow Patterns in the Ladle

Figure 2 shows examples of the negative images of the tracer particles during injection. The nozzle is in the center of the vessel, and an asymmetric plume zone is found in the middle area with a dark black color, which indicates bubbles as shown in Fig. 2(a). As the depth of the nozzle is increased from 6.2 to 8.4 cm, the height of the plume is also increased, but the width does not change in Figs. 2(a)–2(b). During gas injection, PE tracer particles are introduced into the bath from the top surface. Further, flow patterns are not symmetric about the centric nozzle. Similar flow patterns are obtained for an injection time of 50 and 150 sec as shown in Figs. 2(d)–2(i).

The main flow-related phenomena are shown in Fig. 6 for
the nozzle positions of 6.0, 7.2, and 8.4 cm from the top surface. The gas dispersions are formed in the plume zone, and their distribution is asymmetric about the nozzle. At first,
the gas bubble moves upward and transports the tracer particles into the upper portion in Fig. 6(a). The uneven flow discharge from the central nozzle may cause asymmetric and unsteady flow in the vessel or periodic oscillations of the level.\textsuperscript{23} The flow in the vessel is quantified by measuring the magnitude of the top surface level fluctuations, that is, the flow pattern shape. An increase in the depth of the nozzle results in an enlargement of flow shape as shown in Figs. 6(a)–6(b).

In a plume zone, the carrier gas rises to the free surface and induces recirculation flows of fluid within the vessel. According to the macroscopic plume model proposed by Sahai and Guthrie,\textsuperscript{24} the average velocity of a plume, $U_p$, is estimated by

\begin{equation}
U_p = k \frac{Q^{1/3} L^{1/4}}{R^{1/3}}
\end{equation}

where $Q$ is the gas flow, $L$ is the liquid depth, and $R$ is the ladle radius.

The flow patterns generated in these cases are very similar. According to Eq. (1), an increase in the nozzle depth causes the recirculation speeds to increase. Therefore, this results in a reduction in mixing time.

4. Conclusions

A new technique was demonstrated to measure mixing time using image processing. The mixing time for 6.0, 7.2, and 8.4 cm depths is 26, 19 and 20 sec, respectively. The distribution of gas dispersions in the plume zone is asymmetric. An increase in the nozzle depth, which enhances recirculation speeds, results in a reduction in mixing time.
