We compare the results of the transport and time-resolved magneto-luminescence measurements in disordered 2D electron systems in GaAs-AlGaAs heterostructures in the extreme quantum limit, in particular, in the vicinity of the metal-insulator transition (MIT). At filling factors $\nu < 1$, the optical signal has two components: the single-rate exponentially decaying part attributed to a uniform liquid and a power-law long-living tail specific to a microscopically inhomogeneous state of electrons. We interpret this result as a separation of the 2D electron system into a liquid and localized phases, especially because the MIT occurs strikingly close to those filling factors where the liquid occupies $\frac{1}{2}$ of the sample area (the percolation threshold condition in two-component media).
The metal-insulator transition (MIT) in two-dimensional (2D) electron systems still remains to be a hot topic in the semiconductor physics, in particular, because of a variety of transitions between quantum Hall liquids and insulating states in the extreme quantum limit realized at high magnetic fields. Depending on the level of disorder in the system, the MIT can be either due to the Wigner crystallization, or due to localization. In pure enough systems, it has the thermodynamic character and is conventionally attributed to the interaction-induced crystallization of 2D electrons into the Wigner solid. In disordered structures, the dielectric states is formed because of localization of the 2D electrons by a random potential coming from an inhomogeneous charge distribution in the donor layer, and the interest of the present publication is focused on the latter situation.

Although the single-particle scenario of localization of electrons at high magnetic fields was already thoroughly explored some years ago, the most recent theories emphasize the influence of interactions on the MIT also in disordered systems, especially regarding the existence of a hierarchy of strongly correlated quantum Hall liquids. Being inspired by the success of the scaling ideas developed in single-particle models, the search of a global phase diagram of the MIT in the extreme quantum limit has been started in order to describe the growing amount of experimental data. However, one should not ignore such a possibility that, in interacting electron systems, the transition between correlated liquids and disordered insulator is the Mott transition rather than the Anderson one, and that the mesoscopic-scale inhomogeneity in the strength of a random potential itself can result in the separation of the 2D system into phases with locally different properties (liquid versus localized insulator). In this scenario, the portion of a localized phase varies continuously under the variation of a magnetic field due to the sensitivity of the electron-electron correlations to the value of the filling factor, so that the MIT detected in the transport might manifest nothing but the destruction of the percolation through the liquid in a multicomponent media.

To find the truth, it is necessary to make a local measurement which would distinguish between different phases (liquid and insulator) and to evaluate amount of each of them. We solve this problem by using the method based on the analysis of the time-resolved recombination of 2D electrons with a small number of acceptor bound holes in the δ-doped layer. We already know that, in contrast to the quantum Hall effect state at the filling factor ν = 1 that demonstrates the single-exponential decay I(t) ∝ exp(−t/t₀), the magnetically frozen state manifests itself in a broad spectrum of recombination rates which results in the power-law kinetics of the magneto-luminescence. It is a peculiarity of the recombination process involving acceptor bound holes that the latter form a small neutral centers, and that the life-time t of each hole is determined by the local density of 2D electrons at the acceptor position, t⁻¹ ∝ ρe, so that the spectrum I(t⁻¹) of recombination rates t⁻¹ reflects the distribution of the local 2D electron density. The latter can be found from the inverse Laplace transform of the measured temporal dependence I(t) of the luminescence intensity after a short illumination pulse, I(t) ∝ ∫ dτ⁻¹f(τ⁻¹)e⁻τ⁻¹/τ. For example, the mentioned above single-exponential decay of the luminescence at ν = 1 evidences the microscopic-scale homogeneity of the 2D electron density in this incompressible liquid state, whereas the information about the distribution of local values ρe which we extract from the long-living tails of luminescence from any state at ν < 1 may be used for identification of its intrinsic structure, like it has been done before in the Wigner solid regime.

In the present paper we combine the transport measurements with the time-resolved optics to study systematically a series of heterostructures with various densities and level of disorder. In the entire interval of filling factors ν < 1 and in all the samples, the magneto-luminescence kinetics looks as if it is composed of a single-exponential (liquid-type) contribution I_1(t) ∝ exp(−t/t₀) and the universal contribution I_2(t) from inhomogeneous localized state with a power-law long-living asymptotics I_2(t) ∝ (t₀/t)α summed with different weights. This enables us to distinguish between the liquid and localized phases and to estimate their portions in the mixture. Our result shows that for all the samples under investigation the liquid phase fills about 3/4 of the sample area at the MIT point, which coincides with the condition of the percolation threshold in 2D two-component media.

We studied six different quality (see Table 1) GaAs-AlGaAs single heterojunctions with a δ-doped monolayer of Be acceptors (n_A = 1.3 × 10⁹ cm⁻²) located in the wide (1 μm) GaAs buffer layer at a distance about 30 nm from the interface. The magnetoresistance tensor was measured on the Hall bar samples by use of a standard low-frequency (12 Hz) and low-current (10 nA) lock-in technique with a resistance 100 MΩ connected in series with the sample. For photoexcitation, we used pulses from a tunable Ti-Sapphire laser (wavelength 800 nm) with duration 20 ns, peak power of 10⁻⁴ W/cm² and frequency of 10⁻² Hz.

Fig. 1 shows the results of magneto-transport measurements (in the range of temperatures T = 50 – 150 mK) which were used for determining the MIT point in two samples B and E which have identical concentration but very different mobilities (see Table 1). The conductivity measured in samples of different qualities shows quite distinguishable behavior, especially at ν < 1. In particular, in better quality samples (A,B,C) one can find the crossing between σ_xx(B) taken at different temperatures which can be used for determination of the MIT point. However, such an inter-crossing does not appear in the magneto-conductivity data taken in the lowest mobility structures (D,E,F), so that another criterion of the MIT
is desirable. The common feature of all studied samples near the MIT was an abrupt appearance of the out-of-phase signal both in the diagonal and Hall components of resistivity which is accompanied by a drastic decrease of a current and indicates the formation of a dielectric state. Fig. 1 also shows the evolution of the magnetic field dependence of the current through the 2D system with the temperature. Under the decrease of a filling factor, the current shows a threshold at \( \nu_c \) which becomes more pronounced at lower temperatures, and treat this behavior as the indication of the MIT point. The value of \( \nu_c \) determined in such a way is pretty close to the position of the peak in \( \sigma_{xx} \) in samples D-F, which has been used by Glazman et al and others \( \text{[3]} \) as a criterium of MIT. Note that in the present investigation we do not fight for the accuracy of determining \( \nu_c \) better than few percent, since our aim to see a correspondence between the MIT data observed transport and optical data that show no threshold behavior. Indeed, in contrast to the transport, the optical data taken in the same samples demonstrate only a continuous evolution both of the integral and time-resolved spectra. Insets to Fig. 1 (a) and (b) show the raw data of typical recombination kinetics measured in samples (B,E) in different magnetic fields at \( T = 50 \text{mK} \) and we see no critical changes occurring when \( \nu = \nu_c \) is passed.

The magneto-luminescence kinetics measured in lower- and higher-mobility samples has both common features and significant differences. The common feature of the recombination kinetics observed in all the samples is the purely exponential decay, \( I(t) \propto \exp(-t/t_0) \), of the magneto-luminescence intensity at the filling factor \( \nu = 1 \). Since the density of optically active holes is much smaller than the 2D electron density, the time dependence \( I(t) \) is controlled by the recombination rates of holes. In the homogeneous electron system, the latter are determined by the sheet electron density and the distance from the interface to the acceptor mono-layer and are the same for all of them, so that the single-rate \( \tau^{-1} = t_0^{-1} \) exponential decay manifests the microscopic scale homogeneity of the electron density. At \( \nu = 1 \), this is the well known property of a trial many-body wave-function corresponding to a completely filled Landau level \( \text{[1]} \).

For the lower fillings, the slow recombination tail develops, which indicates the formation of a short-range scale inhomogeneity of the local electron density (on the scale of \( n_e^{-1/2} \)). This behavior is common for all samples we studied and evidences a partial localization of the system under an increase of a magnetic field which starts much earlier than the MIT takes place. Here, the difference between low and high mobility samples manifests itself: in the former, the long-living tails develop at considerably higher filling factors (lower magnetic fields). To make a comparison easier, in Fig. 2 we show the kinetics of magneto-luminescence \( I(t) \) for three groups of samples \( \{B, D\}; \{B, C, E\}; \{E, F\} \), each group been studied at the same filling factor \( \nu = 0.19; 0.42; 0.58 \). Within each group of samples, the luminescence intensity presented in Fig. 2 is normalized to the same integral value (e.g., \( \int I^{(B)}(t)dt = \int I^{(D)}(t)dt \) in the first group), which enables us to compare both the form of the long-living tails and their strength in samples with different parameter and at the same or different values of the filling factor.

First of all, after comparing the data taken in different samples at the same \( \nu \), to say, \( B, C \) and \( E \) for \( \nu = 0.42 \), we find that the strength of the long-living recombination tail is systematically more significant in lower quality samples. At the same time, the form of the tails at a long enough delay time is essentially the same for different samples studied at the same values of the filling factor. The presentation of the data in Fig. 2 using the log-log plot has been chosen in order to demonstrate that the recombination kinetics at the long-living tails obey the power law \( \text{[1]} \),

\[
I(t) = A (t_0/t)^\alpha, \quad t > t_0, \tag{1}
\]

and that the exponents \( \alpha \) of the power law dependence coincide in different samples, if we make the measurement at the same filling factor, although the strength of the tail (i.e., parameter \( A \)) is higher when disorder is stronger. The power law kinetics has been predicted by the earlier theory of recombination in the extreme quantum limit \( \text{[6]} \), with the exponent \( \alpha \) which can be approximated by \( \alpha \approx 1 + \nu \) at \( \nu \ll 1 \). The fact that the exponent of the magnetoluminescence kinetics calculated in Ref. \( \text{[6]} \) depends only on the value of the filling factor was the result of the assumption that in the magnetically frozen state electrons are strongly localized at the inter-particle distances - each sitting opposite to its own donor behind a narrow spacer. The spectrum of experimentally derived \( \alpha \)'s for all the available samples and for a broad range of filling factors, \( 0.75 > \nu > 0.15 \), is presented in the inset to Fig. 2. Although these data correspond to the samples of a very different quality and concentration, the experimentally obtained values of \( \alpha \) group near a single filling factor dependence \( \alpha(\nu) \). This is what we call the universality of the power-law recombination kinetics of localized electrons. In a good approximation, the empirical \( \alpha \) has the form \( \alpha \approx (1 - \nu)^{-1} \), which is consistent with the theory by Fal’ko \( \text{[6]} \) for \( \nu \ll 1 \).

As we discussed above, the kinetics of recombination of 2D electrons with acceptor-bound holes in a \( \delta \)-doped layer is governed by the spectrum of the recombination rates of holes, \( \tau^{-1} \propto \rho_e \), which, in its turn, reflects the character of the distribution \( f(\rho_e) \) of the local 2D electron density, \( \rho_e \). From this point of view, the observed power-law kinetics of recombination in Eq. \( \text{[1]} \) can be directly recalculated (using the inverse Laplace transform) into the power-law distribution of the local 2D electron density, \( f(\rho_e) \propto \rho_e^\beta \) with \( \beta = \alpha - 2 \approx (2\nu - 1)/(1 - \nu) \) and the observed universality of the luminescence kinetics has behind it the universality of the distribution of a local density in a localized disordered state of magnetically frozen electrons. Below, we use this fact for
measuring the disorder-dependent portions of insulating and liquid phases in the sample. Fig. 3 shows that the extraction of the power-law tail from the total intensity gives the rest of it which has a typical single-exponential behavior at the intermediate range of the delay time. The parameters (A and α) of the slow recombination tail \( I_s(t) = A(t_0/t)^\alpha \) were determined from a fit of the power law asymptotics at \( t \gg t_0 \). The rest of the recombination intensity, \( I_l = I(t) - I_s(t) \), is represented in Fig. 3 by solid circles and demonstrates an exponential decay, \( I_l(t) \propto \exp(-t/t_0) \) which can be followed over the same number of decades as at \( \nu = 1 \). The single-rate decay is the property of a microscopically homogeneous density, so that we assign this part of the luminescence intensity to the liquid state of electrons and suggest that the 2D electron system represents a mixture of a liquid and disorder-induced localized phases.

The goal of our analysis is to construct a diagram illustrating the evolution of the portion of the sample area, \( S_l(\nu) = \left[ \int I \ dt \right] / \left[ \int I \ dt \right] \), occupied by a liquid under the decrease of the filling factor. The dependence \( S_l(\nu) \) determined for six different samples is shown on Fig. 4. The relative amount of the liquid phase in all the structures tends to decrease under an increase of a magnetic field, which manifests the formation of the freeze-out regime. In the low-mobility samples (D,E,F), the localization is much more efficient and develops smoothly in the entire region of filling factors \( \nu < 1 \).

In the better quality samples (A,B,C), the general tendency of the portion of the liquid to decrease with increasing of a magnetic field is accompanied by oscillations associated with the fractional quantum Hall effect states (see Fig. 4). The amount of the recombination events that we assign to the liquid has clear maxima at \( \nu = \frac{1}{3} \), \( \frac{1}{5} \), \( \frac{1}{7} \), \( \frac{1}{5} \) in samples B and C, and at \( \frac{1}{3}, \frac{1}{5}, \frac{1}{7} \) in the sample A. This is a manifestation of the incompressibility of the Laughlin liquid, in which the interaction effects are strong enough (compared to disorder) to keep the electron density microscopically homogeneous. This supplies us with an additional argument in favor to the assumption that the separation of the system into the liquid and insulating phases at any filling factor is a result of a competition between electron-electron interactions and disorder in which the former tempt to form a homogeneous liquid state whereas the latter tends to break correlations among electrons and to localize them. Note, that even the best quality samples studied in the present paper were disordered enough and did not show abrupt features specific to the Wigner crystallization.

Let us finally focus at the region near the critical filling factor \( \nu_c \) of the MIT determined using the transport measurements (see Fig. 1). For each single sample, the optically characterized level of localization smoothly changes near \( \nu_c \) and shows no striking features. However, been compared in a wide variety of structures, the MIT always occurs strikingly close to those filling factors where the continuously varying portion of a liquid fills one half of the sample area. The fundamental property of the percolation transition in macroscopically inhomogeneous 2D media is that it occurs when the insulating component occupies one half of the sample area, that’s when the percolation path through the conducting phase is destroyed.

Our conclusion is that the magnetic field driven MIT which we observe at \( \nu < 1 \) is related to the percolation threshold through the liquid in the systems with the phase separation into a liquid and disorder insulator.
