Characterisation of Conformational and Ligand Binding Properties of Membrane Proteins Using Synchrotron Radiation Circular Dichroism (SRCD)

Rohanah Hussain and Giuliano Siligardi

Abstract

Membrane proteins are notoriously difficult to crystallise for use in X-ray crystallographic structural determination, or too complex for NMR structural studies. Circular dichroism (CD) is a fast and relatively easy spectroscopic technique to study protein conformational behaviour in solution. The advantage of synchrotron radiation circular dichroism (SRCD) measured with synchrotron beamlines compared to the CD from benchtop instruments is the extended spectral far-UV region that increases the accuracy of secondary structure estimations, in particular under high ionic strength conditions. Membrane proteins are often available in small quantities, and for this SRCD measured at the Diamond B23 beamline has successfully facilitated molecular recognition studies. This was done by probing the local tertiary structure of aromatic amino acid residues upon addition of chiral or non-chiral ligands using long pathlength cells (1–5 cm) of small volume capacity (70 μl–350 μl). In this chapter we describe the use of SRCD to qualitatively and quantitatively screen ligand binding interactions (exemplified by Sbnα, Ace1 and FsrC proteins); to distinguish between functionally similar drugs that exhibit different mechanisms of action towards membrane proteins (exemplified by FsrC); and to identify suitable detergent conditions to observe membrane protein-ligand interactions using stabilised proteins (exemplified by inositol transporters) as well as

the stability of membrane proteins (exemplified by GalP, Ace1). The
importance of the in solution characterisation of the conformational
behaviour and ligand binding properties of proteins in both far- and
near-UV regions and the use of high-throughput CD (HT-CD) using 96-
and 384-well multiplates to study the folding effects in various protein
crystallisation buffers are also discussed.

throughput-CD (HTCD) • SRCD UV-denaturation assay • Ligand binding

4.1 Introduction
Circular Dichroism (CD) and Synchrotron
Radiation CD (SRCD) has been proven to be
highly useful for studies of ligand binding by
soluble proteins, particularly as it is a relatively
quick and easy spectroscopic measurement,
requiring no extensive sample preparation, and it
has the potential to be used in high throughput
(HT-CD) screening (Mason 1982; Fasman 1996;
Berova et al. 2000, 2012; Siligardi and Hussain
1998, 2015; Siligardi et al. 2002; Martin et al.
2011; Johnson 1990; Kelly et al. 2005; Siligardi
and Hussain 2010; Jávorfi et al. 2010; Fiedler
et al. 2013).

CD spectroscopy has been widely used for
the purposes of determining secondary structural
content and integrity of membrane proteins (e.g.
histidine kinases – Potter et al. 2002; Kim et al.
2010; Keegan et al. 2010; Yeo et al. 2008; mem-
brane transporters – Psakis et al. 2009), protein
fragments (e.g. Powl et al. 2010), and protein
unfolding (Psakis et al. 2009; Keegan et al. 2010).
Sreerama and Woody 2004, found that the CD
analysis of secondary structure content of mem-
brane proteins using soluble protein reference
sets was slightly inferior to that obtained for solu-
ble proteins. The inclusion of membrane proteins
in the soluble protein reference sets – now a
common practise – has since improved the CD
analysis for both membrane and soluble proteins.

In the last few decades, drug discovery has
benefited from information about the three-
dimensional structure of proteins at atomic
resolution determined by X-ray crystallography
(Carvalho et al. 2009) and NMR spectroscopy
(Pellecchia et al. 2008). However, the number
of solved human protein structures deposited
in the Protein Data Bank is still only a small
fraction of the approximately 20,000 protein-
coding genes in the human genome (Pennisi
2012). As many proteins that cannot be studied
by either X-ray crystallography due to their
failure to crystallise or by Nuclear magnetic
resonance spectroscopy (NMR) due to their size
or irregular structure, can be characterized in
terms of protein folding by CD, which is the
differential absorption between left and right
circularly polarized light (Fasman 1996), see
Fig. 4.1. CD spectroscopy is sensitive to the
absolute configuration and conformation of chiral
molecules. With the exception of glycine, amino
acids are chiral molecules adopting either L or
either or D stereo-isomers which are non-superimposable
mirror-imaged configurations. Natural proteins
only consist of L amino acids.

The application of CD spectroscopy for ligand
binding studies of membrane proteins has proved
more limited, largely due to the technical chal-
lenges associated with working with hydrophobic
membrane proteins. The use of the B23 beam-
line (Diamond Light Source synchrotron) for
SRCD has overcome the limitations encountered
in studying precious membrane proteins often
available in very small quantities. The B23 beam-
line has enabled the use of small volume ca-
pacity cuvette cells for the measurements in the
far-UV and near-UV spectral regions that could
not otherwise be used with bench-top CD in-
struments. The UV protein denaturation assay,
a unique feature of the B23 beamline, is an-
other method developed to assess ligand binding interactions, in particular for achiral fatty acid ligand analogues or small organic molecules devoid of UV chromophores, which are difficult, if not impossible to investigate with bench-top CD instruments. The higher vacuum UV and far-UV photon flux has proved essential for the spectroscopic characterisation of membrane proteins in high salt concentrations to enhance protein stability, which cannot be achieved satisfactorily with bench-top instruments due to absorption cut-off.

In this chapter, several examples of SRCD spectroscopy applied to the study of membrane proteins in solution using the Diamond B23 beamline (Hussain et al. 2012a, b; Jávorfi et al. 2010) are presented. Qualitative and quantitative assessments of ligand binding interactions of the FsrC, SbmA, and Ace1 membrane proteins, identification of functionally similar but mechanistically distinct drug targeting FsrC, and the characterisation of suitable detergent conditions for ligand-membrane proteins interaction studies are reviewed.
4.2 Diamond B23 Beamline for Synchrotron Radiation Circular Dichroism (SRCD)

The B23 beamline is a bending magnet beamline at Diamond Light Source, UK, dedicated to SRCD spectroscopy. The beamline consists of two distinct end-stations: module A in operation since 2011 and module B in operation since 2009, see Fig. 4.1. The beamline operates in the wavelength range of 125–650 nm, delivering a highly collimated beam with a focal spot size at the sample of 0.5 mm² and a photon flux in excess of $10^{12}$ photons/s. The high brilliance of the beamline, coupled with its highly collimated incident micro-beam is enabling a large variety of measurements and experiments to be carried out, ranging from dilute to highly concentrated solutions, to thin solid films. The end-station of module A operates in the wavelength range of 125–500 nm and is primarily dedicated to the study of thin chiral films, whereas module B operating in the 165–650 nm is dedicated to solutions and liquid samples. A novel vertical sample chamber, which is unique among the other SRCD beamlines around the world, has been developed to accommodate a horizontal X-Y motorised stage that can hold either the temperature controlled stage (such as Linkam™ stage), which can operate in cryogenic and high temperature conditions (from $-150$ °C to $300$ °C), or standard microtiter or microwell plates (96- and 384-well Suprasil quartz plates (Siligardi and Hussain 2015) for high throughput CD (HT-CD) screening.

Module B is dedicated to ligand binding interactions that are often carried out as CD titrations using small aperture cuvette cells that require the ability to optimise beam alignment in a fast and reproducible manner using a manual X-Y stage (Borisenko et al. 2015). This allows for measurements of dilute solutions (as low as 5 nM protein concentration) (Laera et al. 2011) using small volume capacity cells such as 0.800 ml for 10 cm pathlength or 0.020 ml for 1 cm pathlength. SRCD stopped-flow can also be carried out in both modules. The higher photon flux of SRCD beamlines has traditionally been considered detrimental as it promotes protein denaturation. Measures have been put in place to eliminate or greatly reduce this effect, however, this phenomenon, has also been exploited at the B23 beamline as UV protein denaturation (Hussain et al. 2012a, b; Jávorfi et al. 2010) can be conveniently used to measure accelerated protein photo stability as a function of protein formulation and qualitatively assessing and screening ligand binding interactions (Hussain et al. 2012a, b; Longo et al. 2014, 2015). For module B, a rotating sample cell holder has also been introduced to eliminate protein denaturation induced by the higher vacuum UV and far-UV photon flux for experiments where the UV denaturation effect is not desirable, such as thermal denaturation. Finally, to support the capabilities and potential of B23 beamline applications, a concerted software development program has been put in place. Users can now reduce and analyse their data through a single software application developed at the beamline – CDApps (Hussain et al. 2015). The software is available for users on-site, as well as via remote access, and allows novice users to quickly process their data and take full advantage of the technique.

4.3 Ligand Binding Studies of the FsrC, Ace1 and SbmA Membrane Proteins

Protein-ligand binding interactions can be assessed by a variety of techniques such as Isothermal Calorimetry (ITC), Surface Plasmon Resonance (SPR), Fluorescence and Circular Dichroism (CD). Each technique has its own strengths and weaknesses. ITC can often be inconclusive when the thermal effects associated with the displacement of the bound solvent molecules by the ligand are rather small. SPR requires one of the components to be immobilized, which can lead to false positive or false negative results when compared to non-immobilized conditions. Fluorescence requires the presence of a fluorophore that does not absorb and emit light at the same wavelength for the ligand and/or protein (Tryptophan and Tyrosine residues). CD relies on detectable spectral differences between the
observed spectrum of the protein-ligand mixture at \((x:y)\) molar ratio and the calculated sum of the spectra of the protein at \((x)\) molar ratio and ligand at \((y)\) molar ratio. For achiral ligands, the comparison is facilitated by the fact that the ligand chromophore will acquire an induced CD upon binding of a protein site that is chiral. In this case, the detection of any induced CD, which is any spectral difference from that of the protein alone, is unambiguously indicative of the presence of a bound species, as the free achiral form is devoid of any CD from its UV absorbing chromophore (Siligardi and Hussain 1998; Hussain et al. 2012b; Siligardi et al. 2002; Martin et al. 2011). However, for ligands with weak or with no UV chromophore groups, such as sugars, lipids and irregular peptides, the lack of any CD spectral change upon ligand addition does not necessarily signify that there are no binding interactions. The ligand might bind far from the aromatic side-chains of the protein, without causing any detectable secondary structure conformational change. For these cases, the protein UV denaturation assay using the B23 beamline was developed and is now part of the facilities available at the Diamond B23 beamline (Hussain et al. 2012a, b; Jávorfi et al. 2010). High UV photon flux at B23 was used to qualitatively distinguish the binding of ligands to proteins, such as non-steroidal anti-inflammatory drugs to serum albumin, though not a membrane protein is a transporter (Hussain et al. 2012a). UV denaturation can also be used to discriminate the effects of different excipients, such as detergents, salts, and buffers on peptide hormones such as vasoactive peptide VIP, which binds to a GPCR (Longo et al. 2015) and antibodies (such as cetuximab which is an inhibitor of EGFR, a transmembrane protein) on the effect of formulating agents (Longo et al. 2015; Siligardi and Hussain 2015). These measurements are easy to carry out, as it only requires repeated scanning of samples and a plot of the denaturation decay, which will provide differential dynamics properties of the system.

Binding studies using the CD titration method are even more challenging for membrane proteins than they are for soluble proteins. A common limitation encountered with membrane proteins is that they are often expressed in rather small quantities. At the B23 beamline, the highly collimated incident micro-beam \((0.3 \times 0.5 \text{ mm})\) is enabling the use of a small aperture cuvette cells of low volume capacity (from few \(\mu l\) to 25 \(\mu l\) for 0.01 cm to 1 cm pathlengths) to measure the SRCD of precious and scarce membrane proteins.

FsrC, a membrane protein histidine kinase, showed very little conformational changes in secondary structure upon addition of ligand Gelatinase Biosynthesis-Activating Pheromone (GBAP). However, the local tertiary structure of FsrC showed significant changes when GBAP was added, indicating the involvement of aromatic residues binding to GBAP, see Fig. 4.3. Qualitative studies showed that the affinity of the ligand GBAP to FsrC was \(2 \times 10^{-7} \text{ M}\), monitored at a single wavelength of 277 nm. Further competitive binding studies with another ligand, siamycin I, showed that siamycin I did not compete with GBAP and that aromatic side-chain residues should be involved in the interaction with the ligand (Patching et al. 2012; Phillips-Jones et al. 2013).

SbmA, a bacterial inner membrane protein of Gram-negative bacteria is involved in the transport within the cell of prokaryotic and eukaryotic antimicrobial peptides and glycopeptides, as well as of peptide-nucleic acid (PNA) oligomers. A SbmA homolog, BacA, is required for the development of Sinorhizobium meliloti bacteroids within plant cells and favours chronic infections with Brucella abortus and Mycobacterium tuberculosis in mice. A SRCD spectroscopic study provided evidence that SbmA and BacA interact in vitro with Bac7 (1–35), a proline rich peptide. Bac7 was titrated at various molar ratios to SbmA and BacA in both the far-UV (180–260 nm) and near-UV (250–330 nm) regions. In the far-UV region, significant changes of secondary structure were observed upon addition of Bac7 to SbmA (see Fig. 4.4a and Table 4.1) and BacA (Fig. 4.4b) indicating binding interactions. In the near-UV region (Runí et al. 2013), characteristic of the local tertiary structure of aromatic side-chain residues (Tryptophan, Tyrosine and Phenylalanine) (Siligardi et al. 1991; Siligardi and Hussain...
Fig. 4.2 (a) Thirty repeated consecutive SRCD spectra of fatty acid and immunoglobulin free human serum albumin (HSAff). The insert is the rate of protein denaturation at 190 nm. (b) Rate UV protein denaturation of HSAff in H2O with and without ligands such as fatty acid (octanoic acid), diazepam and tolbutamide measured at 190 nm for 100 repeated consecutive SRCD spectra. (c) Rate of UV protein denaturation of antibody Mab-1 in different formulation agents for 30 repeated consecutive SRCD spectra. The graph is reported in percentage of protein folding damage calculated by dividing the ellipticity at 205 nm of the protein-ligand complex by that of the protein alone and multiplied by 100.

1998; Hussain et al. 2012b; Gaspar et al. 2011) no significant changes were observed, which suggests that no aromatic residues were involved at close range (radius of 6 Å) in the interface between ligand and protein. The SRCD spectra were converted to $\Delta A = (A_L - A_R)$ units from millidegree units and the plot of $\Delta A$ intensities at 223 nm versus the concentrations of Bac7 used in the titration was analysed with a non-linear regression method (Siligardi et al. 2002) to quantitatively determine the dissociation constant using CDApps software (Hussain et al. 2015). The results showed that the peptide had similarly high binding affinities to SbmA (Kd of 0.26 $\mu$M) and BacA (Kd of 0.3 $\mu$M).

For the membrane protein Ace1 (actinobacter chlorhexidine efflux transport system 1), no significant conformational changes in the far-UV region (180–250 nm) were observed in the presence of an achiral chlorhexidine antibacterial drug (Hassan et al. 2013). However, in the near-UV region, the SRCD titration unambiguously showed the induced CD of the bound chlorhexidine to the Ace1 membrane protein (Fig. 4.5a). The non-linear regression analysis of the SRCD data revealed adissociation constant...
**Fig. 4.3** Binding interaction properties of FsrC membrane protein determined using the B23 beamline for synchrotron radiation circular dichroism (SRCD) (a, b, c figures redrawn from Patching et al. 2012 and Phillips-Jones et al. 2013). (a) Far-UV SRCD spectra of FsrC membrane protein with (dashed) and without (solid) GBAP ligand Patching et al. 2012. (b) Near-UV SRCD spectra: (top) FsrC with (dashed) and without (solid) GBAP ligand. The insert is the fitting of the GBAP SRCD titration into FsrC protein using a non-linear regression analysis. The Kd calculated from CD data was 2 µM, (bottom) FsrC with (dashed) and without (solid) Siamycin I ligand. (c) Near-UV SRCD spectra of (FsrC + GBAP) (thick black), (FsrC + Siamycin I) (dashed) and (FsrC + GBAP + Siamycin I) (thin black). The unique micro-collimated beam of Diamond’s B23 beamline enabled the measurements to be carried out using a small volume capacity cell (50–100 µl) of 1 cm pathlength otherwise unattainable with bench-top CD instruments.

(Kd) of 6 µM (Fig. 4.5b). In this example the binding was demonstrated by the increased induced CD at about 270 nm, which reach a plateau upon saturation. The ligand binding did not perturb the content of the secondary structure of Ace1, as illustrated by the lack of conformational changes in the far-UV SRCD spectrum.

### 4.4 Protein Stability

Throughout the course of protein production, different batches of proteins are expressed and different protocols or procedures for purification are used. These variables can have an effect on the integrity of the proteins. This is especially relevant to membrane proteins that have to be
**Fig. 4.4** (a) SRCD spectra of SbmA with and without Bac7 in the far-UV (left) and near-UV (right) regions. The insert in the far-UV region shows the determination of the dissociation constant Kd calculated to be 0.28 μM by fitting the CD data at 223 nm versus Bac7 concentration using the non-linear regression analysis (Siligardi et al. 2002) of CDApps (Hussain et al. 2015). (b) SRCD spectra of BacA with and without Bac7 in the far-UV (left) and near-UV (right) regions. The insert in the far-UV region spectra shows the determination of the dissociation constant Kd calculated to be 0.30 μM by fitting the CD data at 223 nm versus Bac7 concentration using the non-linear regression analysis of CDApps.

**Table 4.1** Protein secondary structure content of SbmA and BacA membrane proteins with and without addition of Bac7 ligand up to 1:35 molar ratios calculated from SRCD data using CONTINLL algorithm (Sreerama and Woody 2004) with SMP50 reference data set of 37 soluble proteins and 13 membrane proteins applied through CDApps beamline software (Hussain et al. 2015).

Redrawn from Runti et al. 2013
solubilised in different detergents for stabilisation and for crystallisation with potential ligand molecules.

The example of the FsrC protein (Patching et al. 2012) showed that it required 1.5 h of incubation time for stabilisation, which was determined by measuring consecutive repeated scans of about 3 min each in the 260–180 nm region until the dominating alpha helical spectral feature stopped increasing at about 30 scans, see Fig. 4.6. It was essential to know the specific equilibration time for FsrC, and more generally, the equilibration time for membrane proteins in each specific detergent, when assessing ligand binding interactions, as otherwise it might result in ambiguous results. Interestingly, for FsrC the addition of ligand peptide GBAP appeared to stabilize the protein rather quickly (Fig. 4.6). The sugar transport protein GalP was also monitored for stability over time using the repeated scan method using high UV photon flux (Kalverda et al. 2014) showing that GalP is stable over repeated scans using a smaller bandwidth of 1.1 nm.

**Fig. 4.5** SRCD titration of chlorhexidine into 20 μM purified wild-type AceI protein. (a) Near-UVSRCD spectra of AceI protein with and without chlorhexidine. The arrow indicated the spectra with increased concentration of chlorhexidine. (b) Plot of ellipticity (θ) intensity versus chlorhexidine concentration. The fitting curve (solid line) of the experimental data (solid black circles) was calculated using the non-linear regression analysis with a Kd of 5.9 μM (Siligardi et al. 2002)

### 4.5 Temperature Denaturation

Temperature denaturation studies on proteins are routinely used to determine the thermodynamic properties of wild type proteins, their mutants, and the effect of ligand binding interactions or that of excipients as stabilisers to withstand long protein storage and transport conditions.

However, for the SbmA protein (described in Sect. 4.4) the thermal behaviour was not affected by the addition of peptide Bac-7 (Fig. 4.7a), even though conformational changes by SRCD were observed in the far-UV region (Fig. 4.4) (Runti et al. 2013). The SRCD titration of Bac7 with SbmA indicated that the molecular interaction was accompanied by an 11% decrease in alpha helical content for either SbmA or Bac7 (Table 4.1). The thermal studies, however, showed no significant differences between the melting temperature ($T_m = 55 ^\circ C$) of SbmA and the melting temperature of a mixture of SbmA and Bac7 (Fig 4.7).
In the temperature denaturation study of the Ace1 protein (Kalverda et al. 2014) the protein melting temperatures were measured by ramping the temperature from 5 to 90 °C while monitoring the far-UV CD spectrum, particularly at 209 nm or 222 nm. The wild-type protein was observed to be rather stable at temperatures below 60 °C. However, mutant E50Q Ace1, known to impair resistance to chlorhexidine, showed thermal denaturation at 40 °C. Chlorhexidine binding greatly increased the thermal stability of the E50Q mutant protein in a dose-dependent manner. Importantly, these experiments yielded evidence, albeit indirect, that the Ace1 protein was itself involved in binding chlorhexidine as an integral feature of the resistance mechanism.

In a study by Bettaney et al. (2013), the SRCD spectra of three inositol membrane transport proteins (IolF, IolT, and YfiG) measured with the Diamond B23 beamline showed a cut-off below 180 nm, indicated by the voltage of the photo-
multiplier tube (PMT) detector exceeding 600 V (Fig. 4.8). It is essential for accurate secondary structure estimations that the positive CD bands at about 190–195 nm of the \( \alpha \)-helical conformation are measured with the lowest level of noise possible, which can be readily achieved with synchrotron CD beamlines. Repeated scans can also improve the signal-to-noise-ratio, but at an increased overall time (the noise is reduced by the root square of the number of scans). Following successful confirmation of secondary structural integrity and composition, the specificity of IolF, IolT, and YfiG for a large variety of inositols and sugars of D and L configuration was determined by measuring the cellular uptake of radiolabelled 3H-myo-inositol in the presence of unlabelled competing compounds (Bettaney et al. 2013) as well as differences in thermodynamic properties, which could give indications of any concerns for crystallisation trials.
Fig. 4.8 Analysis of secondary structure and thermal denaturation profiles in the purified proteins. Synchrotron radiation circular dichroism (SRCD) spectra at 20 °C in the far-UV region are shown for the purified IolT(His₆), IolF(His₆) and YfiG(His₆) proteins at a concentration of 20 μM in a buffer containing 0.05% DDM and 10 mM potassium phosphate (pH 7.6) using a 0.2-mm pathlength cell and acquiring spectra with an interval time of 0.5 nm. The spectra are buffer-subtracted and are the average of four scans. The plots show the CD spectrum (CD) and the high tension (HT) voltage values. Inset are thermal stability profiles at a wavelength of 222 nm from CD spectra recorded over a range of temperatures (10–90 °C and then back to 10 °C) for each of the proteins at a concentration of 0.1 mg/ml (redrawn from Bettaney et al. 2013).

4.6 Conformational Analysis and HT-CD Screening of Protein Crystallisation Buffers

The assessment of protein folding in solution is particularly important because conformational changes among a wild type protein and its mutants/constructs are likely to affect the protein activity and stability. Protein folding plays a crucial role in the function of a protein and its characterisation is a prerequisite for the understanding of the mechanism and consequences of sequence amino acid point mutation that could trigger protein misfolding for insulin, α-synuclein, lysozyme, and transthyrethin to name but a few cases with serious health implications (Blancas-Mejía and Ramirez-Alvarado. 2013; Ruzza et al. 2014, 2015; Marchiani et al. 2013).

A recent example regarding the importance of protein folding characterisation (including different constructs of the same protein) by SRCD is the case of the membrane protein GDP-mannose-dependent mannosyltransferase WbdD. In this example, the accurate determination of
the α-helical content of the protein was crucial as a molecular ruler to regulate O-antigen chain length in lipopolysaccharide of *E. coli* 09A (Hagelueken et al. 2015).

WbdD is a membrane-associated protein and its interaction with WbdA (another GDP-mannose-dependent mannosyltransferase) is essential for the ability of the soluble polymerase to act on the membrane-embedded undecaprenyl lipid–linked acceptor (Clarke et al. 2009). The authors investigated two insertion and two deletion variants of WbdD1–556 to gain some structural insight into the effect of the changes in the coiled-coil region. Multi-techniques such as the crystal structure of WbdD1-556 showing the coiled-coil region, molecular modelling and small angle X-ray scatterings (SAXS) models were coupled to elucidate the 3D structure. The study was further expanded with a bioassay of different constructs, giving various lengths of coupled lipopolysaccharides with CD spectroscopy. Circular dichroism analysis of WbdD1–459 and WbdD1–556 using the CONTINLL algorithm (Sreerama and Woody 2004; Hussain et al. 2015) on spectra collected on B23 at Diamond confirmed a detectable increase in α-helical content, as was expected by the addition of a coiled-coil region (Fig. 4.9). This multi-technique study helps to piece together information gathered and complements the limitations of each of the individual techniques into a final and more complete understanding of the role of the coiled-coil region of the protein as a molecular ruler.

The high photon flux of the B23 beamline has been successfully used to develop a protein UV-denaturation assay that can discriminate the relative stability of different types of protein folding and also to qualitatively determine ligand binding interactions (Hussain et al. 2012a, b; Jávorfi et al. 2010; Longo et al. 2014, 2015). The latter application has been very useful to study ligands with weak or no UV chromophores that would otherwise be difficult or impossible to monitor by conventional benchtop CD spectrometer.

The conformation of peptides and proteins is known to be affected by environmental conditions such as buffer composition, pH, salt concentration, detergents, metal ions and precipitants. The latter is widely used in crystallography to enhance crystallisation. However, the use of CD spectroscopy for such characterisations would be rather laborious and time consuming as this would normally be carried out by measuring the samples in a single cuvette cell, one by one. The unique highly collimated incident micro-

*Fig. 4.9* CD spectra of different Wbd constructs and their secondary structure content estimation using CONTINLL (Sreerama and Woody 2004) of CD Apps beamline software (Hussain et al. 2015). On the right is shown the percentage of α-helical content calculated from SRCD data using CONTINLL algorithm in CDApps beamline software.
beam (from 0.3 mm$^2$ to 1.5 mm$^2$ cross section) of the B23 has recently been exploited for the use of 96- or 384-well plates, to allow for high throughput CD (HT-CD) (Fig. 4.10) screening to characterise protein folding in crystallisation conditions and in protein-drug binding interactions (Siligardi and Hussain 2015).

Myoglobin, a highly $\alpha$-helical protein, was investigated by SRCD spectroscopy dissolved in a selection of 48 conditions from the MemGold2 crystallisation screen (Molecular Dimensions) that is widely used for membrane protein crystallization. The corresponding 48 SRCD spectra (Fig. 4.11) showed significant conformational differences that could be attributed to electrolyte concentration and pH. It is important to note that despite myoglobin being a highly $\alpha$-helical soluble protein its conformation can be perturbed by the membrane protein crystallisation buffer MemGold2. This can be readily illustrated in the pie chart of the secondary structure content determined by SRCD spectroscopy using CONTINLL of the SRCD spectra of the 96-well multiplate (Fig. 4.12).

Most membrane proteins are highly helical and it is not inconceivable that they too might behave similarly to myoglobin under various buffer conditions. This is consistent with the fact that membrane proteins only crystallise in certain buffer conditions (Privé 2007; O’Malley 2011) but not in others. This raises the question whether proteins that do not crystallise do not do so because they have different conformations that do not promote association or that their thermodynamic properties are significantly different, inhibiting crystal formation.

The availability of HT-CD facility at the B23 beamline opens up the possibility of finding cross-correlations between buffer conditions and protein conformation, identifying possible buffer targets that could promote crystallisation for further 3D structural determination by X-ray crystallography.

### 4.7 Conclusion

The work described in this chapter highlights the use of CD and SRCD spectroscopy for studies of membrane proteins, particularly when a wide spectral range from far-UV to near-UV region (180–350 nm) is achieved for both protein and ligand. This approach enables the determination of the stability and content of the protein sec-
Characterisation of Conformational and Ligand Binding Properties of Membrane Proteins

Fig. 4.11 SRCD spectra of myoglobin dissolved in 48 distinct buffers of MemGold2 for membrane protein crystallisation.

Fig. 4.12 Secondary structure content of myoglobin dissolved in the 48 crystallographic solvent conditions of the MemGold2 multiplate (well coordinates A1-12, B1-12, C1-12 and D1-12). The pie chart was prepared using B23 CDApps software (Hussain et al., 2015). Although the α-helix content is the dominating element of secondary structure, significant different α-helical contents were induced by some of the MemGold2 solvent conditions. At first glance less helical content can be observed in A3, A4, A6, A8-12, C3, C4, D9 (12 out of 48 or 25%) whilst more helical in B3, B4, B7, B8, B10, B12 and C11 (6 out of 48 or 12.5%).

The amide bond of the protein backbone structure gives information about the protein secondary structure while the aromatic side-chains of the tryptophan, tyrosine and phenylalanine amino acid residues provide details about their local tertiary structure, as such, these are ideal as molecular probes for ligand binding interactions. The chromophore of the ligand can be used to unambiguously determine ligand binding in both far- and near-UV regions and in particular whether protein conformational changes are occurring upon ligand binding. Further development in high throughput allows the screening of crystallization buffers and the potential screen-
ing of ligands in drug discovery with membrane proteins acting as host or target receptor. This broad approach of CD spectroscopy in solution for membrane proteins is advantageous. SRCD in particular provides wavelength extension in the vacuum UV region and higher photon flux, which enables more penetrating measurements with less transparent media (NaCl content up to 500 mM) and in small volume capacity cuvette cells that are unattainable using bench-top CD instruments.

Acknowledgments We gratefully acknowledge the Diamond Light Source Ltd. for the B23 beamtime allocation (www.diamond.ac.uk/Home/ForUsers.html).
