Miniaturized Broadband ENG ZOR Antenna Using a High Permeability Substrate

Seung-Tae Ko · Jeong-Hae Lee

Abstract

This paper presents a miniaturized epsilon negative (ENG) zeroth-order resonance (ZOR) patch antenna with an improved bandwidth. The miniaturization and the broad bandwidth of the ENG ZOR patch antenna are achieved by using a meandered via and a high permeability substrate instead of a straight via and a dielectric substrate. The use of a meandered via allows miniaturization of the ENG ZOR patch antenna without narrowing the bandwidth. The use of a high permeability substrate allows further miniaturization of the ENG ZOR patch antenna and improvement of the bandwidth. A high permeability substrate consisting of a multi-layered substrate is designed to have a small material loss. The antenna ($k_r=0.32$) has a 10 dB fractional bandwidth of $\sim 1\%$, which is 1.74 times as broad as that of an antenna with a dielectric substrate.

Key words: Epsilon Negative (ENG), Zeroth-Order Resonance (ZOR), Meandered Via, High Permeability Substrate, Multi-Layered Substrate.

I. Introduction

Many efforts have been made recently to develop miniaturized antennas having broad bandwidth for use in wireless communication systems. For instance, the epsilon negative (ENG) zeroth-order resonance (ZOR) mushroom patch antenna, which is a low profile omnidirectional radiator, was proposed to achieve miniaturization of a patch antenna [1]. Many ENG ZOR patch antennas are designed by using a high permittivity ($\varepsilon_r>1$) substrate or a periodic structure [1], [2]. These antennas can be further miniaturized, but they suffer from narrow bandwidth.

In this paper, we investigate two methods for designing a miniaturized ENG ZOR patch antenna with broad bandwidth. First, when a straight via of the conventional mushroom ENG ZOR patch antenna is replaced by a meandered via, this induces a large shunt inductance. Using the meandered via, the miniaturization of an antenna can be achieved without narrowing the bandwidth [3]. Second, a high permeability substrate ($\mu_r>1$) is utilized instead of a high permittivity substrate. A high permeability substrate is well known to allow a patch antenna to have broad bandwidth [4]~[6]. As a high permeability substrate, we use a multi-layered substrate (consisting of dielectric and ferrite layers) that is designed to have a small material loss. The miniaturized ENG ZOR patch antennas are designed by combining a meandered via and a high permeability substrate. Finally, the theoretical and experimental results are compared.

II. The ENG ZOR Patch Antenna with a Meandered Via

First, a straight via is replaced by a meandered via to obtain a broad bandwidth. The structure of the conventional mushroom ENG ZOR patch antenna and its equivalent circuit are shown in Fig. 1. The mushroom structure is typically composed of a patch and a straight via. Thus, the corresponding shunt inductance ($L_c$) and capacitance ($C_R$) are induced by a via and a patch, respectively. The ZOR frequency is then obtained by the open-ended boundary condition, and is given by [7]:

$$f_{ZOR} = \frac{1}{2\pi \sqrt{L_C C_R}}.$$  (1)
The shunt capacitance ($C_s$) is calculated as:

$$C_s = \frac{W_f^2}{R_s}.$$  \hspace{1cm} (2)

In this equation, a high permittivity substrate causes a large shunt capacitance ($C_s$). The $Q$ factor of a parallel resonance circuit is written by [8]:

$$Q = \frac{R_s}{\omega_0 L_s} = \frac{\omega_0 R_s}{C_s}$$  \hspace{1cm} (3)

where $R_{sat}$ includes the radiation loss ($R_{rad}$) and the material loss ($R_{loss}$). Equation (3) indicates that a large shunt inductance ($L_s$) and a small shunt capacitance ($C_s$) are required in order to have a broad bandwidth.

Fig. 2 shows two structures of the ENG ZOR patch antennas. The conventional mushroom ENG ZOR patch antenna is shown in Fig. 2(a). This antenna is based on a dielectric substrate that has a relative permittivity of 2.6. The antenna in Fig. 2(b) is the ENG ZOR patch antenna with a meandered via that is placed in the edge of the patch. The antenna in Fig. 2(b) is based on an air substrate. Both antennas are the same size, with the following dimensions: patch width ($W$) of 150 mm (0.1 $\lambda_0$), substrate width ($W_s$) of 250 mm (0.166 $\lambda_0$), and height ($h_s$) of 30 mm (0.02 $\lambda_0$). Both antennas are also designed to have the same operating frequency of 200 MHz. In order to obtain the same operating frequency, a proper dielectric substrate is applied to the antenna in Fig. 2(a).

Fig. 3 shows the simulated return losses for the two antennas using the full wave simulator (Ansoft HFSS). The intrinsic input impedance of the antenna without other external influences is obtained by directly connecting a port between the patch and ground. The input impedance can then be obtained from the simulation result. When the input impedance is normalized as a peak value, a full $S_{11}$ is obtained.

The simulated results for lossless case are shown in Fig. 3(a). The antenna in Fig. 2(a) has a resonance frequency of 194.9 MHz and a 10 dB fractional bandwidth of 0.14 %. The antenna in Fig. 2(b) has a resonance frequency of 196.5 MHz and a broader 10 dB bandwidth of 0.35 %. The radiation efficiencies of the two antennas are obtained at 100 % because no loss is considered. The simulated results, including a conductor loss ($\sigma$ $c$ = 5.8 x 10$^7$ S/m), are shown in Fig. 3(b). The figure shows that each resonance frequency is unchanged, but the radiation efficiencies are decreased because the conductor loss is considered. Thus, the 10 dB fractional bandwidth is broader than for the lossless case. The antennas in Fig. 2(a) and (b) have the 10 dB bandwidth of 0.19 % and 0.49 %, respectively. The radiation efficiencies of the two antennas that include a conductor loss are also obtained as 73.3 % and 70.7 %, respectively. The antenna miniaturization can be achieved by using a high permittivity substrate, but its bandwidth becomes too narrow because of the induction of the large shunt capacitance by a high permittivity substrate, as shown for the antenna in Fig. 2(a). However, the antenna in Fig. 2(b) has a broader bandwidth than the antenna in Fig. 2(a), even though the size and the resonance frequency are equal. The meandered via allows an ENG ZOR patch antenna to have a large inductance, resulting in broader bandwidth.

III. The ENG ZOR Patch Antenna with a High Permeability Substrate

Second, a broad bandwidth is also obtained by using a high permeability substrate instead of a high permittivity substrate. In general, the resonance frequency of the conventional patch antenna is known to depend on $\varepsilon_r$ and $\mu_r$. Therefore, the value of relative permeability ($\mu_r$) is the same as that of relative permittivity ($\varepsilon_r$) for antenna miniaturization. The 10 dB fractional bandwidth for a dominant resonance mode of the conventional patch antenna is given by [9]:

$$\text{Fractional BW}[^\%] = \sqrt{\frac{\mu_r}{\varepsilon_r}} \cdot \sqrt[3]{\frac{9600 h_s}{\varepsilon_r (4 + 17 \sqrt{\mu_r \varepsilon_r})}}$$  \hspace{1cm} (4)

where $h_s$ is a height of the substrate. According to (4),
the miniaturized ENG ZOR patch antenna having a broad bandwidth can be designed when a high permittivity substrate is replaced by a high permeability substrate.

Table 1 shows the simulated bandwidths for the ENG ZOR patch antenna in Fig. 2(b), with three different substrates, while \( \varepsilon \), \( \mu \), is fixed to keep the same size of antenna. Table 1 shows that the 10dB fractional bandwidths are obtained as \( 9.0 \times 10^{-4} \) %, \( 4.0 \times 10^{-3} \) % and \( 8.0 \times 10^{-3} \) % when the values of relative permittivity and relative permeability of the substrate are given by \( \left( \varepsilon, \mu \right) = (25, 1), \left( \varepsilon, \mu \right) = (5, 5) \) and \( \left( \varepsilon, \mu \right) = (1, 25) \), respectively. Note that no loss is included in this simulation. As expected, a high permeability substrate allows the antenna to have the broadest bandwidth.

### IV. The Multi-layered Substrate with High Permeability

Since most ferrites have hundreds or even thousands of permeability values, a high dielectric (or magnetic) loss, and a dispersive property, they are difficult to apply to ENG ZOR antennas. In this paper, we used a Co2Z-type (BaCo2Fe12O31) hexaferrite material with a relative permittivity of 12, a relative permeability of 10, and a magnetic loss tangent (\( \tan \delta_m \)) of 0.03 around 200 MHz. This hexaferrite is manufactured by Trans-Tech Inc. [10]. Although the hexaferrite has a relatively large permeability, it still has several problems. Some modifications are required in order to obtain a smaller relative permittivity and a lower tan \( \delta_m \). Thus, we used the multi-layered substrate shown in Fig. 4. The structure of Fig. 4 consists of 2 layers of hexaferrite and 3 layers of RT/duriod5880 substrates. The RT/duriod5880 substrate has a relative permittivity of 2.2, a relative permeability of 1, and a dielectric loss tangent (\( \tan \delta_d \)) of \( 9.0 \times 10^{-4} \). The heights of the RT/duriod5880 and the hexaferrite substrates are 9.51 mm and 2.5 mm, respectively. Thus, the total height of the multi-layered substrate is 33.53 mm.

To confirm the characteristics of the multi-layered substrate, the equivalent relative permittivity and the equivalent relative permeability need to be extracted. Since the RT/duriod5880 and hexaferrite substrates have material losses, the equivalent parameters should be a complex number. Note that the equivalent permittivity and the equivalent permeability can be expressed as \( \varepsilon_{eq} = \varepsilon' - j \varepsilon'' \) and \( \mu_{eq} = \mu' - j \mu'' \), respectively. As shown in Fig. 5, the equivalent parameters can be extracted in a few steps. First, \( \varepsilon'\) and \( \mu'\) can be extracted from the full wave simulated results for the parallel plate waveguide with a multi-layered substrate, assuming that \( \varepsilon''\) and \( \mu''\) are zero. To extract \( \varepsilon'\) and \( \mu'\), the simulated propagation constant of \( \beta \) and the simulated characteristic impedance of \( Z_0 \) are compared with the analytical ones. Second, if only the dielectric loss tangent of the RT/duriod5880 is considered (\( \tan \delta_d = 9.0 \times 10^{-4}\)) and the hexaferrite is considered as lossless, a complex propagation constant of \( \gamma \).is can be expressed as step 2 in Fig. 5 and \( \varepsilon'' \) can be calculated from the following equation:

\[
\varepsilon'' = \frac{a \beta \varepsilon c^2}{2 \mu' (\pi f)^2}.
\]  

(5)

Similarly, from step 3 in Fig. 5 \( \mu'' \) can be written by:

\[
\mu'' = \frac{a \beta \varepsilon c^2}{2 \varepsilon' (\pi f)^2}.
\]

(6)

where a magnetic loss tangent (\( \tan \delta_m = 0.03 \)) is considered. For the multi-layered substrate in Fig. 4, we can obtain \( \varepsilon' \) of 2.482, \( \tan \delta_d \) of 8.7354\( \times 10^{-3} \), \( \mu' = 2.373 \), and \( \tan \delta_m \) of 0.0193. The multi-layered substrate in
The Co2Z-type hexaferrite layers are placed toward the via, as shown in Fig. 7, because the magnetic field of the antenna is concentrated at the via. In order to match 50 Ohm, a rectangular gap (0.5 mm) is inserted between the feed and the patch. The antenna (kr=0.32) has the following dimensions: patch width (Wp) of 60 mm (0.040 λ₀), patch length (Lp) of 55 mm (0.037 λ₀), substrate width (Ws) of 100 mm (0.067 λ₀), substrate length (Ls) of 110 mm (0.073 λ₀), and height (hs) of 23.14 mm (0.015 λ₀).

The measured S11 is shown in Fig. 8. The solid line shows the simulated S11 and the dashed line shows the measured S11. In the simulated results, the antenna has an operating frequency of 199.2 MHz, a 10 dB bandwidth of 0.88 %, and a radiation efficiency of 5.3 %. The measured operating frequency is 196.1 MHz, the 10 dB fractional bandwidth is 0.99 %, and the radiation efficiency is 6.1 %. Thus, the measured results are in good agreements with the simulated results. This antenna has a poor radiation efficiency because of its material loss.

**V. Measurement**

Fig. 7 shows the one unit cell ENG ZOR patch antenna. The RT/duroid5880 substrates are located in the top and bottom layers and two layers of Co2Z-type hexaferrite are inserted between the RT/duroid5880 substrates. To obtain a lower material loss, air spaces of 5 mm are then added between each layer. In fact, the hexaferrite has a limited size (50.8×50.8×2.5 mm).
However, if the $\tan \delta_m$ of the hexaferrite substrate was $3.0 \times 10^{-4}$, the radiation efficiency of this antenna would be increased up to 32.5 %. A higher efficiency ENG ZOR antenna could also be obtained by increasing the thickness of the copper. For example, if the $\tan \delta_m$ of hexaferrite was $3.0 \times 10^{-4}$ and the thickness of copper was 0.17 mm, the ENG ZOR antenna would have a radiation efficiency of 37.8 % according to the simulated result. If this antenna is built on a pure dielectric substrate ($\varepsilon_r=2.5$, $\mu_r=1$ and $\tan \delta_d=6.0 \times 10^{-3}$) instead of a multi-layered substrate, the operating frequency, the 10 dB fractional bandwidth, and radiation efficiency would be 198.7 MHz, 0.57 %, and 5.2 %, respectively. Note that the dielectric constant ($\varepsilon_r=2.5$) and the loss tangent ($\tan \delta_d=6.0 \times 10^{-3}$) of the dielectric substrate are chosen for the antenna to have the same frequency and efficiency as the multi-layered antenna. Since the fabricated antenna has an asymmetric substrate, extraction of the equivalent parameters is difficult just using the proposed method. However, we can expect that the substrate has a relative permeability that is larger than 1.

Finally, Fig. 9 shows the measured far-field radiation pattern. The fabricated antenna has an omni-directional pattern, as shown in Fig. 9(b). The simulated and measured peak gain are obtained as $-11.2$ dBi and $-8.69$ dBi, respectively.

VI. Conclusion

In this paper, a miniaturized ENG ZOR patch antenna ($kr=0.32$) is proposed that has an improved bandwidth. The broad bandwidth is obtained for the ENG ZOR patch antenna by using a meandered via and a high permeability substrate. A multi-layered substrate is also designed to create the high permeability substrate. The ENG ZOR patch antenna using a meandered via and a high permeability substrate can have a broader bandwidth than a similar antenna using a straight via and a dielectric substrate. The 10 dB fractional bandwidth of the fabricated antenna is 0.99 %, which is 1.74 times as broad as that of the antenna with the dielectric substrate.
