Traditionally one and two-point correlation functions are used to characterize many-body systems. In strongly correlated quantum materials, such as the doped 2D Fermi-Hubbard system, these may no longer be sufficient because higher-order correlations are crucial to understanding the character of the many-body system and can be numerically dominant. Experimentally, such higher-order correlations have recently become accessible in ultracold atom systems. Here we reveal strong non-Gaussian correlations in doped quantum anti-ferromagnets and show that higher order correlations dominate over lower-order terms. We study a single mobile hole in the t – J model using DMRG, and reveal genuine fifth-order correlations which are directly related to the mobility of the dopant. We contrast our results to predictions using models based on doped quantum spin liquids which feature significantly reduced higher-order correlations. Our predictions can be tested at the lowest currently accessible temperatures in quantum simulators of the 2D Fermi-Hubbard model. Finally, we propose to experimentally study the same fifth-order spin-charge correlations as a function of doping. This will help to reveal the microscopic nature of charge carriers in the most debated regime of theHubbard model, relevant for understanding high-$T_c$ superconductivity.

Introduction.– High-temperature superconductors are prime examples of strongly correlated quantum matter. In these quasi-2D systems superconductivity arises when mobile dopant’s are introduced into a parent anti-ferromagnetic (AFM) compound [1, 2], but the detailed mechanism remains elusive. It is widely believed that the interplay of spin and charge degrees of freedom plays a central role for understanding the underlying physics at low doping and can be described theoretically by the Fermi-Hubbard or t – J model [3]. The central goal of this letter is to demonstrate that key features of magnetic dressing of doped holes in the Fermi Hubbard model can be revealed by analyzing five point spin-charge correlation functions. Furthermore, such high order correlation functions are found to be larger than the lower order ones in the regime of low doping and low temperatures.

Understanding the nature of charge carriers in strongly correlated electron systems, such as the doped Fermi Hubbard model, is a central problem of quantum many-body physics. While a single mobile hole inside the 2D quantum Heisenberg AFM forms a magnetic (or spin-) polaron [4–16], with spin and charge quantum numbers, it remains unknown whether spin and charge excitations (spinons and chargons) may become deconfined in the strange metal and pseudogap regimes, usually a characteristic of doped 1D spin chains [17–20]. Direct experimental or numerical evidence remains lacking so far.

A common perspective on the puzzling properties of cuprates is the idea of several competing orders. Thus numerical studies of the Fermi Hubbard and t – J models have often focused on the analysis of two point correlation functions with the goal of characterizing different types of

![FIG. 1. Fifth-order spin-charge correlations](image-url)

In a quantum AFM with a mobile dopant are studied in the 2D t – J model and compared to the corresponding 4th-order correlators in the undoped Heisenberg AFM (a); We use DMRG on a 6 × 12 cylinder and evaluate correlators at the center, in spin-balanced ensembles with $\langle S^z \rangle = 0$. For one mobile dopant, genuine 5-th order correlations $C^{\text{con}}_5$ (Eq. (2), blue) are significantly larger (by a factor ×7) than the lower-order disconnected terms $C^{\text{discon}}_5 = C^{\text{con}}_5 - C^{\text{con}}_4$ (yellow). In the undoped Heisenberg AFM the opposite is true: lower order correlators are dominant, while genuine higher-order correlations are smaller (×0.4). (b) Spin-charge correlators as a function of $t/J$. Our numerical results (data points, bare correlations $C_0$ in red) are explained by a frozen-spin approximation (FSA) ansatz (ribbons; width indicates statistical errors).
broken symmetries. Furthermore, two point correlation functions can be naturally accessed in solid state systems using scattering experiments [21–23] and they play a central role in the development of effective mean-field theories. Recently, with the advent of quantum simulators based on ultracold atoms and ions, and especially quantum gas microscopes [24–31], analysis of higher-order correlation functions, pioneered in Ref. [32], has become a new experimental tool in the study of quantum many-body states [14, 33–38]. They have rarely been studied so far, even though they contain a wealth of information about the underlying quantum states and are expected to become relevant when mean-field theories characterized by Gaussian correlations are no longer sufficient for capturing the physics.

Here, we identify lightly doped quantum AFMs as a system where genuine higher-order spin-charge correlations are present. Different from the situation in the undoped parent spin models, these higher-order correlations even dominate over lower-order terms when $t/J$ is sufficiently large, see Fig. 1 (a). Hence they provide a promising new diagnostic to unravel the nature of charge carriers and distinguish different theoretical models [39]. Indeed, we show that even non-perturbative effective theories, such as doped resonating valence bond (RVB) states, cannot explain the higher-order correlations we find numerically at low doping. Instead, our results can be interpreted as signatures of geometric strings [15, 40] connecting spins and chargons [41–44], reminiscent of an underlying $\mathbb{Z}_2$ Gauss law. Physically, strong five-point correlations indicate that a moving hole leaves behind a string of flipped spins, as shown in Fig. 2.

In this paper, after introducing the higher-order spin-charge correlators, we perform DMRG ground state simulations of one mobile dopant on an extended cylinder. We then compare the latter to effective theories based on doped RVB states and the string picture. Finally, we use exact diagonalization to determine the temperature required for an experimental verification. In a follow-up paper we include the effect of a pinning potential [45].

Higher-order correlators. We consider the following fifth-order ring spin-charge correlator,

$$C_0(r) = \frac{2^4}{(n_h^b)} \langle \hat{n}_r^{\uparrow} \hat{S}^z_{r+e_x} \hat{S}^z_{r+e_y} \hat{S}^z_{r-e_x} \hat{S}^z_{r-e_y} \rangle,$$

where $n_h^b$ is the hole (dopant) density at site $r$ and $\hat{S}^z_j$ denotes the spin operator in $z$-direction at site $j$. To witness the presence of genuine higher-order correlations, we calculate the connected correlator in the co-moving frame with the hole (defined in the supplements). In a spin-balanced ensemble with $\langle \hat{S}^z \rangle = 0$ (see discussion in Ref. [45]), expectation values with an odd number of $\hat{S}^z$ operators vanish and we obtain

$$C_{0}^{\text{con}} = C_0 - 2^4 \sum_{(i,j) \neq (k,l)} \frac{\langle \hat{n}_r^{\uparrow} \hat{S}^z_{r+e_x} \hat{S}^z_{r+e_y} \hat{S}^z_{r-e_x} \hat{S}^z_{r-e_y} \rangle}{\langle \hat{n}_r^{\uparrow} \rangle \langle \hat{n}_r^{\uparrow} \rangle}.$$

FIG. 2. The three-point spin-charge correlator diagonally next to the hole, $(\hat{n}_j^b \hat{S}^z_{j+e_x} \hat{S}^z_{j-e_x} \hat{S}^z_{j+e_y} \hat{S}^z_{j-e_y})$ (green bubble next to gray dot), vanishes for a mobile hole moving through a classical Néel state at the end of an infinitely long $S^z$-string. The fifth-order correlations $C_0 \propto (\hat{n}_j^b \hat{S}^z_{j+e_x} \hat{S}^z_{j+e_y} \hat{S}^z_{j-e_x} \hat{S}^z_{j-e_y})$ remain sizable and negative.

In weakly correlated quantum systems, the values of higher-order correlation functions are dominated by more fundamental lower-order correlators. I.e. connected $n$-th order correlation functions $C_n^{\text{con}}$ decrease with decreasing $n$, $|C_1^{\text{con}}| > |C_2^{\text{con}}| > ...$; For classical (product) states all connected correlations vanish $C_0^{\text{con}} = 0$, while in Gaussian systems only $C_1^{\text{con}}, C_2^{\text{con}} \neq 0$ are non-zero [46].

**Magnetic polarons.** Intriguingly, for a magnetic polaron, formed when a single mobile hole is doped into an AFM, we find that the disconnected contributions from the lower-order correlators, $C_n^{\text{disc}} = C_0 - C_n^{\text{con}}$, are significantly smaller in magnitude than the higher-order correlators: $|C_n^{\text{disc}}| > |C_0^{\text{con}}(r)|, |C_n^{\text{con}}(r)|$. In Fig. 1 we show DMRG results [47] for the ground state of a single hole in the $t - J$ [50] model, as a function of $t/J$. The mobility of the dopant plays an important role for observing sizable higher-order spin-charge correlations. As $t/J$ is increased from $t/J = 1$ to $t/J = 5$, the absolute value of $C_0^{\text{con}}$ approximately doubles. Throughout, the product of the lower-order two-point correlation functions is almost an order of magnitude smaller.

We can define related 4th-order correlators in the absence of doping as $D_0(r) = 2^4 \langle \hat{S}^z_{r+e_x} \hat{S}^z_{r+e_y} \hat{S}^z_{r-e_x} \hat{S}^z_{r-e_y} \rangle$; a corresponding expression as in Eq. (4) is obtained for the connected part $D_0^{\text{con}}(r)$. In the classical Ising AFM, $D_0 = 1$ and $D_0^{\text{con}} = 0$. For the 2D Heisenberg model we performed DMRG simulations on a $6 \times 12$ cylinder and obtain $D_0 = 0.12$ and $D_0^{\text{con}} = -0.083$ in the ground state, as indicated in Fig. 1 (a). The connected 4th-order correlator only becomes negative because we subtract the significantly larger and positive two-point correlators, $D_0^{\text{disc}} = D_0 - D_0^{\text{con}} = 0.20$. As expected for a weakly correlated quantum system, and different from the ground state with a mobile hole in the $t - J$ model, the lower-order correlators dominate in the 2D Heisenberg model: They are more than twice as large as the genuine fourth order correlations.

Orders of magnitude and the signs of $D_0^{\text{con}}$ can be understood from a simple model of spontaneous symmetry breaking. Consider an ensemble of classical Néel states with AFM order parameters pointing in random directions. Because $D_0$ is always measured in the $z$-basis, we average over the entire ensemble and obtain

$$D_0|_{\text{cl}} = 0.2; \quad D_0^{\text{con}}|_{\text{cl}} = -0.133.$$

These correlations are purely classical. Quantum fluctuations are expected to further reduce these values in the

$$|\Psi\rangle = \frac{1}{\sqrt{4}} |\uparrow\rangle + |\downarrow\rangle + |\uparrow\rangle + |\downarrow\rangle.$$
SU(2) invariant Heisenberg model, as confirmed by our DMRG calculations. Geometric and $S^z$-strings.—Negative 5th-order correlations $C_{\text{con}}^{(5)}(r) < 0$ provide a signature of AFM correlations hidden by the motion of dopants. To understand the origin of such higher-order correlations, we first consider a toy model of a single hole in an Ising AFM pointing along the $S^z$-direction. Neglecting string configurations affecting more than one spin in the direct vicinity of the mobile dopant, we notice that $C_{\partial}$ switches sign if the hole is attached to a string $\Sigma$ of over-turned spins ($S^z$-string) of length $\ell > 0$. Hence $C_{\partial}$ can be expressed by the probability $p_{t>0}$ for the string to have non-zero length, namely $C_{\partial} \approx p_{t=0} - p_{t>0}$ or $C_{\partial} \approx 1 - 2p_{t>0}$.

Assuming that the system is in an equal superposition of all string configurations, we can estimate various correlation functions. Because the hole is equally likely to occupy either sublattice, $\langle \hat{h}^z_r \hat{S}^z_{r \pm x,y} \hat{S}^z_{r \pm x,y} \rangle = 0$. Three-point correlations $\langle \hat{h}^z_r \hat{S}^z_{r \pm x,y} \hat{S}^z_{r \pm x,y} \rangle$ vanish, as can be seen by averaging over the four possible orientations of the first string segment, counting from the hole, and neglecting string configurations which affect more than one spin in the immediate vicinity of the hole, see Fig. 2. Hence, Eq. (4) implies $C_{\text{con}}^{(3)}(r) = C_{\partial}(r) \approx -1$ for sufficiently many non-zero strings $p_{t>0} \approx 1$.

In this setting, relevant to the 2D $t-J_z$ model [40, 51], $C_{\partial}$ takes the role of a $Z_2$ Gauss law: the mobile dopants represent $Z_2$ charges and the $Z_2$ electric field lines correspond to $S^z$-strings of overturned spins. Similarly, in the SU(2) invariant $t-J$ or Fermi-Hubbard models the higher-order correlator $C_{\partial}$ serves as an indicator for geometric strings [15, 40] of displaced spins.

The $t/J$ dependence observed in Fig. 1 can be explained within the geometric string trial by a frozen-spin approximation (FSA) ansatz [40]. As in Refs. [52, 53] we start from snapshots of the Heisenberg ground state in the Fock basis along $S^z$ and create a hole by randomly removing one spin. This dopant is subsequently moved through the system in random directions, re-arranging the positions of the surrounding spins while keeping their quantum state frozen; the string length distribution is calculated from a linear string model with string tension $dE/d\ell = 2J(C_{2} - C_{1})$ [40], where $C_{1(2)}$ are nearest (next-nearest) neighbor spin correlations in the undoped AFM. This way, new sets of snapshots are generated for every value of $t/J$, from which the higher-order correlators can then be obtained [52].

Doped spin liquids.—A class of microscopic variational wavefunctions that has been used to model doped quantum spin liquids is based on Anderson’s RVB paradigm [54, 55]. Being able to resolve properties of the many-body wavefunction on microscopic scales, ultracold atom experiments provide an opportunity to put the RVB theory to a rigorous experimental test in a clean system.

Here we calculate the higher-order spin charge correlations $C_{\text{con}}^{(con)}$ for two paradigmatic doped RVB trial states. The uniform RVB state starts from an unpolarized Fermi sea (FS) of free spin-up and spin-down spinons $\tilde{f}_{k,\sigma}$. To describe a free hole excitation moving through the system, one spinon with momentum $k$ and spin $\sigma$ is removed. A meaningful trial state for the $t-J$ model, without double occupancies and independent of $t/J$, is obtained by applying the Gutzwiller projection: $|\Psi_{u\text{RVB}}\rangle = N\tilde{P}_{\text{GW}}\tilde{f}_{k,\sigma}|\text{FS}\rangle$ normalized by $N$. We use standard Metropolis Monte Carlo sampling [56] to evaluate $C_{\text{con}}^{(con)}$ in the trial state $|\Psi_{u\text{RVB}}\rangle$, and show our result in Fig. 3. We find $C_{\text{con}}^{(con)} = -0.049(4)$ with significantly smaller magnitude than found for large values of $t/J$ by DMRG, cf. Fig. 1.

We find a similar result for the doped $\pi$-flux RVB state [57], for which recent agreement with experimental data has recently been reported in ultracold atoms at finite doping [52, 53]. The $\pi$-flux state with a single hole has the same form as the $u$RVB state above, except that the Fermi sea (FS) is replaced by a Dirac semimetal of spinons obtained when introducing $\pi$ magnetic flux per plaquette in the effective spinon Hamiltonian [58]. In this case $C_{\text{con}}^{(con)} = -0.049(3)$ slightly increases and $C_{\partial} = -0.008(3)$ decreases in magnitude. Both are significantly weaker than numerically expected from DMRG when $t > J$.

In a recently proposed extension of the RVB ansatz, geometric strings are included in the trial wavefunction [15, 59]. Now we demonstrate that the presence of such geometric strings increases the expected higher-order correlators. We start from the optimized RVB wavefunction for half filling (no doping) [60, 61], which includes a weak spontaneously formed staggered magnetization along $S^z$-direction. A spinon is removed in the usual way and after the Gutzwiller projection a geometric string is added to the hole, thus re-arranging the spins surrounding the dopant; see Refs. [15, 59] for details.

![Comparison of RVB and geometric string trial states](image-url)
FIG. 4. Temperature dependence of the higher-order correlations $C_0$ (red) and the disconnected $C_0^{\text{disc}}$ (yellow) parts (using Eq. (2)). We compare the corresponding correlators $D_0$ in the undoped Heisenberg model (top) to predictions for a mobile dopant (with $t/J = 2$), using the FSA based on Heisenberg quantum Monte Carlo (QMC) snapshots and ED simulations in a periodic $4 \times 4$ system.

In Fig. 3 (right panel) we show how $C_0^{\text{(con)}}$ evaluated for this string wavefunction depends on the ratio of hole tunneling $t$ and the linear string tension $dE/d\ell$ underlying the model. When $t/J = 0$ the length of geometric strings is zero and the observed increase of the higher-order correlator is due to the staggered magnetization along $S^z$ included in the trial wavefunction. For increasing tunneling $t$ the string length grows and another significant increase of $C_0^{\text{(con)}}$ is observed. This supports our picture that the mobility of dopants leads to long geometric strings, which in turn underly strong higher-order spin-charge correlations.

Experimental considerations. – We turn to a discussion of the limitations and requirements to observe higher-order correlations in the doped Hubbard model.

Fig. 4 demonstrates how thermal fluctuations suppress higher-order correlations. We show the lower-order disconnected terms $C_0^{\text{disc}}$ and compare them to the higher-order correlators $C_0$, in two cases: For the undoped Heisenberg model we use quantum Monte Carlo simulations [62]. For a single mobile dopant our predictions are based on the frozen-spin approximation (FSA / geometric strings) [40, 52, 53] described above; The correlators are evaluated from $10^4$ snapshots for each $T/J$. We also compare to exact diagonalization (ED) calculations in a 4 × 4 system and find good agreement.

In the geometric string theory, $C_0^{\text{disc}}$ is approximately zero up to temperatures $T \lesssim 0.5J$, while the higher-order correlator $C_0$ is of the order of $-0.1$. Without a hole, the disconnected part $D_0^{\text{disc}}$ is significantly larger than $D_0$ for these small temperatures. For $T \gtrsim 0.6J$ the correlations decay quickly. The relevant temperature range has already been accessed experimentally [63], and we expect that more quantum gas microscopes operating in this regime will follow in the near future [27, 29, 34, 64, 65].

Similar to quantum gas microscopy, the higher-order correlations in Fig. 4 are extracted from snapshots. We expect that the main experimental challenge will be to collect sufficient amounts of data to obtain acceptable errorbars. Current experiments offering simultaneous spin- and charge resolution [36] are very close to the temperature regime required for observing the higher-order correlations proposed here.

Summary and Outlook. – We propose to study fifth-order spin-charge correlations to explore the microscopic nature of charge carriers in the doped Hubbard model from a new perspective. Such correlators have recently become accessible in state-of-the-art quantum gas microscopes. The observables we consider are direct generalizations of the three-point spin-charge correlators $\langle S_{z-1} \rangle \langle n_y S_{z+1} \rangle$ underlying hidden AFM correlations in the 1D doped Hubbard model [66, 67]. We analyze similar correlations in 2D, which can only be understood by theories with non-Gaussian correlations.

Our numerical studies for a single doped hole reveal the importance of the hole mobility for establishing such higher-order correlations and making them become the dominant spin-charge correlations in the system. In a subsequent work, we demonstrate this explicitly by considering the effect of a localized pinning potential for the hole [45]. Here we also established that doped quantum spin liquids have reduced higher-order correlations, whereas fluctuating geometric strings can explain the observed enhancement when $t/J$ is increased.

An interesting question concerns the behavior of the higher-order correlations when doping is increased and numerical studies of the Fermi-Hubbard model become more challenging [68]. In this regime we propose to measure the higher-order correlators by state-of-the-art ultracold atom experiments. Such studies can shed new light on the nature of charge carriers in the pseudogap and strange-metal [69] regimes or the pairing mechanism between dopants. They also provide a new experimental route to distinguish theoretical trial states, e.g. in the RVB class. While a recent machine-learning analysis [53] suggests that up to $\approx 15\%$ doping a model based on geometric strings may be favorable compared to doped $\pi$-flux RVB states, further refined experiments as proposed here will be required to establish where and how the nature of charge carriers changes upon doping.

Our results can be applied to extend studies of the formation dynamics of magnetic polarons [70–72], or to investigate correlation effects in Bose polaron problems in an optical lattice [73]. Other possible extensions include the study of SU(2) invariant generalizations of the higher-order spin-charge correlators introduced here.

SUPPLEMENTS

We define the connected correlator in the co-moving frame with the hole as,

$$C_{\text{con}}^{\text{con}}(r) = C_{\text{con}}(r) - 2^{4} \left[ \sum_{l \notin (i,j,k)} \frac{\langle \hat{n}_{l}^{b} \hat{S}_{r+i}^{z} \hat{S}_{r+j}^{z} \hat{S}_{l+k}^{z} \rangle_c}{\langle \hat{n}_{l}^{b} \rangle} + \sum_{(i,j) \notin (k,l)} \frac{\langle \hat{n}_{l}^{b} \hat{S}_{r+i}^{z} \hat{S}_{r+j}^{z} \rangle_c}{\langle \hat{n}_{l}^{b} \rangle} \right]$$

$$+ \sum_{l \neq j \notin (k,l)} \frac{\langle \hat{n}_{l}^{b} \hat{S}_{r+i}^{z} \rangle_c}{\langle \hat{n}_{l}^{b} \rangle} \frac{\langle \hat{n}_{j}^{b} \hat{S}_{r+j}^{z} \rangle_c}{\langle \hat{n}_{j}^{b} \rangle} \frac{\langle \hat{n}_{l}^{b} \hat{S}_{r+k}^{z} \rangle_c}{\langle \hat{n}_{l}^{b} \rangle} \frac{\langle \hat{n}_{l}^{b} \hat{S}_{r+l}^{z} \rangle_c}{\langle \hat{n}_{l}^{b} \rangle},$$

where the sums are over disjoint sets of lower-order connected correlators (defined equivalently) involving sites $i,j,k,l = \pm e_{x,y}$ measured relative to the hole. In a spin-balanced ensemble (see discussion in Ref. [45]), the expectation values $\langle \hat{n}_{l}^{b} \hat{S}_{r+l}^{z} \rangle_c = 0$ vanish and we obtain Eq. (2).

In Fig. 5 we show the connected correlators $C_{\text{con}}^{\text{con}}$ corresponding to the data from Fig. 4.

![Graph of C_{\text{con}}^{\text{con}} and D_{\text{con}}^{\text{con}}](image-url)

FIG. 5. For the data shown in Fig. 4 of the main text, we plot the connected correlators $C_{\text{con}}^{\text{con}}$ (left) and $D_{\text{con}}^{\text{con}}$ (right).
