Relativistic ionized accretion disc models of MCG–6-30-15

1 INTRODUCTION

MCG–6-30-15 is a bright nearby (z = 0.008) Seyfert 1 galaxy, and has thus been observed by various X-ray telescopes over the last 20 years (e.g., Pineda et al. 1984; Pounds, Turner & Warwick 1986; Nandra et al. 1988; Nandra, Pounds & Stewart 1990; Fabian et al. 1994). These studies culminated in the first detection of a relativistically broadened iron Kα line (Tanaka et al. 1995). The shape of the line is consistent with being emitted from fluorescing, optically thick material which is orbiting very close to a black hole (Fabian et al. 1989), and is difficult to explain by other processes (Fabian et al. 1995). Subsequent deep ASCA observations have found evidence for broad Fe Kα lines in other Seyfert 1 galaxies (Nandra et al. 1997), illustrating that these features may be common in type 1 Active Galactic Nuclei (AGN). Due to the proximity of MCG–6-30-15, its Fe Kα line has been studied many times at high signal-to-noise and has been shown to be variable, both in strength and in shape (Wasawa et al. 1996, 1999; Lee et al. 2000; Vaughan & Edelson 2001).

Recently, Branduardi-Raymont et al. (2001) reported results from observations of MCG–6-30-15 and another Seyfert 1 galaxy Mrk 766 using the Reflection Grating Spectrometer (RGS) on XMM-Newton. These authors claim that features in the soft X-ray band that were traditionally interpreted in lower-resolution data as photoelectric absorption edges could actually be relativistically broadened Kα lines of O VIII, N VII and C VI. However, a non-simultaneous observation of MCG–6-30-15 by the High-Energy Transmission Grating (HETG) on Chandra (which has higher spectral resolution than the RGS) does not confirm the above interpretation (Lee et al. 2001). These authors find that the spectral features in the soft X-rays are well fit by a dusty warm absorber model.

Regardless of which interpretation is correct, the idea of other relativistic emission lines in the X-ray spectra of Seyfert galaxies is intriguing, and is worth further investigation. This can be done by employing ionized reflection models (e.g., Ross & Fabian 1993; Ross, Fabian & Young 1999; Nayakshin, Kazanas & Kallman 2000; Ballantyne, Ross & Fabian 2001) to predict the reflection spectrum from an ionized disc. These models cannot be fit to gratings data as there is no Fe Kα line or easily determined continuum to “anchor” the model. Therefore, in this paper, we pursue a complementary approach, and fit the hard X-ray spectrum of MCG–6-30-15 from ASCA, thereby taking advantage of the well-defined Fe Kα line and continuum to fix the parameters of the model. Although the model is fit only to the high energy data it will have specific predictions for the strength of the soft X-ray spectral

ABSTRACT

We present results from fitting ionized accretion disc models to three long ASCA observations of the Seyfert 1 galaxy MCG–6-30-15. All three datasets can be fit by a model consisting of ionized reflection from the inner region of the accretion disc (with twice solar Fe abundance) and a separate diskline component from farther out on the disc. The diskline is required to fit the height of the observed Fe Kα line profile. However, we show that a much simpler model of reflection from a very weakly ionized constant density disc also fits the data. In this case only a single cold Fe Kα line at 6.4 keV is required to fit the observed line. The ionized disc models predict that O VIII Kα, C VI Kα, Fe XVII Lα, and Fe XVIII Lα lines will appear in the soft X-ray region of the reflection spectrum, but are greatly blurred due to Compton scattering. The equivalent width (EW) of O VIII Kα is estimated to be about 10 eV and seems to be as strong as the blend of the Fe L lines. This result creates difficulty for the claim of a strong relativistic O VIII line in the XMM-Newton grating spectrum of MCG–6-30-15, although we can not strictly rule it out since MCG–6-30-15 was in an anomalously low state during that observation. We find that increasing the O abundance or breaking the continuum below 2 keV will not significantly strengthen the line. The second Fe Kα line component in the ionized disc model may arise from neutral reflection from a flared disc, or from a second illumination event. The data cannot distinguish between the two cases, and we conclude that single zone ionized disc models have difficulty fitting these hard X-ray data of MCG–6-30-15.

Key words: accretion, accretion discs – line: profiles – galaxies: active – galaxies: individual: MCG–6-30-15 – galaxies: Seyfert – X-rays: galaxies
features, which may be useful in the interpretation of the grating data.

The paper is organized as follows. First, in Sect. 2 we describe the ionized disc model that is used and present our fits to the ASCA data of MCG–6-30-15. Then we discuss the strength of the predicted low-energy features and other consequences of our model in Sect. 3. Finally, conclusions are drawn in Sect. 4.

2 IONIZED DISC MODELS AND FITTING

Long observations of MCG–6-30-15 were obtained by ASCA in 1994 (200 ks), 1997 (200 ks) and 1999 (400 ks). A description of the data reduction can be found in the paper by Iwasawa et al. (1996) for the 1994 data and in the paper by Iwasawa et al. (1999) for the 1997 data. Analogous procedures were used in the reduction of the unpublished 1999 data, except for the inclusion of a new CTI file (sisph2pi_130201.fits) to deal with recent calibration problems in the SIS detectors. Fits were performed using the time-averaged data from all four detectors between 3 and 10 keV. Since the ASCA detectors had yet to suffer much damage, and the calibration is now well established, the experimental fitting was done using the 1994 data. The model that best fit this dataset was then used on the 1997 and 1999 dataset to check the robustness of the model and to investigate variations in the parameters.

The ionized reflection models were computed with the code described by Ballantyne et al. (2001). These simulations compute the reflection spectrum as well as the temperature, ionization and density structure of the top five Thomson depths of an accretion disc that is irradiated by a power-law continuum of X-rays. As shown by Ballantyne et al. (2001), the features in the reflection spectrum depend on the system parameters (such as black hole mass, accretion rate and radius along the disc), on the value of the irradiating flux and photon index of the incident spectrum (Γ), and the incidence angle of the radiation (θ).

The reflection spectra that were fit to the ASCA data of MCG–6-30-15 were computed assuming a black hole mass of $10^7 \, M_\odot$, an accretion rate of 0.01 times the Eddington rate (so the disc was radiation pressure dominated), and that the reflection was occurring at 4 Schwarzschild radii from the black hole. These values are appropriate for a typical Seyfert 1 galaxy like MCG–6-30-15. The choice of irradiating flux and incidence angle should ideally be determined by a specific model for how an accretion disc is illuminated. We have chosen an illuminating flux of 10$^{-2}$ cm$^{-2}$ s$^{-1}$ keV$^{-1}$ and an incidence angle of θ = 54.7 degrees to the normal (so that cos θ = 1/\sqrt{3}, a crude approximation to isotropic illumination) was assumed.

With these parameters fixed, two sets of reflection spectra were calculated with Γ varied between 1.5 and 2.15: one with solar abundance of Fe (as given by Morrison & McCammon 1983) and the other with twice solar Fe abundance. Each set was weighted by the reflection fraction $R \leq 3.0$ and then added to the illuminating power-law. Finally, both 2-dimensional grids were converted into a XSPEC `table' file for use in fitting the data. Relativistic blurring appropriate for a Schwarzschild metric and assuming a disc emissivity law (i.e., emissivity $\propto (1 - \beta/\gamma)^2/r^2$; Fabian et al. 1989) was applied to the spectra during fitting. The XSPEC command `extend' was used to increase the energy range of the response matrices because this convolution requires evaluating the model at energies outside the 3–10 keV range. Galactic absorption was also included in the fit and fixed at the value of 4.06 × 10$^{20}$ cm$^{-2}$, but will have a negligible affect at energies greater than 3 keV. XSPEC v.11.0.1z1 (Arnaud 1996) was used for fitting, and the uncertainties in the model parameters are the 1-σ errorbars for one interesting parameter.

2.1 Results of spectral fitting

The results of the spectral fitting are shown in Table 1. The first model tabulated is a simple absorbed power-law model that was fit to the data in the range 3–4 keV and 8–10 keV. This fit gives a measurement of the underlying continuum in the data, and we would like the more complex ionized disc models to give a photon index that is compatible with this value.

Fitting the data with a straightforward ionized disc model does not give a very satisfactory result. The line in the model is not strong enough to fit the data, and the fit can only be improved by increasing the reflection fraction, R. Furthermore, the derived photon-index is not consistent with the power-law fit, and the inclination angle is very small.

A more satisfying, although still problematic, fit can be obtained by doubling the Fe abundance in the disc model. That MCG–6-30-15 might have an overabundance of Fe was first suggested by Lee et al. (1999) in order to explain the strength of the Fe Kα line seen in the 1997 ASCA spectrum. These authors also utilize higher energy data from RXTE to constrain the reflection fraction to be around one. Indeed, the twice solar Fe model lowers the reflection fraction, but the model still cannot account for all the flux in the Fe Kα line. The problem is that the predicted Fe Kα lines from the ionized disc models are not strong enough to simultaneously fit both the large red wing and the large peak of the line profile, and thus the Fe abundance in MCG–6-30-15 would have to be very large to account for the Fe Kα line. A simple and straightforward way to resolve this problem is to add in another line component (cf., Misra 2001).

The idea that multiple Fe Kα components may be common in
the line profiles of Seyfert 1 galaxies has been gaining momentum with the recent detections of narrow 6.4 keV lines in NGC 3783 (Kaspi et al. 2001) and NGC 5548 (Yaqoob et al. 2001). However, in this case, a narrow line was not sufficient to account for the missing line flux, so a broadened diskline (also calculated with a disc emissivity profile) was added to the model. With this addition the $\chi^2$ dropped by $\sim 80$ for the addition of 3 degrees of freedom - clearly a significant improvement in the fit - and the inclination angle (which was fixed to be the same for the ionized disc and diskline component) was now comparable with the results of Tanaka et al. (1997). There-
Figure 2. The reflection spectrum between 0.3 and 10 keV predicted by the constant density models of Ross & Fabian (1993) after fitting to the 1994 ASCA spectrum of MCG–6-30-15 ($\chi^2$/dof=1659/1652). The incident power-law is included in this prediction. The fit parameters are $\Gamma = 1.98 \pm 0.01$, $\xi=10^{-14}$, $r_{in} = 7.5$ $r_g$, $r_{out} = 13$ $r_g$, and $i = 28$ degrees. Twice solar Fe abundance was assumed in the model.

Figure 3. The reflection spectrum predicted by the 2×Fe ionized disc + diskline model when fit to the 1994 ASCA data of MCG–6-30-15. The incident power-law is included in this prediction. The solid line denotes the model with solar abundance of oxygen, while the dotted line shows the model (with the same fit parameters) with five times solar abundance of oxygen. Emission lines that are emitted by the disc are indicated in the plot. The high-frequency “bumpiness” in the continuum is a result of the interpolation and binning that XSPEC must do to produce the figure. Recall that nitrogen is not included in the model.

Fe XVII and Fe XVIII. Nitrogen is not included in our calculations, so we are unable to place constraints on its strength. As a result of the Compton broadening, it was difficult to accurately measure the equivalent widths (EW) of the O line and the Fe L blend. The EW estimate was made by assuming that the O line was equally as strong as the Fe L blend. The weakly ionized constant density model does not suffer from much Comptonization, and so the EWs were calculated directly from the spectrum. All the EW results are shown in Table 2. We find that the O line has an EW about 6 eV. This is much smaller than the EW∼150 eV O VIII Kα line claimed by BR01 using their RGS observation of MCG–6-30-15. However, the comparison is not strictly valid, as BR01 requires that the continuum turn over so that $\Gamma = 1.33$ below $\sim 2$ keV. To check how this break in the continuum will affect the strength of the soft X-ray features, we computed a model with $\Gamma = 1.91$ for $E > 2$ keV and $\Gamma = 1.33$ for $E < 2$ keV, short-dashed line). Both of these curves have been scaled downwards by a factor of $5 \times 10^{25}$. When the reflection spectrum is added to the continuum and fit to the 1994 ASCA data of MCG–6-30-15 the resulting best-fit ($\chi^2$/dof=1679/1650) is given by the long-dashed and dotted lines. The resulting O VIII line is very weak.

Returning to models with unbroken power-laws, we investigated abundance effects by running computations with three times and five times solar oxygen abundances. Substituting these models for the solar abundance model did not greatly affect the $\chi^2$ of the fit. The EWs of the soft lines in these models are also shown in Table 2. When the O abundance is increased to 5 times solar, O VII recombination lines are prominent and are blended with the O VIII line (see Fig. 3). The resolution of the RGS is high enough that lines from O VII should be distinguishable from O VIII Kα even with extreme relativistic blurring, so a supersolar abundance of O cannot account for the strength of the line claimed by BR01. Finally, it is important to note that if there is another soft component

### Table 2. Equivalent widths in eV of the soft X-ray features predicted by ionized disc models of MCG–6-30-15.

| O abundance  | C VII | O VIII |
|--------------|------|--------|
| solar        | 5.0  | 6.0    |
| 3× solar     | 4.2  | 5.4†   |
| 5× solar     | 7.7  | 16.0†  |

*† estimated as half the EW of the O VIII-Fe L blend from the constant density model (Fig. 2)*

in the spectrum, such as a soft excess, then the EWs will be even smaller than those measured here.

Another important prediction of these ionized disc models is that there should be \( \alpha \) lines from Fe XVII and Fe XVIII which, when blended together, seem to have about the same strength as the O VIII \( \alpha \) line. These are not seen in the RGS spectra of MCG-6-30-15 (BR01). Although it is possible to ionize Fe to states higher than Fe XVIII and leave sufficient quantities of O VIII to produce a line, this will result in a highly ionized atmosphere with a weak Fe \( \alpha \) line and would not increase the strength of the O line.

3.2 Multiple Fe \( \alpha \) line components

In order to adequately fit the Fe \( \alpha \) line in the ASCA spectra of MCG-6-30-15 with the ionized disc models, it was necessary to add a separate diskline component to the model. This enabled the model to fit both the broad red wing of the Fe \( \alpha \) line (through the ionized disc component) and the height of the profile (through the diskline) simultaneously. The diskline is too wide to originate from a distant reflector, such as a molecular torus (e.g., Krolik, Madau & Zycki 1994), so it must arise from elsewhere on the disc. Possible mechanisms for a second line component include reflection of X-rays from the central engine as a result of any warping or flaring of the disc (e.g., Blackman 1999), and reflection from a second illumination event on the disc which might be expected from a magnetically active and patchy corona (e.g., Galeev, Rosner & Vaiana 1979). Haardt & Maraschi 1993.

In the first scenario, the flared region of the disc would see the same \( \Gamma \) as the inner regions, but the illuminating flux would be much lower and neutral reflection would dominate. To test this idea, the diskline component was placed by a constant density reflector. This component had its photon-index fixed to the same value as the inner reflector, and we fit for the value of the ionization parameter. These results are shown in Table 3. We find that neutral reflection from a large region of the disc is needed to account for the second Fe \( \alpha \) line component. However, this result is not unique, as ionized reflection from a smaller, more central region of the disc can also fit the data.

If the second Fe \( \alpha \) line component results from another illumination event then it is not necessary for the \( \Gamma \) of the two events to be the same, and the observed photon-index is a weighted sum of the two. Models of this type were constructed using two hydrostatic ionized disc models, and the results are also shown in Table 3. A decent fit to the 1994 data was found with the inner reflector subject to a \( \Gamma = 1.78 \) power-law and the outer to a softer \( \Gamma = 2.14 \) power-law, although a very low value of the inclination angle was found in this case suggesting further reflection components are necessary.

These results emphasize that it is very difficult to fit the 1994 hard X-ray spectrum of MCG-6-30-15 with a simple ionized disc model. At least two different reflection components are needed to adequately fit the Fe \( \alpha \) line profile which suggests a very complicated illumination geometry. However, multiple Fe \( \alpha \) line components are a natural consequence of the magnetic flare model, and could provide the explanation to the perplexing variability of the Fe \( \alpha \) line. In contrast, a very acceptable fit to the same data was obtained using just one reflection component from a predominantly neutral disc which suggests a very simple illumination geometry. Unfortunately, current data cannot distinguish between the two cases, but our calculations show that measurements of soft X-ray disc emission features could lead to constraints on the ionization state of the accretion disc surface.

4 CONCLUSIONS

The main results of this paper are:

- The 1994, 1997 and 1999 ASCA observations of MCG-6-30-15 can be fit with a relativistic ionized disc model which has twice solar Fe abundance. However, a diskline component must be included to fully account for the shape of the Fe \( \alpha \) line.
- Alternatively, the 1994 data can be well fit by a single reflection component from a weakly ionized (\( \xi = 10 \)) constant density disc with twice solar Fe abundance. In this case, one cold Fe \( \alpha \) line at 6.4 keV can completely describe the observed line.
- Both reflection models predict that the EW of the O VIII \( \alpha \) line is \( \sim 10 \) eV. This can be made larger by increasing the O abundance, but O VIII lines will eventually become prominent. The ionized disc models also predict that Fe XVII & Fe XVIII \( \alpha \) lines will be found along with the O VIII line.
- These results cast doubt on the claims of relativistic lines found in the soft X-rays by BR01 because broad Fe L lines are not seen in their spectra, and EWs \( > 100 \) eV are required for the O VIII and C VI lines. However, MCG-6-30-15 was in an unusually low state when observed by BR01, so we cannot strictly rule out their result.
- Emission from multiple regions on the disc was needed to adequately fit the Fe \( \alpha \) line profile with the ionized disc models. The data are unable to distinguish between secondary reflection from a flared disc, or from other independent illumination/reflection events.
