Abstract (J Korean Assoc Oral Maxillofac Surg 2015;41:78-83)

Squamous cell carcinoma (SCC) is the most common malignant tumor in the oral cavity, and it accounts for about 90% of all oral cancers. Several risk factors for oral SCC have been identified; however, SCC associated with odontogenic keratocysts have rarely been reported. The present study describes the case of a 36-year-old man with SCC of the right ramus of the mandible, which was initially diagnosed as a benign odontogenic cyst. He underwent enucleation at another hospital followed by segmental mandibulectomy and fibular free flap reconstruction at our institution. In this case, we introduce a patient with oral cancer associated with odontogenic cyst on the mandible and report a satisfactory outcome with wide resection and immediate free flap reconstruction.

I. Introduction

Squamous cell carcinoma (SCC) in the oral cavity is a common disease that is associated with several risk factors, including smoking, alcohol use, viral infection, immunosuppression, malnutrition, chronic irritation as well as previous disease such as odontogenic cyst.

SCC associated with odontogenic cysts are extremely rare, and those arising within the jawbones occur with an incidence of approximately one or two person per thousand¹.

Recently, we treated a 36-year-old male patient with SCC. He was first diagnosed with benign odontogenic cyst and underwent enucleation of right ramus of the mandible at another hospital. We further treated the same site in our hospital using segmental mandibulectomy and fibular free flap reconstruction.

The aim of this report is to introduce a clinical case of mandibulectomy and fibular free flap reconstruction in a patient with oral cancer associated with odontogenic cyst and to review the current literature.

II. Case Report

A 36-year-old male patient without specific underlying diseases visited us with intraosseous SCC in his mandibular right ascending ramus with jaw pain and limited mouth opening as chief complaints. His right mandibular pain started in May 2013, and based on the initial diagnosis of a benign odontogenic cyst, he underwent cyst enucleation in July 2013 at another university hospital. Then in the same month, based on biopsies, he was diagnosed with SCC with an odontogenic keratocyst (OKC), and he was transferred to our hospital. Based on clinical tests performed upon his arrival at our hospital, there were no specific findings in the intraoral or extraoral areas, and the patient did not complain of any severe...
pain or edema. Preoperative blood testing likewise revealed no specific findings. On facial examination, the patient complained of limitation in his mouth opening to approximately 20 mm and mild hyposensitivity from his right mandible to his lower lip. (Fig. 1) The preoperative radiographic findings from the cone-beam computed tomography (CT) images were a multilocular radiolucent lesion with a clear margin, a right submandibular space, and a soft tissue accessory lesion that invaded the right medial pterygoid muscle. The positron emission tomography (PET) CT images showed an increase in local uptake from the mandibular right corner and ascending ramus to the osteoclastic lesion with level of SUV max of 7.7 of PET. On magnetic resonance imaging, multiple affected lymph nodes up to levels IB, II, III, and IV were observed. (Fig. 2, 3)

Accordingly, the patient was diagnosed with SCC caused by OKC. On August 22, tracheostomy for intubation and adequate airway control along with a wide excision with segmental mandibulectomy, supraomohyoid neck dissection (right) and reconstruction using an osteocutaneous fibular free flap were performed under general anesthesia. During the surgery, the sternocleidomastoid muscle, external jugular vein, greater auricular nerve, vagus nerve, and carotid sheath without cancer invasion were confirmed and conserved. The lower cheek flap design was used for the neck dissection, and the extended Risdon approach was used for the incision. For the segmental mandibulectomy, the incision started from

findings from the intraoral and extraoral PET and CT images. Accordingly, no post-operative radiographic treatments were performed, but continued follow-up was planned. The cone-beam CT images obtained at eight months postoperatively yielded no specific findings. In the PET CT images obtained at 15 months postoperatively, no recurrence or metastasis in cervical lymph nodes or other organs was observed. The patient had a favorable course, clinically and aesthetically. (Fig. 4-6) Mandibular Reconstruction Angled Plate (Stryker, Kalamazoo, MI, USA), after being bent into form on an rapid prototype (RP) model preoperatively, was used as the reconstruction plate after the plate was cut according to bone defect size.

In the postoperative final main lesion biopsy, SCC was confirmed, and no metastasis was observed in the levels I, II, and III lymph nodes. Mouth-opening at six months postoperatively improved to about 40 mm, and there were no specific findings from the intraoral and extraoral PET and CT images. Accordingly, no post-operative radiographic treatments were performed, but continued follow-up was planned. The cone-beam CT images obtained at eight months postoperatively yielded no specific findings. In the PET CT images obtained at 15 months postoperatively, no recurrence or metastasis in cervical lymph nodes or other organs was observed. The patient had a favorable course, clinically and aesthetically. (Fig. 7, 8) At 24 months postoperatively, iliac bone graft and implant placement were scheduled in the superior area of the fibular bone, and the reconstruction plate will be removed.

III. Discussion

OKC is a cyst covered with thin keratinized epithelia and is the most aggressive and recurrent odontogenic cyst\(^1\). When...
Mandibular intraosseous SCC lesion associated with OKC

If not treated properly, it can develop into intractable disease. Moreover, it has a high probability of malignant transformation. Many maxillar and mandibular cancers are known to develop from a keratinized cyst. Loos first described a malignant change in the odontogenic tumor in 1913, after which Schwimmer et al., Keszler and Piloni, and Tan et al. reported odontogenic-cyst-induced malignant tumor cases. The mechanism of the malignant variation of the odontogenic cyst epithelia has not been clearly understood. In a study by Gardner, 25 cases of malignant odontogenic cyst were analyzed using literature published between 1889 and 1967. When the odontogenic cyst is positioned in the maxilla or the mandible for a long time, the stratified squamous epithelia can become malignant due to chronic inflammation. There is a report that suggested that chronic inflammation of cyst epithelium could be the main predisposing factor for malignant transforma-

according to the location, size, and grade of the cyst, but they are often subclinical in the earlier stages and found accidentally on an X-ray. With their progression, symptoms such as facial bone and facial swelling, tooth pain and mobility, mastication and mouth opening disorders, and ulcers may develop. Marsupialization is contraindicated in the treatment of suspected odontogenic-cyst-induced cancer due to the possibility of epithelial transformation to malignancy. Instead, removal of the nearby lymph nodes and surgical excision are recommended by Elzay, as at least 66% of patients experience recurrence at least once. In a study by Bereket et al., the two-year survival rate is between 53% and 63%. According to a study by Gardner, odontogenic-cyst-induced cancer frequently developed in the mandible (15 cases) and the maxilla (nine cases). The present case developed in the right mandible. The clinical manifestations vary according to the location, size, and grade of the cyst, but they are often subclinical in the earlier stages and found accidentally on an X-ray. therapy was not performed. In the follow-up PET CT images at one year postoperatively, there were no metastatic findings in the lesion, cervical lymph nodes, or other organs. After the mandibulectomy, a fibular free flap and a reconstruction plate were used for immediate reconstruction for jaw function and cosmesis. The advantages of the pre-bended titanium reconstruction plate include: easy application, stability, minimal damage in the blood supply to the underlying bone, low cost, a short operative time, and postoperative aesthetic satisfaction. However, complications such as instability and delayed union, non-union, and infection due to screw loosening may develop

Notable in this study was the simulated operation using a skull RP model and referable fibular bone resin block for aesthetic jaw form after the wide excision and reconstruction. The free flap was designed on the subject’s right ramus, and the measurements were applied to the prepared fibular bone resin block. The prepared skull RP model was used with fibular resin block for surgery simulation to save time and to reduce errors during the actual surgery. Although a preoperative guide stent and simulation surgery using computer aided design/computer aided manufacturing were not used in this study, the skull RP model, pre-bent reconstruction plate, and guided fibular resin model were used effectively for instant reconstruction during the conventional surgery. As a result, accurate postoperative facial symmetry was achieved. One and half years postoperatively, the subject shows a symmetrical profile with a high degree of self-satisfaction regarding jaw function and aesthetics without cancer recurrence. A 5-year follow-up is needed to confirm complete healing. Further studies, including a literature review on odontogenic-cyst-induced cancer, may be needed in the future.
