Cortical lesions constitute an important part of multiple sclerosis pathology. Although inflammation appears to play a role in their formation, the mechanisms leading to demyelination and neurodegeneration are poorly understood. We aimed to identify some of these mechanisms by combining gene expression studies with neuropathological analysis. In our study, we showed that the combination of inflammation, plaque-like primary demyelination and neurodegeneration in the cortex is specific for multiple sclerosis and is not seen in other chronic inflammatory diseases mediated by CD8-positive T cells (Rasmussen's encephalitis), B cells (B cell lymphoma) or complex chronic inflammation (tuberculous meningitis, luetic meningitis or chronic purulent meningitis). In addition, we performed genome-wide microarray analysis comparing micro-dissected active cortical multiple sclerosis lesions with those of tuberculous meningitis (inflammatory control), Alzheimer's disease (neurodegenerative control) and with cortices of age-matched controls. More than 80% of the identified multiple sclerosis-specific genes were related to T cell-mediated inflammation, plaque-like primary demyelination and neurodegeneration in the cortex is specific for multiple sclerosis and is not seen in other chronic inflammatory diseases mediated by CD8-positive T cells (Rasmussen's encephalitis), B cells (B cell lymphoma) or complex chronic inflammation (tuberculous meningitis, luetic meningitis or chronic purulent meningitis). In addition, we performed genome-wide microarray analysis comparing micro-dissected active cortical multiple sclerosis lesions with those of tuberculous meningitis (inflammatory control), Alzheimer's disease (neurodegenerative control) and with cortices of age-matched controls. More than 80% of the identified multiple sclerosis-specific genes were related to T cell-mediated inflammation, microglia activation, oxidative injury, DNA damage and repair, remyelination and regenerative processes. Finally, we confirmed by immunohistochemistry that oxidative damage in cortical multiple sclerosis lesions is associated with oligodendrocyte and neuronal injury, the latter also affecting axons and dendrites. Our study provides new insights into the complex mechanisms of neurodegeneration and regeneration in the cortex of patients with multiple sclerosis.

Keywords: multiple sclerosis; cortex; gene expression; demyelination; neurodegeneration

Abbreviation: PLP = proteolipid protein; TUNEL = terminal deoxynucleotidyl transferase dUTP nick end labelling
Introduction

Multiple sclerosis is traditionally seen as a disease that affects the white matter giving rise to focal inflammatory demyelinating lesions (Lassmann et al., 2007). Recent studies on the pathology of multiple sclerosis, however, challenged this concept by providing evidence for extensive grey matter lesions in the cerebral (Peterson et al., 2001; Bo et al., 2003; Kutzelnigg et al., 2005) and cerebellar cortex (Kutzelnigg et al., 2007) and in the hippocampus (Geurts et al., 2007). Despite the primary demyelinating nature of cortical lesions, profound degeneration also affects cortical neurons, axons and synapses (Peterson et al., 2001; Wegner et al., 2006; Dutta and Trapp, 2011).

Cortical lesions arising during early (Lucchinetti et al., 2011) and late (Kutzelnigg et al., 2005; Howell et al., 2011) disease stages are associated with inflammation. In lesions developing in the progressive stage, the degree of meningeal inflammation correlates with the extent of active demyelination and neurodegeneration (Howell et al., 2011; Choi et al., 2012). Thus, inflammation may drive cortical lesions, but it remains unresolved, whether cortical primary demyelination is a multiple sclerosis-specific event, which types of inflammatory cells are involved and which molecular mechanisms evoke tissue injury. In this study, we compared cortical pathology in multiple sclerosis with that seen in a large spectrum of other inflammatory and neurodegenerative brain diseases and found that the combination of inflammation, plaque-like primary demyelination and neurodegeneration is specific for multiple sclerosis. The second part of the study focused on global gene expression studies analysing potential molecular pathways of tissue injury in active cortical multiple sclerosis lesions. The latter were defined by the presence of macrophages containing degradation products reactive for myelin or neuronal antigens. Since the data suggested oxidative injury, DNA damage, and apoptosis as potential mechanisms of tissue degeneration, we analysed the expression of proteins involved in oxidative burst as well as the presence of oxidized lipids and DNA fragmentation in a broad sample of cortical multiple sclerosis lesions in comparison with the normal and diseased controls using immunohistochemistry and terminal deoxynucleotidyl transferase dUTP nick end labelling (TUNEL) staining.

Materials and methods

Sample characterization

Archival formaldehyde-fixed and paraffin-embedded (FFPE) autopsy material collected in the archives of the Centre for Brain Research and the Institute of Neurology were used (Table 1). The study was approved by the Ethical Committee of the Medical University of Vienna (EK. No. 535/2004 and 087/01/2012). It included 21 cases of multiple sclerosis comprising acute multiple sclerosis (n = 6), relapsing-remitting multiple sclerosis (n = 1), secondary progressive multiple sclerosis (n = 7) and primary progressive multiple sclerosis (n = 7). As controls, cases of chronic tuberculocellular meningitis (n = 4), luetic meningitis (n = 1), chronic purulent meningitis (n = 1), Rasmussen’s encephalitis (n = 5), B cell lymphomas affecting meninges and cortex (including one EBV+ lymphoma; n = 4), Alzheimer’s disease (n = 11) and age-matched controls without any detectable brain disease (control subjects; n = 17) were included. For basic neuropathology of each case, multiple tissue blocks from all brain regions were stained with haematoxylin/eosin, Luxol Fast blue myelin stain and Bielschowsky silver impregnation. The selection of tissue blocks taken for microarray and neuropathological analysis depended on the clinical diagnosis of each patient (Table 1). For microarray analysis we selected frontal association cortex for multiple sclerosis and controls, frontobasal (TB1 and TB2) and temporobasal (TB3) cortex for tuberculous meningitis and temporal cortex for Alzheimer’s disease. For neuropathological studies the blocks (between three and eight) from patients with Alzheimer’s disease or tuberculous meningitis included cortical areas (frontal, temporal, parietal and occipital), while in case of B cell lymphoma between one and three blocks were chosen, which contained infiltration of neoplastic B cells in meninges or cortex (frontal and parietal). Tissue samples from patients with Rasmussen’s encephalitis derived from temporal cortico/subcortical neurosurgical resections and were, thus, restricted to one block per case. For control cases, basic neuropathology was performed on eight to 15 tissue blocks from all brain regions to exclude confounding pathology. From those three to six blocks comprising frontal, parietal, and temporal cortex were selected for further analysis. In multiple sclerosis cases, cortical lesions were either identified by analysis of multiple tissue blocks (n = 10 cases) or were specifically trimmed from hemispheric or double hemispheric sections (n = 11 cases). The architecture of active cortical lesions was complex. In general, they contained a fully demyelinated area, which was surrounded by an area of variable size with reduced myelin density and profound microglia activation, located between the demyelinated lesion and the normal appearing grey matter. However, microglia activation alone was not sufficient for the identification of an active lesion, since a rim of activated (iron containing) microglia can be seen in multiple sclerosis lesions, which do not expand in the subsequent years (Bian et al., 2012). Thus, we used the presence of degradation products in macrophages reactive for myelin or neuronal antigens, such as neurofilament, as an additional marker for active cortical lesions (Fig. 1 and Supplementary Fig. 1). For the investigation of molecular mechanisms of tissue injury by microarray analysis, we selected subpial cortical lesions with a zone of perilesional activity as defined above.

Immunohistochemistry

Consecutive 5-μm thick serial sections were cut, routinely deparaffinized and endogenous peroxidase was blocked with H2O2/methanol. Non-specific antibody binding was blocked by incubating the section in 10% foetal calf serum. Antigen retrieval procedures and primary antibodies used for immunohistochemistry are listed in Table 2. Primary antibodies were applied overnight at 4°C. For immunohistochemical controls, either primary antibodies were omitted or unrelated sera or monoclonal antibodies of the same immunoglobulin class were used. Antibody binding was routinely visualized using 3,3’-diaminobenzidine, which was occasionally enhanced by biotinylated tyramine amplification (King et al., 1997). Alternatively, Fast blue B salt or 3-amino-9-ethylcarbazole were used for signal development. Before mounting of sections, cell nuclei were counterstained with haematoxylin.

Confocal fluorescence immunohistochemistry was performed on paraffin sections as described for light microscopy with some modifications. For fluorescent double labelling with primary antibodies from different species (mouse-anti-E06 and goat-anti-carbonic anhydrase II, rabbit-anti-GFAP, rabbit-anti-neurofilament or rabbit-anti-calbindin,

MS = multiple sclerosis; AMS = acute MS; RRMS = relapsing remitting MS; PPMS = primary progressive multiple sclerosis; SPMS = secondary progressive multiple sclerosis; TB = tuberculous meningitis; LU = luetic meningitis; ME = chronic purulent meningitis; BLY = B-cell lymphoma; RAE = Rasmussen’s encephalitis; AD = Alzheimer’s disease; Braak = Braak stages of Alzheimer’s disease; CO = control without neurological disease or brain lesions; f = female; m = male; n.a. = data not available; * = case included in microarray study printed in bold; Block types: A = double hemispheric blocks; B = single hemispheric blocks; C = conventional blocks (2 × 3 cm).

TUNEL staining for DNA damage

TUNEL staining was performed essentially as described previously (Gold et al., 1993) and has already successfully been applied previously for analysis of DNA fragmentation in Alzheimer’s disease and controls (Lassmann et al., 1995). In the present study we used the In Situ Cell Death Detection Kit (Roche).

Quantification of immunohistochemistry and TUNEL staining

CD3-positive T cells, CD68-positive macrophages, TPPP/p25-positive oligodendrocytes, neurofilament-reactive dystrophic axons, neuronal cell bodies, E06-positive neurons and TUNEL-positive cells were counted. In case of neuronal quantification, only neurons containing a nucleus with a prominent nucleolus were included. Counting of neurons, oligodendrocytes, dystrophic axons and TUNEL-positive cells was performed in cortical layers III to V. Quantitative analysis was done using a morphometric grid within the ocular lens counting 10 microscopic fields of 0.0576 mm² per region of interest (normal appearing grey matter and lesion). Presented values were calculated as counts/mm² tissue area. Quantitative enumeration of T cells and macrophages was done in the entire cortex, including the meninges, positioning the grid areas in parallel rows, spanning the entire cortical ribbon. The percentage of neurons with intense cytoplasmic reactivity for oxidized phospholipids (E06 reactivity) is shown in relation to the
Figure 1  Plaque-like primary demyelination is specific for multiple sclerosis. (A–E) Highly inflammatory, active cortical lesion from Case MS1. Extensive subpial demyelination [A; immunohistochemistry (IHC) for PLP] is associated with inflammatory infiltrates in the meninges and the perivascular space. Profound activation of microglia is visible in the lesion and in the adjacent periplaque grey matter (B; IHC for HLA-D). CD3-positive T lymphocytes are present in the perivascular inflammatory cuffs and diffusely dispersed throughout the lesion (C; IHC for CD3). Phagocytic macrophages are also present in the perivascular inflammatory cuffs and in the parenchyma (D; IHC for CD68). They in part contain myelin degradation products reactive for PLP (E; IHC for PLP). (F–I) Chronic, active cortical lesion from (continued)
total number of counted cortical neurons. To examine the extent of demyelination, proteolipid protein (PLP)-stained slides were scanned and the extent of demyelination was calculated as demyelinated area in relation to total cortex area.

**RNA extraction and microarrays**

For gene expression studies, three active multiple sclerosis lesions (the fulminate active lesion of Case MS1 and two chronic active lesions from Cases MS2 and MS3), three cortex samples from patients with tuberculous meningitis, three Alzheimer’s disease cases, and three controls without brain pathology were selected (Table 1).

As archival formaldehyde-fixed and paraffin-embedded autopsy material with unknown time spans and storage conditions between sampling and fixation was used, RNA preservation of more than 150 multiple sclerosis tissue blocks and 40 tissue blocks containing control material (Alzheimer’s disease, tuberculous meningitis, control subjects), was assessed by in situ hybridization for PLP as described (Breitschopf et al., 1992). Tissue blocks with strong and specific in situ hybridization signals in oligodendrocytes after short development time (<10 h) were selected for further studies. Ten to 20 6–10-μm thick sections were cut under RNase-free conditions. Cortical tissue blocks for microarray analysis were selected according to the presence of lesions typical for the different disease entities. Cortical areas including all cortical layers from Alzheimer’s disease, tuberculous meningitis and control subjects were micro-dissected. In tuberculous meningitis cases, these cortical areas were further restricted to sites with profound meningeal and parenchymal inflammation. For multiple sclerosis cases, we micro-dissected cortical areas with subpial demyelination of at least the outer four cortical layers. These lesions contained a broad zone around the plaque with profound microglia activation and the presence of macrophages with degradation products reactive for myelin or neuronal antigens. Thus, for messenger RNA analysis, these multiple sclerosis blocks also contained all cortical layers and, dependent on the degree of activity, a zone of variable size with signs of active tissue injury. Isolation, amplification, and quality assessment of messenger RNA were done as extensively described before (Fischer et al., 2012).

Briefly, total RNA was isolated using the High Pure FFPE RNA Micro Kit (Roche) according to the manufacturer’s instructions. The concentration of isolated total RNA was too low for any RNA integrity measurements. Instead, messenger RNA was amplified using poly(T) primers and the Arcturus® Paradise® FFPE Amplification Kit (Applied Biosystems, Life Technology). After the first round of in vitro transcription, the quality of the samples was tested. Owing to RNA fragmentation and cross-linking during formaldehyde fixation, it is almost impossible to isolate full length RNA from formaldehyde-fixed and paraffin-embedded tissue. Therefore, routine endpoint PCR for the housekeeping gene actin, beta (ACTB) was performed to verify that RNA fragments were sufficiently long to use them as probes for microarrays. Primers were designed in such a way that the forward primer binds 472 bases upstream of the poly(A) tail. Endpoint PCR was run with the following settings: forward: 5’-TTGACTCAGGATTTAAAA ACTGG-3’; reverse: 5’-AGGGACTTCCTGTAACAACGC-3’; 10 min denaturation; followed by 40 cycles of denaturation (30 s, 95°C), annealing (30 s, 55°C), and extension (30 s, 72°C). Only when a sufficient amount of PCR product was found, the samples qualified for a second round of in vitro amplification. The resulting antisense RNA was sent out for hybridization to Agilent-014850 Whole-Human Genome Microarrays 4x44K (G4112F). RNA labelling, microarray hybridization and scanning, as well as quantile normalization of raw data were carried out externally (Source BioScience imaGenes GmbH).

For data analysis, two different approaches were used. On the one hand, all genes significantly changed (P < 0.01; Student’s t-test) in cases with multiple sclerosis (Cases MS1–3) in comparison with other cases (Alzheimer’s disease, tuberculous meningitis and control subjects) were evaluated. On the other hand, to have the ability to assess the inflammatory component of the fulminate lesion of Case MS1, all massively up- or down regulated genes (log2 fold-changes > 4 or < −4.5, respectively) in Case MS1 in comparison with all other cases (other multiple sclerosis, Alzheimer’s disease, tuberculous meningitis and control subjects) were examined. As significance testing was not possible for this analysis approach, restrictive cut-offs were used instead. They were based on the observation that above and below a log2 fold-change of 4 and 4.5, respectively, the detected differences were granted to be exclusively present in Case MS1, whereas the gene expression values in all other cases (tuberculous meningitis, Alzheimer’s disease and control subjects) were low. Functions of the multiple sclerosis-specific genes were determined based on several sources: PhosphoSitePlus® (http://www.phosphosite.org), NCBI (http://www.ncbi.nlm.nih.gov/), Panther classification system (http://www.pantherDB.org).
pantherdb.org), and KEGG Kyoto Encyclopaedia of Genes and Genomes (http://www.genome.jp/kegg). Particularly, PubMed was screened for genes with known functions in multiple sclerosis or experimental autoimmune encephalomyelitis.

Based on the microarray data (deposited in NCBI’s Gene Expression Omnibus; GEO Accession Number GSE32645), genes related to inflammation, structural changes, or oxidative injury were selected and immunohistochemistry was performed on serial sections immediately adjacent to the sections used for gene expression profiling. For these exemplary genes, it could be shown that protein expression visualized by immunohistochemistry followed the up- and down regulation trends of the microarray data (Supplementary Fig. 1). Furthermore, TaqMan® real-time PCR was performed to validate selected multiple sclerosis-specific genes (Supplementary Table 4).

### Statistical analysis

Descriptive analysis included median value and range, percentages, scatter plots and box plots. For comparisons of multiple groups, the Kruskal-Wallis test was used, followed by pair-wise Mann-Whitney U-tests and Bonferroni-Holm correction. For the analysis of microarray data (Cases MS1–3 in comparison with all other cases pooled in one group), Student’s t-tests were performed. The reported P-values are results of two-sided tests. A P-value ≤ 0.05 was considered statistically significant. Analyses were done using PASW Statistics 18 (SPSS Inc.).

### Results

#### Focal lesions of primary demyelination are specific for multiple sclerosis

In a first step, we analysed demyelination and neurodegeneration in the cortex of patients with multiple sclerosis in comparison with other inflammatory and neurodegenerative diseases. In multiple sclerosis, cortical pathology was characterized by the presence of...
large plaques of primary demyelination (complete loss of myelin with axonal preservation such as preservation of phosphorylated neurofilament-reactive profiles) as described previously (Peterson et al., 2001; Kutzelnigg et al., 2005). In one case of secondary progressive multiple sclerosis (Case MS1), fulminate inflammatory cortical lesions were present, similar to those described in early multiple sclerosis (Lucchinetti et al., 2011) with profound inflammation in the meninges (Fig. 1B), abundant perivascular inflammatory cuffs (Fig. 1D and Supplementary Fig. 1) and T and B lymphocyte infiltration into the cortical parenchyma (Fig. 1C and Supplementary Table 1). Active cortical demyelination (Fig. 1A) was reflected by the presence of activated macrophages containing myelin degradation products reactive for PLP (Fig. 1E). The other multiple sclerosis cases (shown representatively by Case MS2 in Fig. 1F–I) exhibited cortical demyelinated lesions as described (Howell et al., 2011). In these expanding cortical lesions, lymphocyte infiltration was restricted to the meninges and the zones of lesional activity. A variable degree of microglia activation was observed, forming a band of high cell density at the margin towards the normal appearing grey matter (see Supplementary Fig. 1). In these areas, few diffusely dispersed T cells were present (Fig. 1H) and microglia cells contained myelin degradation products.

Cortical lesions in patients with tuberculous or luetic meningitis also showed strong meningeal and parenchymal inflammation with a similar cellular composition of T cells, B cells, plasma cells, and macrophages as in multiple sclerosis (Fig. 1K–M). In some cases, the infiltrates additionally contained granulocytes. Despite the massive inflammatory reaction in the cortex, no focal primary plaque-like demyelination was present (Fig. 1J).

Cortical lesions from patients with Rasmussen’s encephalitis (a paradigmatic example of encephalitis mediated by MHC class I restricted T cells) showed only minor meningeal inflammation, dominated by T cells and macrophages, but profound diffuse T cell infiltration of the cortical parenchyma (Fig. 1P). These infiltrates were associated with massive microglia activation and neuronal and astrocytic degeneration (Fig. 1O) (Bien et al., 2002; Bauer et al., 2007). Again, no indication for focal multiple sclerosis-like primary demyelination was found (Fig. 1N and Q).

In B cell lymphomas affecting the cortex, massive infiltration of the meninges and the cortical parenchyma by neoplastic B cells (Fig. 1S) and a variable extent of T cell infiltration and microglia activation were seen. In severely affected regions, this resulted in displacement of the cortical parenchyma by neoplastic cells. In areas of very dense B cell infiltration, myelin was pushed aside by aggregated B lymphocytes (Fig. 1T), but there was no indication of primary demyelination (Fig. 1R).

No plaque-like demyelination was present in the cortex of patients with Alzheimer’s disease (Fig. 1U). However, immunohistochemistry for proteolipid protein revealed a minor loss of myelin within the core and the vicinity of amyloid plaques (Fig. 1V–X) (Mitew et al., 2010).

These data indicate that the formation of plaque-like primary demyelinating cortical lesions is multiple sclerosis-specific and does not simply reflect tissue damage induced by inflammatory mechanisms or mediators.

### Comparative analysis of gene expression in cortical lesions

Quantitative immunohistochemistry (Table 3) of disease and control cases selected for our microarray study confirmed that inflammation mediated by T cells, B cells, and microglia activation were most pronounced in tuberculous meningitis, whereas demyelination and oligodendrocyte loss were restricted to multiple sclerosis lesions. Neuronal and axonal injury was present in multiple sclerosis, tuberculous meningitis, and Alzheimer’s disease, but was highest in multiple sclerosis compared with the other diseases.

Analysing our microarray data, we found 109 genes significantly up- or downregulated in multiple sclerosis in comparison with all other disease and control cases ($P < 0.01$; Supplementary Table 2). In a separate approach, we examined gene expression in Case MS1, which presented with fulminate inflammatory cortical demyelination. Comparing this single multiple sclerosis case with all other cases included in our gene expression study allowed us to specifically examine the inflammatory component of this active cortical lesion. As a restrictive cut-off point we chose genes that were differentially up- ($>4$-fold log$_2$) or downregulated ($<-4.5$-fold log$_2$) compared with all other cases, including tuberculous meningitis cases showing the highest extent of inflammation. This resulted in 192 hits (144 upregulated and 48 downregulated; Supplementary Table 3). Taking together the two analysis approaches, we identified 301 multiple sclerosis-specific genes. Among those genes, 82% could be grouped into three major categories (Fig. 2 and Supplementary Tables 2 and 3): inflammation and immune cell activation/migration (24%), oxidative injury, DNA damage/repair, and cell death (28%), and tissue repair/regeneration (52%). Assignment of genes to multiple categories was tolerated. A comprehensive tabular summary of all multiple sclerosis-specific genes including log$_2$ fold-changes, $P$-values, gene accessions and gene functions, can be found in Supplementary Tables 2 and 3.

#### Category 1: genes associated with inflammation

Differential expression of inflammation-associated genes was mainly seen in the highly inflammatory cortical lesions of Case MS1 (Supplementary Table 3). Functional grouping revealed that many of the identified genes code for proteins involved in antigen recognition of class I and class II restricted T cells and in the regulation of Th1 and Th17 T-cell responses (10 genes), in microglia and macrophage function (seven genes), and in chemokine/cytokine signalling and leucocyte recruitment (18 genes). Profound multiple sclerosis-specific changes were also seen for genes involved in synthesis and function of selectins.

#### Category 2: genes associated with cell death, DNA damage and DNA repair

The most prominent changes in gene expression (Fig. 2, Table 4, Supplementary Tables 2 and 3) were found for genes involved in different steps of apoptosis, DNA damage, p53 function and DNA
repair (Table 4). They also included potassium and chloride channels controlling cell volume in the course of cell body or cell process degeneration, or genes involved in the modulation of excitotoxic or ischaemic cell death. This was in line with the identification of another cluster of genes with multiple sclerosis-specific expression, which was related to hypoxia, oxidative stress and mitochondria (Table 4).

Category 3: reaction to tissue injury and association with tissue repair

This category constituted the largest one (Fig. 2, Table 5, Supplementary Tables 2 and 3). A major subgroup included genes coding for proteins involved in RNA metabolism or regulation of transcription or translation. Another considerable cluster was related to development in general and to brain development in particular. It comprised genes necessary for various cellular functions such as cell survival, growth, and differentiation or control of cytoskeletal components (in particular tubulin turnover). One further group contained genes functionally associated with axonal and synaptic biology and regeneration (Table 5). The majority of these were either involved in axonal growth and guidance, or in synapse function. As expected, we also found significantly increased expression of some myelin- and oligodendrocyte-related genes in multiple sclerosis. Their expression was highest in Cases MS2 and MS3, which contained demyelinated and remyelinating lesion centres with rims of active demyelination at the border to the white matter.

Table 3  Inflammation and tissue injury in the cortices of cases selected for microarray analysis

|                         | Multiple sclerosis (n = 3) | Tuberculous meningitis (n = 3) | Alzheimer’s disease (n = 3) | Controls (n = 3) |
|-------------------------|---------------------------|-------------------------------|----------------------------|----------------|
| T cells                 | 91 (55)                   | 541 (860)                     | 11 (9)                     | 11 (24)        |
| Microglia/macrophages   | 757 (596)                 | 2301 (1449)                  | 552 (218)                  | 544 (252)      |
| Extent of demyelination | 41 (23)                   | 1 (1)                        | 0 (0)                      | 0 (0)          |
| Oligodendrocytes        | 23 (14) / 105 (52)        | 50 (32)                      | 82 (23)                    | 67 (107)       |
| Neurons                 | 154 (70) / 221 (60)       | 214 (24)                     | 198 (43)                   | 235 (15)       |
| Axonal spheroids        | 8 (93) / 6 (30)           | 3 (7)                        | 8 (26)                     | 0 (2)          |

This table summarizes the quantification of immunohistochemical results to determine the levels of inflammation, demyelination, and neurodegeneration in disease cases selected for microarray analysis. CD3-positive T cells, CD68-positive microglia/macrophages, TPPP/p25-positive oligodendrocytes, neurons and neurofilament-reactive dystrophic axons were counted (counts/mm²). The extent of demyelination was calculated as demyelinated area in relation to total cortex area. Results are presented as median value and range (in brackets). + = lesion centre; # = lesion edge.

Figure 2  Based on their known functions, multiple sclerosis-specific genes can be grouped into three major categories. Summary of differentially expressed genes in multiple sclerosis lesions compared with tuberculous meningitis, Alzheimer’s disease and control cortex. The genes are grouped according to their possible functions into inflammation-, tissue injury- and regeneration-related genes. Detailed lists of the differentially expressed genes are provided in Supplementary Tables 2 and 3. Potential molecular pathways of tissue injury are summarized in the lower half of the figure. The most important multiple sclerosis-specific genes concerning tissue injury and regeneration are listed in Tables 4 and 5. ROS/NOS = reactive oxygen species/nitric oxide synthase.
Table 4 Microarray analysis: most important genes regarding tissue injury

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|---------------------------|------|---------|
| GGTLC1      | Gamma-glutamyltransferase light chain 1 (glutathione metabolism) | 5.70 |         |
| DDAH2       | Dimethylarginine dimethylaminohydrolase 2 (NOS synthesis) | 5.54 |         |
| TXNIP       | Thioredoxin interacting protein (increases production of ROS) | 4.76 |         |
| SMOX        | Spermine oxidase (radical scavenger) | 4.38 |         |
| GSTT1       | Glutathione S-transferase theta 1 (antioxidant) | 4.07 |         |
| OGDHL       | Oxoglutarate dehydrogenase-like (oxidoreductase) | 2.77 | <0.001 |
| ARHGEF18    | Rho/rac guanine nucleotide exchange factor 18 (ROS production) | 2.28 | 0.001  |
| HP          | Haptoglobin (cellular iron ion homeostasis) | 2.01 | 0.005  |
| ASPHD1      | Aspartate beta-hydroxylase domain containing 1 (oxidoreductase) | 1.48 | 0.001  |
| NOS1AP      | Nitric oxide synthase 1 adaptor protein (neuronal nitric oxide synthesis) | 0.91 | 0.009  |
| NAPRT1      | Nicotinate phosphoribosyltransferase domain containing 1 (oxidative stress response) | 0.88 | 0.005  |

**Excitotoxicity/ischaemia**

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|---------------------------|------|---------|
| CLCA1       | Chloride channel, calcium activated, family member 1 (NMDAR-induced ischemic cell death) | 6.91 |         |
| SLCBA1      | Solute carrier family 8 (sodium/calcium exchanger), member 1 (protective role in ischemia) | 5.39 |         |
| ACMSD       | Aminocarboxymuconate semialdehyde decarboxylase (may inhibit excitotoxicity) | −4.91|         |
| CACNA1E     | Calcium channel, voltage-dependent, R type, alpha 1E subunit (protective role in ischemia) | −5.13|         |

**Hypoxia**

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|---------------------------|------|---------|
| OS9         | Amplified in osteosarcoma (binds and inactivates HIF1α) | 4.81 |         |
| CITED4      | Cbp/p300-interacting transactivator, with Glu/Asp-rich carboxy-terminal domain, 4 (inhibits HIF1α signalling) | 0.90 | 0.009  |
| CITED2      | Cbp/p300-interacting transactivator, with Glu/Asp-rich carboxy-terminal domain, 2 (negative regulator for HIF1α) | −4.54|         |
| HSD11B2     | Hydroxysteroid (11-beta) dehydrogenase 2 (response to hypoxia) | −4.55|         |
| USP20       | Ubiquitin specific peptidase 20 (deubiquitinates HIF1α) | −4.74|         |

**Mitochondrial injury**

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|---------------------------|------|---------|
| SLC25A4     | Solute carrier family 25 (mitochondrial carrier; adenine nucleotide translocator), member 4 (exchange of cytoplasmic ADP with mitochondrial ATP) | 5.96 |         |
| PYCR1       | Pyrroline-5-carboxylate reductase 1 (NADP+ generation) | 5.31 |         |
| ND6         | NADH-ubiquinone oxidoreductase chain 6 (mitochondrial respiratory chain) | 5.07 |         |
| TSFM        | Ts translation elongation factor, mitochondrial (translation of mitochondrial proteins) | 2.04 | 0.006  |

**p53 signalling**

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|---------------------------|------|---------|
| ZMIZ1       | Zinc finger, MIZ-type containing 1 (coactivator of p53) | 5.34 |         |
| RNF144B     | Ring finger 144B (induces p53-dependent cell death) | 4.77 |         |
| P2RX6       | P2X purinoceptor 6 (p53 responsive gene) | 4.30 |         |
| IGBP7       | Insulin-like growth factor binding protein 7 (p53 responsive gene) | 4.21 |         |
| CUL9        | p53-associated parkin-like cytoplasmic protein (regulation of p53 localization) | 2.14 | 0.007  |
| ZNHIT1      | Zinc finger, HIT type 1 (induces p53-mediated apoptosis) | 1.76 | 0.008  |
| BRD7        | Bromodomain containing 7 (p53 interactor) | 1.43 | 0.005  |
| MEG3        | Maternally expressed 3 (p53 interactor) | 0.97 | 0.009  |
| PSRC1       | Proline/serine-rich coiled-coil 1 (p53-regulated growth suppression) | −4.54|         |

| PACS2       | Phosphofructin acidic cluster sorting protein 2 (induces mitochondrial cytochrome C release) | 4.69 |         |

(continued)
Increased oxidative damage and DNA strand breaks in cortical multiple sclerosis lesions compared with tuberculous meningitis and other controls

So far, our microarray data suggested multiple sclerosis-specific changes in the expression of genes related to oxidative injury and DNA damage in cortical lesions. We therefore attempted to confirm these data in the entire sample or cases with multiple sclerosis listed in Table 1. From the individual cases with multiple sclerosis, cortical lesions were selected, which contained a demyelinated area with oligodendrocyte loss, surrounded by an area of microglia activation with interspersed macrophages containing early tissue degradation products and an adjacent area of normal appearing grey matter. In comparison with control cortices, a significant loss of neurons (31.1% loss; \( P < 0.01 \)) was seen in the demyelinated areas of multiple sclerosis cortex, which is in the range of that described previously (Vercellino et al., 2005; Wegner

### Table 4 Continued

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|--------------------------|------|--------|
| ASAH2       | N-acylsphingosine amidohydrolase (non-lysosomal ceramidase) 2 (blocks ceramide-induced apoptosis) | 4.68 |        |
| HRASLS3     | HRAS-like suppressor 3 (involved in interferon-induced cell death) | 4.00 |        |
| MAP3K10     | Mitogen-activated protein kinase kinase kinase 10 (nerve growth factor-induced neuronal apoptosis) | 3.28 | 0.001  |
| TMEM16H     | Transmembrane protein 16H (may function during apoptotic cell death) | 2.70 | <0.001 |
| PRKZ        | Protein kinase C, zeta (Fas ligand-induced apoptosis) | 2.55 | 0.004  |
| TNFAIP1     | Tumor necrosis factor, alpha-induced protein 1 (proapoptotic) | 2.38 | 0.002  |
| PKD1        | Polycystic kidney disease 1 (proapoptotic) | 2.11 | 0.004  |
| TRADD       | TNFRSF1A-associated via death domain (proapoptotic) | 1.67 | 0.004  |
| CMTI65      | CKLF-like MARVEL transmembrane domain containing (induces apoptosis in synergy with TNFα) | 1.52 | <0.001 |
| WISP1       | WNT1 inducible signaling pathway protein 1 (attenuates apoptosis) | –5.94|        |

Genes of both microarray analysis approaches are included. For Comparison 1 [significantly \( P < 0.01 \) changed genes in Cases MS1–3 in comparison with all other cases (Cases TB1–3, AD1–3 and CO1–3; \( n = 9 \))], \( \log_2 \) fold-changes as well as the corresponding P-values are shown. For Comparison 2 [massively up- or downregulated genes (\( \log_2 \) fold-changes >4 or < −4.5, respectively) in Case MS1 in comparison with all other cases], only the \( \log_2 \)-transformed fold-changes are given. A complete gene list is provided in Supplementary Tables 2 and 3. NOS = nitric oxide synthase; ROS = Reactive oxygen species.

### Table 5 Microarray analysis: most important genes regarding the regeneration of neuronal processes

| Gene symbol | Gene name (gene function) | Log2 | P-value |
|-------------|--------------------------|------|--------|
| GPM6A       | Glycoprotein M6A (neuronal differentiation; neurite outgrowth; neuronal plasticity) | 6.10 |        |
| PHF10       | PHD finger protein 10 (dendrite growth) | 5.71 |        |
| CACNB2      | Calcium channel, voltage-dependent, beta 2 subunit (axon guidance; synaptic transmission) | 5.63 |        |
| TNN         | Tenasin N (axon repulsion) | 5.48 |        |
| NEO1        | Neogenin homolog 1 (axon guidance) | 4.12 |        |
| ANKS3       | Ankyrin repeat and sterile alpha motif domain containing 3 (axon guidance) | 4.03 |        |
| CARTPT      | CART prepropeptide (neuronal development) | 2.54 | 0.000  |
| LRFN2       | Leucine rich repeat and fibronectin type III domain containing 2 (dendrite outgrowth; synapse formation) | 1.79 | 0.000  |
| MYLK2       | Myosin light chain kinase 2 (synaptic plasticity) | 1.50 | 0.001  |
| SLIT1       | Slit homolog 1 (axon guidance) | 1.47 | 0.003  |
| SORL1       | Sortilin-related receptor, L(DLR class) A repeats-containing (discussed for axon regeneration) | 1.42 | 0.003  |
| TRIM2       | Tripartite motif-containing 2 (axon outgrowth) | 1.25 | 0.003  |
| STMN3       | Stathmin-like 3 (neurite development) | 1.23 | 0.009  |
| JSLR2       | Immunoglobulin superfamily containing leucine-rich repeat 2 (axon outgrowth) | 0.94 | 0.007  |
| CAMK2B      | Calcium/calmodulin-dependent protein kinase (CaM kinase) II beta (plasticity of glutamatergic synapses) | −4.60|        |
| ACTL6B      | Actin-like 6B (neuronal development; dendrite morphogenesis) | −4.85|        |
| SEMA6B      | Sema domain, transmembrane domain (TM), and cytoplasmic domain, (semaphorin) 6B (axon guidance) | −5.39|        |

Genes of both microarray analysis approaches are included. For Comparison 1 [significantly \( P < 0.01 \) changed genes in Cases MS1–3 in comparison with all other cases (TB1–3, AD1–3, and CO1–3; \( n = 9 \))], \( \log_2 \) fold-changes as well as the corresponding P-values are shown. For Comparison 2 [massively up- or downregulated genes (\( \log_2 \) fold-changes >4 or < −4.5, respectively) in MS1 in comparison with all other cases], only the \( \log_2 \)-transformed fold-changes are given. A complete gene list is provided in Supplementary Tables 2 and 3.
or control cases (Fig. 5F). Our previous studies of active white matter lesions (Haider et al., 2011; Fischer et al., 2012) indicated that immunohistochemistry for oxidized phospholipids (E06 immunoreactivity) is a sensitive marker for degenerating oligodendrocytes and dystrophic axons. In cortical multiple sclerosis lesions, we observed a similar immunoreactivity for oxidized phospholipids in the mentioned cell types, concentrated at sites of ongoing demyelination (Fig. 3A and M). Neurons with intense cytoplasmic accumulation of oxidized phospholipids (Fig. 3N) were significantly more abundant in active cortical multiple sclerosis lesions than in lesions of tuberculous meningitis, luetic meningitis, chronic purulent meningitis (P < 0.05), Alzheimer’s disease (P < 0.05) or controls (P < 0.001; Figs 3A–D and 4A). In addition, oxidatively damaged neurons showed process fragmentation (Fig. 3E–H, O and P) or nuclear changes of necrosis- or apoptosis-like cell death as defined earlier (Muller et al., 2004) (Fig. 3I and J). Furthermore, nerve cells exhibiting central chromatolysis, a sign of proximal axon transection, also showed profound E06 immunoreactivity (Fig. 3K and L). Additionally, we performed TUNEL staining for DNA strand breaks. TUNEL-positive nuclei of neurons and oligodendrocytes were most frequently seen in multiple sclerosis lesions in the areas of active demyelination and tissue injury (Fig. 3R), whereas their number was much smaller in the demyleinated lesion centre and the normal appearing grey matter (Fig. 4B). Few TUNEL-positive nuclei were seen in the cortex of controls or patients with tuberculous meningitis (Figs 3S and 4B). Double staining for TUNEL and oxidized phospholipids showed that neurons with oxidative damage either contained condensed nuclei with high TUNEL reactivity, suggestive for apoptosis (Fig. 3U), or nuclei with small focal spots of damaged DNA (Fig. 3T). Immunohistochemistry for activated caspase 3 was negative throughout the whole tissue sample, suggesting caspase-independent cell death (data not shown). Apoptosis inducing factor was present in the mitochondria of healthy neurons in control and multiple sclerosis tissue (Fig. 3V). In active multiple sclerosis lesions, however, neurons were seen, which in addition to mitochondrialy located apoptosis inducing factor also showed diffuse apoptosis inducing factor immunoreactivity in the cytoplasm and presence of apoptosis inducing factor in cell nuclei (Fig. 3W).

Cells with cytoplasmic accumulation of oxidized phospholipids were mainly present in cortical areas with high density of activated microglia expressing the NADPH oxidase component p22phox (Fig. 5A). Processes of p22phox-positive microglia were attached either to the cell body (Fig. 5B) or to dendrites of neurons with oxidative injury (Fig. 5C). Immunohistochemistry for inducible nitric oxide synthase (iNOS) revealed that active cortical multiple sclerosis lesions contain only few inducible nitric oxide synthase-reactive cell bodies or processes of microglia (Fig. 5D). Macrophages with high inducible nitric oxide synthase immunoreactivity were seen in more advanced white matter lesions (Fig. 5E). These findings are in line with our microarray results showing an up-regulation of certain NADPH oxidase subunits (mainly components of NOX1 and NOX2 complexes) in cortical multiple sclerosis lesions in comparison with tuberculous meningitis or control cases (Fig. 5F).

**Discussion**

Active cortical demyelination and neurodegeneration in multiple sclerosis are associated with inflammation in the cortical tissue itself (Lucchinetti et al., 2011) or in the meninges (Kutzelnigg et al., 2005; Howell et al., 2011). It has thus been suggested that tissue injury is either mediated by inflammatory cells or their soluble mediators diffusing into the cortex and inducing tissue damage either directly or indirectly through microglia activation (Howell et al., 2011). Several types of inflammatory cells, including T cells or B cells, are regarded as particularly important in multiple sclerosis pathogenesis and thought to trigger demyelination and neurodegeneration in a non-specific ‘bystander’ fashion (Wisniewski and Bloom, 1975). A previous study (Moll et al., 2008) indicated that cortical demyelination may be multiple sclerosis-specific, but this conclusion was based on diseases with inflammatory reactions quite different from multiple sclerosis. In our study, we confirm this view by focusing on diseases, which to our knowledge more closely reflect key inflammatory components operating in multiple sclerosis lesions. Thus, demyelination and neurodegeneration in multiple sclerosis are not unspecific consequences of inflammation, but appear to involve multiple sclerosis-specific mechanisms of tissue injury.

Microarray studies have been performed on cortical tissue of multiple sclerosis before. They revealed changes related to mitochondrial function in the non-demyelinated motor cortex (Dutta et al., 2006), to axonal transport and synaptic function (Dutta et al., 2011), to the regulation of oligodendrocyte differentiation (Schmidt et al., 2012) and to intrathecal immunoglobulin synthesis (Torkildsen et al., 2010). In contrast to our current study, they focused on normal appearing grey matter or demyelinated areas, but not on areas of active demyelination and tissue injury. Furthermore, they did not include other disease controls. Thus, the prominent expression of immunoglobulin related genes described by Torkildsen et al., (2010) did not appear in our results, because tuberculous meningitis, similar to multiple sclerosis, shows profound intrathecal immunoglobulin synthesis.

Our results showed multiple sclerosis-specific gene expression changes in mainly three different molecular pathways: inflammation, oxidative stress associated with DNA damage, and regenerative mechanisms affecting oligodendrocytes, neurons and neuronal cell processes.

Multiple sclerosis-specific gene expression related to inflammation (Supplementary Tables 2 and 3) involved molecules important for antigen presentation and polarization of MHC class I and II restricted T cells towards Th1 and Th17 pathways (Tzartos et al., 2008) or macrophage/microglia activation. Downregulation of the expression of the co-stimulatory molecule CTLA4 in active cortical lesions (Supplementary Table 3) is in agreement with the proposed anti-inflammatory function of this molecule in patients with multiple sclerosis (Joller et al., 2012). Results supporting our current data have been reported before in other gene expression studies (Whitney et al., 1999; Lock et al., 2002; Mycko et al., 2003) and interpretation of the data is in agreement with inflammatory pathways identified in genome-wide association studies on multiple sclerosis susceptibility (Sawcer et al., 2011). Our study further
Figure 3  Cytoplasmic accumulation of oxidized phospholipids (E06 reactivity) in cortical multiple sclerosis lesions. (A–D) Cortical tissue from multiple sclerosis (A; MS1), tuberculous meningitis (B; TB2), and Alzheimer's disease (C; AD2) patients and control (D; CO3) cases. Numerous cells with strong cytoplasmic E06 immunoreactivity are seen in the multiple sclerosis cortex (A), while only sparse E06-positive cells are seen in the other conditions (B–D). However, some granular, lipofuscin-like E06 immunoreactivity is visible mainly within neurons and macrophages in all examined cases. (E–H) Neurons with extensive cytoplasmic accumulation of oxidized phospholipids show beading and fragmentation of their processes in active cortical multiple sclerosis lesions. (I and J) Patterns of degeneration (Muller et al., 2004) in neurons with extensive accumulation of oxidized phospholipids. Neurons with numerous fine speckles of condensed chromatin resembling
identified a number of molecules that are instrumental in leucocyte trafficking into inflammatory lesions including integrin alpha 9, a binding partner of vascular cell adhesion molecule (VCAM). Blockade of VCAM/integrin interaction is currently a very effective anti-inflammatory treatment in patients with multiple sclerosis (Polman et al., 2006). Our results also indicate that selectins, which mediate inflammation in peripheral organs and the brain through integrin activation (Prendergast and Anderton, 2009; Alvarez et al., 2011; Zarbock et al., 2012), may play a role in regulating leucocyte trafficking in cortical multiple sclerosis lesions in the progressive stage of the disease. High expression of some selectins has also been shown before in microarray studies on microdissected blood vessels from patients with multiple sclerosis (Cunnea et al., 2010).

Regarding mechanisms of tissue injury, which were in the main focus of our study, our results suggest that oxidative damage plays a major role in the processes of cortical oligodendrocyte degeneration, demyelination and neuronal damage. These resemble mechanisms observed previously in active white matter lesions and adjacent normal appearing white matter. Expression of enzymes involved in oxygen (Gray et al., 2008; Fischer et al., 2012) and nitric oxide radical production (Liu et al., 2001; Mark et al., 2007; Zeis et al., 2009), the abundance of oxidized lipids and DNA in degenerating oligodendrocytes and axons (Haider et al., 2011), the increased expression of molecules involved in antioxidant defence (van Horssen et al., 2008) and the presence of hypoxia-like tissue injury in active lesions and the adjacent normal appearing white matter (Aboul-Enein et al., 2003; Graumann et al., 2003; Trapp and Stys, 2009) have been shown before. Oxidative stress is assumed to lead to mitochondrial injury in multiple sclerosis lesions (Dutta et al., 2006; Mahad et al., 2008; Campbell et al., 2011; Lassmann et al., 2012). Here we show that immunoreactivity for oxidized phospholipids is much higher in neurons of active cortical multiple sclerosis lesions than in all other conditions studied (tuberculous meningitis, Alzheimer’s disease, and control subjects). Furthermore, the expression of genes involved in DNA damage and repair was highly up-regulated in multiple sclerosis lesions in comparison with other inflammatory or neurodegenerative controls such as tuberculous meningitis or Alzheimer’s disease (Table 4, Supplementary Tables 2 and 3). This was also confirmed by the much higher incidence of cells with TUNEL reactivity in areas of active demyelination and tissue injury. TUNEL reactivity, which has been shown before to occur in low incidence in inactive cortical multiple sclerosis lesions (Peterson et al., 2001), may reflect apoptotic cell death, but also reversible DNA injury. In line with previous studies, apoptosis in multiple sclerosis lesions was not associated with caspase 3 activation (Barnett and Prineas, 2004), but with the liberation of apoptosis inducing factor from mitochondria and its nuclear translocation (Veto et al., 2010). Neuronal cell death within active lesion areas may at least in part be responsible for neuronal loss in established lesions.

The mechanisms that drive oxidative injury and neurodegenerative processes in multiple sclerosis lesions are currently not fully understood. Persistent inflammation in meninges and cortical parenchyma appears to be one important driving force (Howell et al., 2011; Choi et al., 2012; Lucchetti et al., 2011). In addition, factors related to ageing and to chronicity of the disease may play a role. As an example, age-related iron accumulation in the human brain may amplify oxidative injury (Lassmann et al., 2012). Furthermore, it was shown in a recent study that the topography of cortical lesions may be related to distant lesions within the white or deep grey matter (Kolasinski et al., 2012), indicating a role of anterograde or retrograde degeneration in the precipitation of cortical lesions. This may also in part explain the differences between cortical lesions in multiple sclerosis and tuberculous meningitis, the latter exposing the cortex to inflammation in the absence of pre-existing distant neurodegeneration.

An interesting observation of our study is that oxidative injury of neurons in the multiple sclerosis cortex coincides with beading and fragmentation of axons and dendrites. Degeneration of neuronal processes was present in cells, in which the peri-nuclear cell body remained morphologically intact. This is further supported by our microarray analyses comprising many genes related to axonal, dendritic, and synaptic regeneration. A similar result has been obtained in previous work analysing gene expression in hippocampal multiple sclerosis lesions (Dutta et al., 2011), and it was suggested that the profound axonal injury in cortical multiple sclerosis lesions is related to increased vulnerability of demyelinated axons.

**Figure 3 Continued**

‘necrosis-like’ cell death (I) as well as neurons with large fragments of condensed chromatin resembling ‘apoptosis-like’ cell death (J) can be found. (K and L) Neurons with central chromatolysis as a reaction to proximal axonal transection show intense reactivity for oxidized phospholipids. (M) E06 reactivity in oligodendrocytes in active cortical multiple sclerosis lesion of Case MS1. The figure shows two normal oligodendrocytes (white arrows), one oligodendrocyte with accumulation of oxidized phospholipids (white arrowhead) and an astrocyte (white asterisk). Triple antibody labeling for E06 (green), carboanhydrase (red), and glial fibrillary acidic protein (blue). (N) Calbindin-positive nerve cell in a cortical multiple sclerosis lesion with cytoplasmic E06 immunoreactivity. Double antibody labelling for E06 (green) and synaptophysin (red) shows individual dystrophic axons with E06 immunoreactivity. (Q) Double staining for E06 (green) and synaptophysin (red) shows a neuron with oxidized phospholipids, but no E06 immunoreactivity in synaptophysin-positive synapses. (R) Cortical lesion of Case MS1 stained for DNA strand breaks with TUNEL (black nuclei); the number of nuclei with DNA strand breaks is similar to the number of cells stained for oxidized phospholipids, shown in A. (S) TUNEL staining of control cortex (CO3); no nuclear TUNEL reactivity is seen. (T and U) Double staining for TUNEL (black) and E06 (red) shows either spotted TUNEL reactivity in E06 positive neurons with otherwise intact nuclei (T) or intense TUNEL reactivity in neurons with condensed apoptotic like nuclei (U). (V and W) Apoptosis inducing factor immunoreactivity is present in a staining pattern resembling mitochondria in normal neurons (V), but in addition shows diffuse cytoplasmic staining and nuclear reactivity in neurons with beaded cell processes (W). Scale bars: A–D = 100 μm; E–Q and T–W = 50 μm; R and S = 200 μm.
(Dutta et al., 2011). Our study proposes an additional mechanism: direct oxidative injury and focal damage of axons and dendrites due to the primary destructive events. Partial repair of neuronal cell processes in cortical multiple sclerosis lesions may occur in parallel with remyelination (Albert et al., 2007) and may be associated with functional plasticity seen in MRI studies (Rocca and Filippi, 2007; Caramia et al., 2010).

We are aware that our study has limitations regarding the analysis of whole-genome microarrays. RNA was isolated from formaldehyde-fixed and paraffin-embedded material, which is known to be inferior in comparison with fresh frozen tissue. Eisele et al. (2012) published a comprehensive study comparing formaldehyde-fixed and paraffin-embedded to fresh frozen material using, among others, tissue derived from our archives. Eisele et al. (2012) showed that although integrity measurements of RNA isolated from formaldehyde-fixed and paraffin-embedded material resulted in very low integrity numbers, amplicons with a length of <150 bp were still detectable. Eisele et al. (2012) performed quantitative PCR-based transcript profiling analysing the expression of 84 extracellular matrix-related genes and identified a transcript loss of 47% in formaldehyde-fixed and paraffin-embedded-derived samples in comparison with fresh frozen material. Of course, such false negative results can be expected in our study as well. We tried to minimize this problem accordingly by first of all using only tissue blocks that showed reasonable RNA preservation, as evidenced by strong in situ hybridization signals after a short time of development. Secondly, stringent RNA quality criteria were applied to ensure that only samples with sufficiently long RNA fragments were further processed. Thirdly, we used whole-genome microarrays from Agilent. As shown in Supplementary Table 4, most of the probes of Agilent arrays were located within the last exon. Because the RNA fragments contained in our samples were amplified using poly(A) tail primers, the binding probability to the corresponding microarray probes was maximized. Fourthly, we focused on either highly significantly changed genes \((P < 0.01)\) or used restrictive cut-offs (\(\log_2\) fold-changes >4 or \(< -4.5\)). Additionally, we did not focus on single gene analysis, which would require much more stringent molecular and biochemical confirmation of the identified molecules. Instead, we used the microarray data for the identification of interconnected pathways within specific and extremely well characterized lesions. The involvement of these pathways in multiple sclerosis pathology, but not necessarily the involvement of single pathway-revealing molecules, was then evaluated in immunohistochemical analyses using a much larger sample of cases and lesions. We want to point out that our microarray analyses also included a single case comparison (Case MS1 in comparison with all other cases). This was done, since this case showed an extreme degree of cortical inflammatory demyelinating activity, which is extremely rare in multiple sclerosis tissue available for pathological analysis (Kutzelnigg et al., 2005; Lucchinetti et al., 2011) and for this reason may be particularly informative with respect to the questions addressed in this study. Despite these limitations, a strong argument for the validity of our data is the fact that >80% of
Figure 5  Oxidative damage in cortical multiple sclerosis lesions is mainly driven by NADPH oxidases. (A–C) Cells containing oxidized phospholipids (brown) are located in areas with numerous microglia expressing the NADPH oxidase component p22phox (blue). P22phox-positive, activated microglia embrace oxidatively damaged neurons with their processes (B) or are in contact with neuronal cell processes (C). (D and E) Double labelling for E06 (brown) and inducible nitric oxide synthase (iNOS; blue). Cortical multiple sclerosis lesions with profound cellular accumulation of oxidized phospholipids contain only few microglia cells or processes reactive for inducible nitric oxide synthase (D). In contrast, macrophages with high immunoreactivity for inducible nitric oxide synthase are seen in more advanced lesions in the white matter of the same section (E). (F) The heat map presents colour-coded log₂-transformed fold-changes of genes coding for NADPH oxidase components or nitric oxide synthase enzymes. For this analysis, the fulminate Case MS1 was compared with either tuberculous meningitis (TB1–3; left column) or controls (CO1–3; right column). The comparisons are in line with immunohistochemical studies suggesting oxidative damage to be driven by NOX1 and NOX2 components of NADPH oxidases and not by nitric oxide synthase enzymes. The colour gradient was computed using 10th, 50th, and 90th percentiles. Green, black and red colours indicate downregulated, unchanged, and upregulated genes, respectively. The official gene symbol and RefSeq annotation number are shown for each gene. MS = multiple sclerosis; TB = tuberculous meningitis; CO = control; Scale bars: A = 200 μm; B and C = 50 μm; D and E = 100 μm.
gene expression changes identified by our approach are related to interconnected molecular pathways, which in part have been suggested to operate in multiple sclerosis lesions before.

In conclusion, our study shows that focal plaque-like demyelination is a specific feature of cortical multiple sclerosis lesions and is associated with excessive oxidative damage, mainly affecting oligodendrocytes, neurons and their cell processes. The reason for excessive oxidative injury remains currently unresolved and may be related to the nature of the inflammatory process or to factors determining the susceptibility of neuronal tissue to inflammation in multiple sclerosis, such as brain ageing or accumulation of pre-existing damage. To answer this question, more extensive studies are necessary concentrating on highly active and inflammatory cortical multiple sclerosis lesions, which are very rare in archival autopsy material, but are sometimes seen in biopsies of multiple sclerosis brain tissue obtained during the early stages of the disease (Lucchetti et al., 2011).
