The connection between time-local and time-nonlocal perturbation expansions

There exist two canonical approaches to describe open quantum systems by a time-evolution equation: the Nakajima-Zwanzig quantum master equation, featuring a time-nonlocal memory kernel $\mathcal{K}$, and the time-convolutionless equation with a time-local generator $\mathcal{G}$. These key quantities have recently been shown to be connected by an exact fixed-point relation [Phys. Rev. X 11, 021041 (2021)]. Here we show that this implies a recursive relation between their perturbative expansions, allowing a series for the kernel $\mathcal{K}$ to be translated directly into a corresponding series for the more complicated generator $\mathcal{G}$. This leads to an elegant way of computing the generator using well-developed, standard memory-kernel techniques for strongly interacting open systems. Moreover, it allows for an unbiased comparison of time-local and time-nonlocal approaches independent of the particular technique chosen to calculate expansions of $\mathcal{K}$ and $\mathcal{G}$ (Nakajima-Zwanzig projections, real-time diagrams, etc.). We illustrate this for leading and next-to-leading order calculations of $\mathcal{K}$ and $\mathcal{G}$ for the single impurity Anderson model using both the bare expansion in the system-environment coupling and a more advanced renormalized series. We compare the different expansions obtained, quantify the legimity of the generated dynamics (complete positivity) and benchmark with the exact result in the non-interacting limit.

I. INTRODUCTION

In contrast to closed quantum systems, which are always described by the Schrödinger equation, a peculiar feature of the description of open quantum systems is that one has to choose between two equivalent exact quantum master equations. On the one hand, there is the time-nonlocal quantum master equation (Nakajima-Zwanzig), producing the evolution map $\rho(t) = \Pi(t, t_0)\rho(t_0)$ by convolution with a memory kernel $\mathcal{K}$:

$$\frac{d}{dt}\Pi(t, t_0) = -i \int_{t_0}^{t} ds \mathcal{K}(t, s)\Pi(s, t_0). \tag{1}$$

The time-local quantum master equation, on the other hand, features a time-dependent generator $\mathcal{G}$

$$\frac{d}{dt}\Pi(t, t_0) = -i\mathcal{G}(t, t_0)\Pi(t, t_0). \tag{2}$$

The time-nonlocal memory kernel $\mathcal{K}$ is closely connected to the microscopic point of view and perturbation expansions, which are at the focus of this paper. It captures the retarded effect of the environment on the system (memory). Several methods have been developed to compute $\mathcal{K}$, even for complicated models featuring strong interaction and memory effects [2–12]. The opposite point of view predominant in quantum information and dynamics is of independent interest, where one starts from given general properties of the dynamical map $\Pi$, which are more easily related to the generator $\mathcal{G}$. However, the computation of the time-local generator is much more challenging. Nevertheless this has been approached from various angles [13–17] motivated, for example, by the fact that $\mathcal{G}$ is the quantity of choice for understanding the “(non-)Markovianity” [18–21] of the dynamics by its connection to both $\mathcal{P}$- [22, 23] and $\mathcal{CP}$-divisibility [24–26]. This seems practically impossible to achieve with a description of the dynamics based on $\mathcal{K}$ [27–29]. Also, the widely applied stochastic simulation methods [30] are also invariably based on $\mathcal{G}$ [31–33]. Finally, it is only using $\mathcal{G}$ that one can directly study geometric and possible topological phases in open quantum systems [34–38], which emerge, for example, in the study of pumping [39–41].

In Ref. [42] we recently found that $\mathcal{G}$ is a fixed point of a Laplace-like transformation functional induced by $\mathcal{K}$, in short $\mathcal{G} = \mathcal{K}[\mathcal{G}]$, and related work was reported in Refs. [43–45]. Besides revealing surprising exact relations between spectral properties of $\mathcal{G}$, $\mathcal{K}$ and $\Pi$ this result makes it possible to compute $\mathcal{G}$ from $\mathcal{K}$ without first constructing the full propagator $\Pi$. In the present paper we apply this relation, reviewed in Sec. II, to solve another open problem in the field of open system dynamics: We show it can be used to translate a given perturbation series for $\mathcal{K}$ into a corresponding series for the more complicated $\mathcal{G}$. Importantly, approximations to $\mathcal{K}$ and $\mathcal{G}$ computed to the same order using the same perturbative scheme give different approximate evolutions $\Pi$ due to the difference in time (non-)locality of Eqs. (1)–(2). It is an intriguing and delicate question which of the two expansions does “better”. This issue calls for a general way to meaningfully compare such expansions. In Sec. III we illustrate how this can be done both analytically and numerically using the interacting Anderson quantum dot as an example by calculating both $\mathcal{K}$ and $\mathcal{G}$ using a particular diagrammatic technique [5, 46]. We stress that...
this strategy is not at all essential to our central result. The same result is obtained, for instance, using the Nakajima-Zwanzig projection technique instead. Moreover, we are also flexible in the choice of the expansion reference, allowing us to explore another, renormalized perturbation theory, to extend the potential usefulness of our results in regimes of strong coupling. This more powerful expansion was initially developed for $K$ as first stage of a continuous RG-flow method for open quantum systems [5, 47, 48] to deal with strong dissipative coupling and non-equilibrium. It was later studied on its own merits [46, 49–51] and revealed powerful exact relations [50, 52]. However, applications to the transient time-evolution of interacting systems analyzed in the present work were not yet explored.

II. FIXED-POINT EQUATION CONNECTING GENERATOR AND MEMORY-KERNEL

Given a memory kernel $K$ (or an approximation to it), we ask the question how to construct a corresponding (approximation to the) generator $G$. One way to achieve this is to first solve Eq. (1) for the evolution $\Pi$, from which one can then reverse engineer the generator

$$-iG(t, t_0) = \left[ \frac{d}{dt} \Pi(t, t_0) \right] \Pi(t, t_0)^{-1}. \hspace{1cm} (3)$$

Interestingly, it was shown in Ref. [42] that it is also possible to compute $G$ from $K$ without solving for the complete evolution first. To do so, for the given kernel $K$ one considers the functional $\hat{K}[X]$, which maps a time-dependent superoperator $X(t, t_0)$ to another such object,

$$\hat{K}[X](t, t_0) := \int_{t_0}^t ds \, K(t, s) \mathcal{T}_- e^{s} \int_s^t d\tau X(\tau, t_0), \hspace{1cm} (4)$$

where $\mathcal{T}_-$ denotes anti-time-ordering. It then follows that $G$ is a fixed point of this functional [42],

$$G(t, t_0) = \hat{K}[G](t, t_0). \hspace{1cm} (5)$$

One possible way to use this for computing $G$ is to first find a reasonable initial guess for the generator denoted $G_0$, and then to iterate the functional $i = 1, 2, 3, \ldots$ times,

$$G_i(t, t_0) := \hat{K}[G_{i-1}](t, t_0). \hspace{1cm} (6)$$

It was shown for specific models that this iteration converges with $i \to \infty$ to the exact generator, and that this is even possible if $G$ has physical singularities at isolated times [42]. A mathematical analysis of the success of this strategy is certainly interesting and should address questions of uniqueness and stability of the fixed point raised in Ref. [42]. In this paper we instead focus on useful formal implications of the fixed-point equation (5), in particular, how it leads to a natural reorganization of perturbation expansions when the time-(non)locality of the quantum master equation is altered.

Thus, the goal is to find a perturbative expansion for $G$ based on a corresponding expansion for $K$. By “corresponding” we mean that both series count powers of the same formal expansion parameter. We start by decomposing $K$ as

$$K(t, s) = K_L \delta(t - s) + K_N(t, s). \hspace{1cm} (7)$$

with a $\delta$ distribution normalized as $\int_0^\infty dsf(s)\delta(t - s) = f(t)$. Here $K_L$ determines a time-local part, which at first is taken to be the uncoupled system Liouvillian, and $K_N$ denotes the remaining environment part due to non-zero coupling, which contains time-nonlocal contributions. The kernel $K^{(i)}(t, s) = K_L \delta(t - s)$ producing semigroup dynamics $\Pi^{(i)} = e^{-i K_L t}$ via Eq. (1) will be the reference point of the perturbation theory. Importantly, we will also allow for a renormalized expansion, in which a further time-local contribution—which was still contained in $K_N$—is included in $K_L$, making the reference evolution $\Pi^{(0)}$ dissipative, see details below [Eq. (34)]. In either case we assume for simplicity that $K_L$ is time-independent, but this is not a limiting assumption.

Decomposing $G(t, t_0) = K_L + G_N(t, t_0)$ analogously, the fixed point equation (5) implies that $G_N$ obeys

$$G_N(t, t_0) = \int_{t_0}^t ds \, K_N(t, s) \mathcal{T}_- e^{i} \int_s^t d\tau K_L(\tau, t_0). \hspace{1cm} (8)$$

We correspondingly use $G^{(0)} = K_L$ as a reference for the expansion of $G$. Assuming that the nonlocal part of the memory kernel is given by a series in some formal parameter, $K_N = K^{(1)} + K^{(2)} + \ldots$, we can derive the corresponding series for $G_N = G^{(1)} + G^{(2)} + \ldots$ in the same parameter by first expanding the anti-time-ordered exponential in Eq. (8) and then matching orders. The first two terms explicitly read

$$G^{(1)}(t, t_0) = \int_{t_0}^t ds \, K^{(1)}(t, s) e^{-i K_L(s-t)}, \hspace{1cm} (9)$$

$$G^{(2)}(t, t_0) = \int_{t_0}^t ds \, K^{(2)}(t, s) e^{-i K_L(s-t)} + i \int_{t_0}^t ds \, \int_s^t d\tau K^{(1)}(\tau, s) \times e^{-i K_L(t-\tau)} G^{(1)}(\tau, t_0) e^{-i K_L(t-\tau)}. \hspace{1cm} (10)$$

The general $n$-th order $G^{(n)}$ is similarly given by
where the second sum runs over \( m_0, \ldots, m_l > 0 \). We thus see that the fixed-point equation automatically organizes the series expansion of \( G_N \) into a recursive form. It is well known that when computing the memory kernel \( K \), for example using standard projection operator or diagrammatic techniques, one obtains only time-ordered contributions (convolutions), whereas the generator \( G \) has a more complicated structure involving combinations of non-time ordered integrations. The recursive reorganization implied by the fixed-point relation completely disentangles this nontrivial structure: Eq. (11) reveals that collecting all time-ordered contributions one obtains precisely the various memory kernel components \( K^{(n)} \) — obtainable by well-developed standard techniques — and that the remaining integrations are exclusively anti-time ordered. In the remainder of the paper we will exploit this insight using the diagrammatic approach, noting that one may equivalently use the projection operator technique.

So far we refrained from making use of the propagator. However, if the orders of \( \Pi \) are formally known this can be useful. By similarly expanding \( \Pi = \Pi^{(0)} + \Pi^{(1)} + \ldots \) and inserting into \( G_N \Pi = K_N \Pi \) [Eq. (2) = Eq. (1)], written as \( G_N = [K_N * \Pi - G_N (\Pi - e^{-i K_L t})] e^{i K_L t} \), one obtains a useful reorganization, expressing the \( n \)-th order of \( G \) in terms of its lower orders with the help of both the memory kernel \( K \) and the propagator up to order \( n \),

\[
G^{(n)}(t) = \sum_{l=0}^{n-1} \sum_{m_0=m_l=n} \int d\tau_0 \cdots d\tau_l K^{(m_0)}(t, \tau_0) e^{-i K_L (\tau_0 - \tau_1)} G^{(m_1)}(\tau_1) e^{-i K_L (\tau_1 - \tau_2)} G^{(m_2)}(\tau_2) \cdots G^{(m_l)}(\tau_l) e^{-i K_L (\tau_l - t)},
\]

(11)

corresponds to contrasting the well-established bare perturbation expansions of \( K \) [2, 3, 53] and \( G \) [13, 54–59] whose traditional derivations are very difficult to compare. Since we are able to treat both expansions in the same, standard way a comparison becomes possible.

As a remark, we point out another way of exploiting the fixed-point equation. It namely defines an approximate self-consistent generator \( G_{sc} \), which produces exactly the same evolution via Eq. (2) as the perturbative \( K_{pert} \) does via Eq. (1). In other words [60], it satisfies the fixed-point equation \( G_{sc} = K_{pert} [G_{sc}] \) being self-consistent relative to the kernel approximation. This approximate but self-consistent generator differs from the one considered in this paper, \( G_{sc} \neq G_{pert} \). One should realize that when using \( G_{sc} \) one essentially gives up calculating the generator directly but formulates all approximations using \( K \) and afterwards produces the equivalent generator (as opposed to corresponding). The advantage of the fixed-point equation is that one achieves this without first constructing the solution \( \Pi_{pert} \) from \( K_{pert} \), by a self-consistent iterative computation which was numerically explored in Ref. [42] for an exactly known \( K \). The self-consistent generator \( G_{sc} \), being self-consistent, is of independent interest, but beyond the present scope and will not be considered here. We merely note that this is useful, since it allows, for example, to determine whether the evolution generated by an approximate kernel \( K_{pert} \) is Markovian in either the P- or CP-divisible sense, since this can only be decided by inspection of the equivalent time-local generator \( G_{sc} \) written in the Gorini–Kossakowski–Sudarshan–Lindblad (GKLS) form [22, 24, 26]. As another example, with \( G_{sc} \) in hand one can investigate individual quantum trajectories of approximations to non-Markovian dynamics using well-developed stochastic simulation techniques [31–33] based on the time-local QME, avoiding the memory-integrals required by time-nonlocal stochastic simulation methods [61, 62].

III. TRANSIENT BEHAVIOR OF THE SINGLE IMPURITY ANDERSON MODEL

A. Anderson model in Liouville space

As an example, we consider a single orbital quantum dot with spin described by

\[
H = \epsilon (n_\uparrow + n_\downarrow) + Un_\uparrow n_\downarrow.
\]

(13)
Here $\epsilon$ is the energy of the orbital, $n_\sigma = d_\sigma^\dagger d_\sigma$ the number operator for spin $\sigma$ and $U$ is the Coulomb interaction. This quantum dot is connected to several free electron reservoirs

$$H_R = \sum_{\sigma} \int d\omega (\omega + \mu_\sigma) a_\sigma^\dagger(\omega) a_\sigma(\omega).$$

We allow that the reservoirs labeled by $r$ are initially in thermal equilibrium at different temperatures $T_r$ and chemical potentials $\mu_r$ but in illustrations we focus on $T_r = T$. The tunnel junctions are modeled with the Hamiltonian

$$H_T = \sum_{\sigma} \int d\omega \frac{\Gamma_{\sigma}}{2\pi} (d_\sigma a_\sigma^\dagger(\omega) + a_\sigma(\omega)d_\sigma^\dagger),$$

where $\Gamma_{\sigma}$ is the real-valued, spin-dependent spectral density of reservoir $r$ assumed to be energy independent (wideband limit). Thus the total Hamiltonian is

$$H_{\text{tot}} = H + H_R + H_T.$$

For the calculation of the open system dynamics a formalism based on superoperators is convenient. Here we use the superfermion approach to Liouville space introduced in Ref. [5] using the later formulation of Ref. [46], where details and comparison with other constructions can be found. Defining first the shorthand notation

$$d_{\eta\sigma} := \begin{cases} d_\sigma^\dagger & \text{for } \eta = +, \\ d_\sigma & \text{for } \eta = -, \end{cases}$$

the superfermions are superoperators defined as

$$G_{\eta\sigma} := \frac{1}{2} (d_{\eta\sigma} \bullet + p(-1)^p \bullet (-1)^n d_{\eta\sigma}),$$

where $p = +$ gives a creation and $p = -$ an annihilation superoperator and $(-1)^n := (1 - 2n_\uparrow)(1 - 2n_\downarrow)$ denotes the fermion parity operator. The superfermions act in the Liouville-Fock space analogously to the way that ordinary creation/annihilation operators act in the Hilbert-Fock space. The supervacuum state $|0\rangle$ corresponding to Eq. (18) is given by the infinite-temperature stationary state $|0\rangle := \frac{1}{\Gamma} \mathbb{1}$ considered as a supervector. From this a complete basis for the Liouville-Fock space is generated by the superfermionic creation operators ($G_{\eta\sigma}^+$) in the usual way [49]. This choice of fields and vacuum is particularly well-adapted to the perturbation expansion, as we will see [Eq. (33)]. Furthermore, the superfermions anticommute,

$$\{G_{\eta_1\sigma_1}^{p_1}, G_{\eta_2\sigma_2}^{p_2}\} = \delta_{p_1,p_2} \delta_{\eta_1,-\eta_2} \delta_{\sigma_1,\sigma_2},$$

where $\bar{x} := -x$, and they satisfy a super-Pauli principle, which states that it is formally impossible to create or destroy two identical superfermions

$$\left(G_{\eta\sigma}^p\right)^2 = 0.$$
C. Bare perturbation theory

1. Bare perturbation theory for kernel \( K \)

One systematic way of computing \( K \) is by a bare perturbation expansion in the coupling to the environment. This is substantially simplified \([49, 70–72]\) by combining diagrammatic \([3, 6]\) and Liouville-Fock space techniques \([5, 8, 50]\) and exploiting the wideband limit from the very beginning. We refer the reader to Ref. \([46]\) for further details.

Because the total Hamiltonian \( H_{\text{tot}} \) is time-independent, the kernel only depends on the difference of its time arguments, \( K(t, s) = K(t - s) \). Using the decomposition (7) we have \( K_L = L \) and the goal is to compute the nonlocal part \( K_N = K^{(1)} + K^{(2)} + \ldots \), where each term \( K^{(n)} \) contains \( n \) tunneling contributions \([\text{Eq. (15)}]\). Because of the bilinear structure of \( H_T \) it follows that all odd orders vanish. The first two nonvanishing orders are then diagrammatically represented by

\[
-iK^{(2)}(t) = \begin{array}{c}
\text{diagram 1} \\
\text{diagram 2}
\end{array}
\]

The diagrams are specifically given by

\[
-iK^{(4)}(t) = \begin{array}{c}
\text{diagram 3} \\
\text{diagram 4}
\end{array}
\]

The \( p \)-th order diagram can be written as

\[
-iK^{(p)}(t) = \begin{array}{l}
\text{diagram } p\text{-th order}
\end{array}
\]

The diagrams \( p \)-th order correspond to \( \gamma_{\sigma_{i} \sigma_{j}}^{p}(t) \), where the \( \gamma_{\sigma_{i} \sigma_{j}}^{p}(t) \) contraction arises due to the wideband limit, which was already incorporated into the definition of the Hamiltonians. As another consequence of this, the time-nonlocal \( \gamma_{\sigma_{i} \sigma_{j}}^{p}(t) \) contractions contains a singularity at \( t = 0 \). Importantly, in App. A we show that the special algebra of the superfermions elegantly ensures that all shown diagrams stay finite nevertheless. There it is explained how the contributions combine to yield convergent time integrals, which can be straightforwardly implemented.

We illustrate the above for a generic set of parameters in Fig. 1(a–b). There we solve the time-nonlocal equation (1) using the numerically computed second and fourth order kernels. Referring to the solutions as \( \rho_{K, \text{bare}}^{(2)}(t) \) and \( \rho_{K, \text{bare}}^{(4)}(t) \) respectively, we plot their trace distance to the exact solution \( \rho_{\text{exact}}(t) \) for the noninteracting case \( U = 0 \) as function of time \( t \) and temperature \( T \). As expected, the quality of each approximation is improved with higher temperature and the fourth order solution \( \rho_{K, \text{bare}}^{(4)}(t) \) has a larger range of validity than \( \rho_{K, \text{bare}}^{(2)}(t) \). At small temperatures the approximations work well only for short times \( T^* \lesssim 1 \) where the infinite-temperature contributions dominate the dynamics. This is also reflected by the more basic check of the complete positivity (CP) of the propagator \( \Pi(t) \), which is violated in the black and gray areas. It can be seen that \( \rho_{K, \text{bare}}^{(2)}(t) \) suffers from unphysical regimes, which become smaller when going to the next order \( \rho_{K, \text{bare}}^{(4)}(t) \). Importantly, when only checking whether the specific output state \( \rho(t) = \Pi(t)\rho_{0} \) is unphysical (non-positive), which is the case in the gray areas, one misses that in the black areas the approximation has already failed, because the propagator does not handle entanglement correctly (non-CP). These latter regimes are thus especially dangerous in practice.

Finally, in Fig. 1(c–d) we show that when turning on the interaction \( U \) the unphysical area of the second order solution \( \rho_{K, \text{bare}}^{(2)}(t) \) increases. This is different for \( \rho_{K, \text{bare}}^{(4)}(t) \) for the chosen parameters: whereas the detailed shape of the unphysical areas do change with interaction, the overall size does not significantly increase.

2. Bare perturbation theory for generator \( \mathcal{G} \)

With the orders of the kernel \( K \) in hand and decomposing \( \mathcal{G} = K_L + G^{(1)} + G^{(2)} + \ldots \) as before our key results \((9)–(10)\) make it straightforward to compute the orders of \( \mathcal{G} \) taking \( K_L = L \). Using our recursive relation (12) it is furthermore straightforward to infer a diagrammatic representation for \( \mathcal{G} \) using only standard diagrams of \( K \) and \( \Pi \). The shorthand \( \Pi_0 = e^{-iLt} \) is defined as

\[
-i\mathcal{G}^{(2)}(t) = \begin{array}{c}
\text{diagram 5} \\
\text{diagram 6}
\end{array}
\]

\[
-i\mathcal{G}^{(4)}(t) = \begin{array}{c}
\text{diagram 7} \\
\text{diagram 8}
\end{array}
\]

Thus, no new technique and no new diagrammatic representation are required. We see that the general structure consists of backward bare propagations \( \Pi_{0}^{\dagger} \) followed by blocks of \( K \) and \( \Pi \), which only propagate forward. This is not unexpected: by the definition of the generator, \( \mathcal{G} = i\Pi\Pi^{-1} \), any expansion for \( \mathcal{G} \) will contain both propagations forward (from \( \Pi \)) and backward (from \( \Pi^{-1} \)).
This is precisely what makes the expansion of $\mathcal{G}$ more complicated than that of $\mathcal{K}$ [Eqs. (24)–(25)].

In Fig. 2 we analyze the trace distance of the time-local approximations to the exact solution in the noninteracting case $U = 0$. We emphasize again that the second and fourth order time-local solutions, $\rho_{\mathcal{G},\text{bare}}^{(2)}(t)$ and $\rho_{\mathcal{G},\text{bare}}^{(4)}(t)$ respectively, will be different from the time-nonlocal solutions of the same order: $\rho_{\mathcal{G},\text{bare}}^{(j)}(t) \neq \rho_{\mathcal{K},\text{bare}}^{(j)}(t)$.

The general characteristics however stay the same: higher temperature improves the quality of the approximations and $\rho_{\mathcal{G},\text{bare}}^{(4)}(t)$ outperforms $\rho_{\mathcal{G},\text{bare}}^{(2)}(t)$. Compared to the time-nonlocal perturbation theory there are however considerable differences: The area where $\rho_{\mathcal{G},\text{bare}}^{(2)}(t)$ is unphysical is noticeably smaller than for $\rho_{\mathcal{K},\text{bare}}^{(2)}(t)$. Furthermore, $\rho_{\mathcal{G},\text{bare}}^{(4)}(t)$ is even physical everywhere in the plotted parameter regime. Surprisingly this is even true for strong interactions, for example of the order $U \approx 10\Gamma$. Notably, neither $\rho_{\mathcal{K},\text{bare}}^{(2)}(t)$ nor $\rho_{\mathcal{K},\text{bare}}^{(4)}(t)$ shows deceptive regimes where the state is positive, but the propagator is nevertheless not completely positive. These observations suggest in a very basic way that for the Anderson model the bare time-local perturbation theory is superior to the time-nonlocal one, even for the strong interaction.

\section{Renormalized perturbation theory}

\subsection{Renormalized perturbation theory for kernel $\mathcal{K}$}

In Eq. (29) the occurrence of the time-local $\delta$ function in the $\gamma_{\eta\sigma}$ contraction hints at a possible simplification. Indeed it is possible to resum all these semigroup contributions systematically as was shown in Ref. [46]. The starting point lies in the observation that the $\gamma_{\eta\sigma}$ contraction vanishes when taking the high-temperature limit.
for all reservoirs, \( \lim_{T \to \infty} \gamma_{\eta \sigma} = 0 \). Then the infinite temperature kernel is exactly given by \( \lim_{T \to \infty} K_N(t) = \Sigma_\infty \delta(t) \) with

\[
\Sigma_\infty := -\frac{i}{2} \sum_{\eta \sigma} \Gamma_{\eta \sigma} G^{\dagger}_{\eta \sigma} G_{\eta \sigma}.
\]

(32)

Thus the time-nonlocal part of the kernel becomes time-local in this limit, from which the exact propagator can be deduced:

\[
\Pi(t) := \lim_{T \to \infty} \Pi(t) = e^{-i(L + \Sigma_\infty)t}.
\]

(33)

Now the main idea is to set up a perturbation theory around the infinite temperature limit. Here the choice of the supervacuum \([0] \) and the associated fields \( G_{\eta \sigma} \) provide the key advantage as follows: One makes two simple changes to the bare perturbation theory of Eqs. (26)-(27) [46]. First, all Liouvillians are replaced by

\[
L \to L_\infty := L + \Sigma_\infty.
\]

(34)

By this step one extracts in Eq. (7) a time-local part \( \Sigma_\infty \) from the reservoir induced dynamics \( K_N \) and incorporates this into \( K_L \), leaving their sum \( K \) unaltered. Second, \( \gamma^+_{\eta \sigma} \) contractions or, equivalently, \( G_{\eta \sigma} \) vertices are no longer allowed. Thus, in the renormalized perturbation theory we have \( K_L = L_\infty \) and

\[
h_{\eta \sigma} = -\sum_{\eta \sigma} \gamma_{\eta \sigma}(t) G^{\dagger}_{\eta \sigma} e^{-i(t-t_1)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}}, \quad (35a)
\]

\[
h_{\eta \sigma} = \sum_{\eta \sigma} \sum_{\eta \sigma} \int_0^t dt_1 \int_0^t dt_2 \gamma_{\eta \sigma}(t) \gamma_{\eta \sigma}^{\dagger}(t_1-t_2) G_{\eta \sigma}^{\dagger} e^{-i(t-t_1)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}}
\]

\[
\times e^{-i(t_1-t_2)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}} e^{-i(t-t_1)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}}, \quad (35b)
\]

\[
h_{\eta \sigma} = -\sum_{\eta \sigma} \sum_{\eta \sigma} \int_0^t dt_1 \int_0^t dt_2 \gamma_{\eta \sigma}(t) \gamma_{\eta \sigma}^{\dagger}(t_1-t_2) G_{\eta \sigma}^{\dagger} e^{-i(t-t_1)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}}
\]

\[
\times e^{-i(t_1-t_2)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}} e^{-i(t-t_1)G_{\eta \sigma}^{\dagger}G_{\eta \sigma}}, \quad (35c)
\]

Notably, the renormalized perturbation theory is at the same time more powerful \textit{and} simpler than the original one: since \( \gamma^+ \) contractions are no longer allowed, there are considerably fewer terms in the renormalized perturbation theory that need to be computed. Moreover, for vanishing interaction \( U = 0 \) it can be shown that the renormalized series terminates and the terms (35a)–(35c) already give the exact kernel for the Anderson dot [46].

Compared to the bare perturbation theory the intermediate propagations between vertices are damped on a timescale of the bare tunnel rate \( \sim \Gamma^{-1} \) [Eq. (32)], which leads to improved convergence in the time integrations. Since this is the largest rate of decay, the higher order corrections of the renormalized perturbation theory are needed for smaller rates, i.e., they must effectively suppress decay. One thus expects that in the lower orders of this perturbation theory the oscillations described by \( L \) are damped.

For the explored parameters, we find that even for strong interactions the renormalized fourth order solution \( \rho^{(4)}_{K,\Delta} \) always stays physical (same parameters as in Fig. 3 (d), data not shown). This is however not the case for the second order renormalized solution \( \rho^{(2)}_{K,\Delta} \), which becomes unphysical at low temperatures, even for \( U = 0 \) (data not shown). Larger interaction has a negative impact on the positivity of \( \rho^{(2)}_{K,\Delta} \).

In Fig. 3 (a,c,f) we see that overall compared to the bare \( K \) perturbation theory the renormalized version replaces oscillatory behavior occurring off resonance (\( \epsilon \gtrsim \Gamma \)) at low \( T \lesssim \Gamma \) by a rapid decay to the stationary value. We discuss the details in the next section.
2. Renormalized perturbation theory for generator $G$

We now set up a corresponding approach for the time-local generator, which to our knowledge has not been explored yet. The renormalized expansion of $K$ can be translated to the generator $G$ using the same steps as for the bare $G$ expansion [Eqs. (30)–(31)]. Compared to Eqs. (30)–(31) one now uses the renormalized $K$ and $\Pi$ diagrams, where only $G_{n\sigma}^{\sigma}$ vertices are allowed and the renormalization $L \rightarrow L_{\infty} = L + \Sigma_{\infty}$ is made. Importantly, one thus also needs to replace the backward evolutions by

$$\Pi_{0}^{\uparrow}(t) = e^{iLt} \rightarrow e^{iL_{\infty}t} = \Pi_{\infty}^{\downarrow}(t). \tag{36}$$

For the $U = 0$ limit this implies that because the renormalized series for $K$ terminates at fourth order to give the exact result, the fourth order generator $G = L_{\infty} + G_{\text{ren}}^{(2)} + G_{\text{ren}}^{(4)}$ is also exact at $U = 0$. Surprisingly however, it turns out that at $U = 0$ the fourth order contribution also vanishes, $G_{\text{ren}}^{(4)} = 0$, which we verify in App. B. Thus, we conclude that the leading-order renormalized generator $G = L_{\infty} + G_{\text{ren}}^{(2)}$ is already exact for $U = 0$, one order lower then for the memory kernel $K = L_{\infty} + K_{\text{ren}}^{(2)} + K_{\text{ren}}^{(4)}$.

In Fig. 3 we compare the different fourth order methods. In Fig. 3(a) we show results at low temperature $T < \Gamma$ and small interaction $U < \Gamma$. We see that the renormalized solutions coincide, but clearly differ from the bare solutions, which are distinct. Initially the bare solutions also coincide (up to $t\Gamma \simeq 1$) and decay like the renormalized ones, but at a smaller rate. They then start to oscillate while their renormalized counterparts have already reached their stationary values. The stationary values are similar for all methods. We focused on the off resonant case $\epsilon > \Gamma > U \simeq T$ since here the fourth order corrections are important, also in the renormalized methods.

In Fig. 3(b) we verify that at the symmetry point $\epsilon = -U/2$ the occupations converge to the same stationary value $n_{1} = n_{1} = \frac{1}{2}$ as they should by symmetry. However, the bare $K$ solution predicts an oscillation, which is not predicted by the other methods. By contrast, the bare $G$ method agrees with the renormalized methods showing no oscillations, even though $U = 10\Gamma$ is rather large.

It is thus interesting to consider less constrained parameters with detuning $\epsilon \gtrsim \Gamma$ in the tail of the resonance. For $U > \Gamma$ we find that at high temperature, $T > 5\Gamma$, all methods coincide for these parameters. However, in Fig. 3(c) we see that already for $T = 2\Gamma$ the renormalized $G$ method predicts a different stationary occupation.

When lowering the temperature further in Fig. 3(d) we see that all methods after the initial rise predict decay ($t\Gamma \gtrsim \frac{1}{2}$), except that the renormalized $G$ method gives a larger rate. Whereas the renormalized $K$ method reaches stationarity after this, all other methods show similar overdamped oscillations. Because for the renormalized $G$ method the initial decay is slower and last longer, this oscillation is out of phase with the other ones. Furthermore, it can be seen that every method predicts a different stationary value.

This picture persists when temperature is lowered further in Fig. 3(e)-(f). The above mentioned damped oscillations grow, whereas the renormalized $K$ method further reduces the stationary value without introducing oscillations. The renormalized $G$ method instead features pronounced oscillations with a visible second harmonic and an approximately $\frac{\pi}{2}$ phase shift. At $T = 0$ the oscillations of the bare solutions even show negative damping, diverging at long times. This means that one of the complex frequency poles of the propagator has moved into the unphysical part of the complex plane $[8]$ and the stationary state is never reached.

The fact that the oscillations in Fig. 3(e)-(f) don’t quickly decay for the renormalized $G$ method may seem surprising at first, since the renormalized propagator $\Pi_{\infty}$ [Eq. (33)] overdamps oscillatory contributions to the dynamics as mentioned earlier. However, this is counteracted by insisting on a time-local formulation of the renormalized approach. This is immediately clear from our central result Eq. (9)-(11): in a renormalized expansion with decaying free reference evolution the partial backward time integration will partially undo this decay.

Another way of seeing that time locality is the problem here, is by considering the formal definition of the generator $G = i\Pi^{-1}$. In order to obtain any perturbative series for $G$ it is necessary to expand the inverse propagator $\Pi^{-1}$. For the renormalized expansion Eqs. (9)-(11) this involves expanding

$$\Pi^{-1} = \left[\Pi_{\infty} + \Pi_{\text{ren}}^{(2)} + \Pi_{\text{ren}}^{(4)} + \cdots\right]^{-1} \tag{37}$$

$$= \Pi_{\text{ren}}^{-1} - \Pi_{\text{ren}}^{(2)}\Pi_{\text{ren}}^{-1} + \cdots. \tag{38}$$

Since $\Pi_{\infty}$ contains oscillating and decaying contributions (from $L$ and $\Sigma_{\infty}$ respectively [Eq. (33)]), it follows that $\Pi_{\text{ren}}^{(2)}$ is exponentially increasing in time. However, the geometric series is only guaranteed to converge if

$$\left\Vert\Pi_{\text{ren}}^{(2)} + \Pi_{\text{ren}}^{(4)} + \cdots\right\Vert < 1. \tag{39}$$

Because $\Pi_{\text{ren}}^{(2)} + \Pi_{\text{ren}}^{(4)} + \cdots$ converges to a stationary (non-zero) value $\Pi_{\text{ren}}^{(2)}(\infty) + \Pi_{\text{ren}}^{(4)}(\infty) + \cdots$ condition (39) is violated after a short time and the time local generator becomes problematic. Note carefully that only for $U = 0$ no problems arise with the renormalized $G$, because higher order corrections are identically zero by the algebraic structure of the model [App. B] and convergence of $G$ is not an issue. By contrast, in the bare perturbation theory for $G$ discussed in Sec. III C 2 this problem did not occur, because the unitary reference evolution $\Pi_{\text{ref}}^{(2)}$ is always bounded. This shows that the application of renormalized perturbation expansions is much more subtle in the time-local framework than in the time-nonlocal one. This seems to be a generic problem of any
perturbative expansion of $\mathcal{G}$ around a reference solution that already incorporates some dissipative/decaying behavior. This is, however, a key idea behind renormalization strategies for open system [5, 8, 10–12], which through their use of the kernel $\mathcal{K}$ suffer no such failure. It remains an intriguing open question whether similar schemes can be developed for $\mathcal{G}$.

IV. SUMMARY

We have shown that the recently discovered [42] fixed-point relation (5) between the memory kernel $\mathcal{K}$ and the generator $\mathcal{G}$ implies a recursive relation between time-local and time-nonlocal perturbation series based on the common expansion reference $\mathcal{K}_{\text{L}}$. This relation can be exploited to set up calculations of these quantities irrespective of the chosen technique (diagrammatics, projection operators, etc.). Importantly, it allows for an unbiased comparison of the different approximations that result when performing the same expansion in a time-local or time-nonlocal picture, independent of model specifics. The flexibility in the choice of expansion reference $\mathcal{K}_{\text{L}}$ allows to compare bare expansions with renormalized ones.

For the bare expansion ($\mathcal{K}_{\text{L}} = L = [H, \mathbf{1}]$) discussed in Sec. III C, we developed a diagrammatic technique for computing the time-local generator $\mathcal{G}$, in close analogy to the well-developed technique for the memory kernel $\mathcal{K}$. Judging by the very basic criterion of legitimacy of the approximate propagator (complete positivity), performing the expansion in the time-local formulation leads to a better behaved solution in application to strongly interacting open systems than performing the corresponding expansion in the time-nonlocal one. Combined with its inherent advantages in addressing questions related to non-Markovianity [22–26] and quantum information, this suggests that the time-local approach made more accessible here via the standard time-nonlocal one can be a useful alternative to the existing time-local methods [13, 54–59]. We also note that for the time evolution
of transport observables – measured outside the system – similar memory kernels can be calculated using the same standard techniques [5, 8]. The present paper also provides a starting point for transposing these techniques to the time-local calculation of transport observables.

For the renormalization expansion \( \mathcal{K}_L = L + \Sigma_\infty \) that we additionally developed in Sec. III D this advantage of \( \mathcal{G} \) over \( \mathcal{K} \) at first seems to be confirmed. Expanding about the infinite temperature limit, we found that in the time-local framework the non-interacting Anderson dot is exactly solved by the leading order result, one order lower than in the time-nonlocal framework. However, in the presence of interaction the unbounded growth of the dissipative backward evolution with time leads to problems. We noted that the expansion of the inverse propagator, implicitly required by the expansion of the timelocal generator is questionable on times of the order of the inverse decay rate \( \Gamma^{-1} \).

As explained at the end of Sec. II, the versatile fixed-point equation of Ref. [42] may provide an additional route to a renormalized time-local approach: Noting that the renormalized time-nonlocal approach allows to obtain an approximate time-local generator \( \mathcal{G}_{\text{sc}} \), which self-consistently accounts for the backward evolutions. This provides a simplification different from the truncated renormalized approach to \( \mathcal{G} \) explored here, which follows the traditional approach of expanding \( \mathcal{G} \) itself. Overall, we thus illustrated how the fixed-point relation can be used to transpose standard memory kernel techniques to the interesting but more challenging time-local framework. Our systematic comparison of the time-local and time-nonlocal framework highlighted their complementary merits and limitations, underscoring the importance of improving our understanding of the connection between these canonical approaches to open-system dynamics.

We thank V. Bruch, J. Schuenlenborg and B. Vacchini for useful discussions. K.N. acknowledges support by the Deutsche Forschungsgemeinschaft (RTG 1995).

**Appendix A: Well-definedness of the perturbation theory in second and fourth order**

It is at first unclear whether the diagrams in Eqs. (26)–(27) and Eqs. (35a)–(35b) of the bare and renormalized \( \mathcal{K} \) perturbation theory respectively are actually well defined because of the singularity in the contraction function \( \gamma_{\sigma \bar{\sigma}}(t) \) [Eq. (29)] at \( t = 0 \). This arises because we have taken the bandwidth limit from start. In Ref. [49] the bandwidth dependence was discussed [Eq. (75)–(76) loc. cit.] in the frequency representation but not in the time-representation used here. Here we specifically show the finiteness of the renormalized perturbation theory up to fourth order using corresponding arguments. By replacing \( L_\infty \rightarrow L \) everywhere the exact same steps establish the finiteness of the bare perturbation theory. First note that \( \gamma_{\sigma \bar{\sigma}}(t) \) diverges as \( 1/t \) for \( t \to 0 \), in particular

\[
\lim_{t \to 0} \gamma_{\sigma \bar{\sigma}}(t) = -i \sum_r \frac{\Gamma_{r \sigma}}{\pi}.
\]

However, because the superfermion superoperators anticommute [Eq. (19)] we have

\[
\sum_{\eta} \gamma_{\eta \sigma}(t)G_{\eta \sigma}^+G_{\eta \sigma}^- = \frac{1}{2} \sum_{\eta} [\gamma_{\eta \sigma}(t)G_{\eta \sigma}^+G_{\eta \sigma}^- + \gamma_{\eta \sigma}(t)G_{\eta \sigma}^-G_{\eta \sigma}^+] = \frac{1}{2} \sum_{\eta} [\gamma_{\eta \sigma}(t)G_{\eta \sigma}^+G_{\eta \sigma}^- - \gamma_{\eta \sigma}(t)G_{\eta \sigma}^-G_{\eta \sigma}^+] = \frac{1}{2} \sum_{\eta} [\gamma_{\eta \sigma}(t) - \gamma_{\eta \sigma}(t)] G_{\eta \sigma}^+G_{\eta \sigma}^-= 0.
\]

As explained at the end of Sec. II, the versatile fixed-point equation of Ref. [42] may provide an additional route to a renormalized time-local approach: Noting that the renormalized time-nonlocal approach allows to obtain an approximate time-local generator \( \mathcal{G}_{\text{sc}} \), which self-consistently accounts for the backward evolutions. This provides a simplification different from the truncated renormalized approach to \( \mathcal{G} \) explored here, which follows the traditional approach of expanding \( \mathcal{G} \) itself. Overall, we thus illustrated how the fixed-point relation can be used to transpose standard memory kernel techniques to the interesting but more challenging time-local framework. Our systematic comparison of the time-local and time-nonlocal framework highlighted their complementary merits and limitations, underscoring the importance of improving our understanding of the connection between these canonical approaches to open-system dynamics.
This is because the outer contraction $\gamma_{\eta_1\sigma_1}(t)$ diverges as $1/t$, but the inner integrals $\int_0^t dt_1 \int_0^{dt_1} dt_2 \cdots = \mathcal{O}(t^2)$ vanish quadratically. To see the well-definedness of the other fourth order diagram we decompose it as

$$F_1(t) = F_1(t) + F_2(t), \quad (A14)$$

$$F_1(t) := -\sum_{\eta_1 \eta_2 \sigma_2} \int_0^t dt_1 \int_0^{t_1} dt_2 \gamma_{\eta_1\sigma_1}(t-t_2) \gamma_{\eta_2\sigma_2}(t_1)$$

$$\times G^+_{\eta_2\sigma_2} e^{-iL_{\infty}}(t-t_1) G^+_{\eta_2\sigma_2}$$

$$\times \left[ e^{-iL_{\infty}(t_1-t_2)} - I \right] G^+_{\eta_1\sigma_1} e^{-iL_{\infty}t_2} G^+_{\eta_2\sigma_2}, \quad (A15)$$

$$F_2(t) := -\sum_{\eta_1 \eta_2 \sigma_2} \int_0^t dt_1 \int_0^{t_1} dt_2 \gamma_{\eta_1\sigma_1}(t-t_2) \gamma_{\eta_2\sigma_2}(t_1)$$

$$\times G^+_{\eta_1\sigma_1} e^{-iL_{\infty}(t-t_1)} G^+_{\eta_2\sigma_2} G^+_{\eta_1\sigma_1} e^{-iL_{\infty}t_2} G^+_{\eta_2\sigma_2}. \quad (A16)$$

The first contraction $\gamma_{\eta_1\sigma_1}(t-t_2)$ in $F_1(t)$ diverges if $t_2 \to t$. But in this limit the factor $e^{-iL_{\infty}(t_1-t_2)} - I$ vanishes with $\mathcal{O}(t_1-t_2)$ because of the time ordering $t \geq t_1 \geq t_2$. Therefore the divergence in $\gamma_{\eta_1\sigma_1}(t-t_2)$ is always regularized. The second contraction $\gamma_{\eta_2\sigma_2}(t_1)$ in $F_1(t)$ diverges for $t_1 \to 0$, which is regularized by the inner integral $\int_0^t dt_2 = \mathcal{O}(t_1)$. Hence $F_1(t)$ is always finite. In the second term $F_2(t)$ one first uses the anticommutation $G^+_{\eta_2\sigma_2} G^+_{\eta_1\sigma_1} = -G^+_{\eta_1\sigma_1} G^+_{\eta_2\sigma_2}$. Note again that in the limit $t_2 \to t$ we also have $t_1 \to t$ because of the time ordering. This means that the factor

$$\gamma_{\eta_1\sigma_1}(t-t_2) G^+_{\eta_1\sigma_1} e^{-iL_{\infty}(t-t_1)} G^+_{\eta_1\sigma_1}, \quad (A17)$$

is always finite for $t_2 \to t$ following the same argument which established that Eq. (A10) has the finite limit

$$\gamma_{\eta_1\sigma_1}(t_1) G^+_{\eta_2\sigma_2} e^{-iL_{\infty}t_2} G^+_{\eta_2\sigma_2}. \quad (A18)$$

is finite for $t_1 \to 0$. Therefore $F_2(t)$ is also always finite, establishing the well-definedness of this last diagram.

**Appendix B: Exact generator at $U = 0$**

Here we show that the renormalized second order generator $G = L_{\infty} + G^{(2)}_{\text{ren}}$ is already exact in the noninteracting case by showing that the fourth order correction is identically zero, $G^{(4)}_{\text{ren}} = 0$, by a nontrivial cancellation of terms. To do so we split up the fourth order renormalized generator into two contributions

$$-iG^{(4)}_{\text{gen}}(t) = A_1(t) - A_2(t), \quad (B1)$$

$$A_1(t) := \sum_{\eta_1 \eta_2 \sigma_2} \int_0^t dt_1 \int_0^{t_1} dt_2 \gamma_{\eta_1 \sigma_1}(t-t_2) \gamma_{\eta_2 \sigma_2}(t_1)$$

$$\times G^+_{\eta_2 \sigma_2} e^{-iL_{\infty}(t_1-t_2)} G^+_{\eta_2 \sigma_2}$$

$$\times \left[ e^{-iL_{\infty}(t_1-t_2)} - I \right] G^+_{\eta_1 \sigma_1} e^{-iL_{\infty}t_2} G^+_{\eta_2 \sigma_2}, \quad (B2)$$

$$A_2(t) := \sum_{\eta_1 \eta_2 \sigma_2} \int_0^t dt_1 \int_0^{t_1} dt_2 \gamma_{\eta_1 \sigma_1}(t-t_2) \gamma_{\eta_2 \sigma_2}(t_1)$$

$$\times G^+_{\eta_1 \sigma_1} e^{-iL_{\infty}(t-t_1)} G^+_{\eta_2 \sigma_2} G^+_{\eta_1 \sigma_1} e^{-iL_{\infty}t_2} G^+_{\eta_2 \sigma_2}. \quad (B3)$$

$$A_1(t) = \frac{1}{\Pi_{\infty}^{-1}}, \quad (B4)$$

$$A_2(t) = \frac{1}{\Pi_{\infty}^{-1}}, \quad (B5)$$

and show that $A_1(t) = A_2(t)$. The main simplification for $U = 0$ is that the renormalized free Liouvillian $L_{\infty}$ and the superfermions satisfy the commutation relation

$$\left[ L_{\infty}, G^+_{\eta \sigma} \right] = \left( \eta \epsilon - \frac{i}{2} \sum_r \Gamma_{r \sigma} \right) G^+_{\eta \sigma}, \quad (B6)$$

see Eq. (118) in Ref. [46]. From this it follows that

$$G^+_{\eta \sigma}(t) := e^{iL_{\infty}t} G^+_{\eta \sigma} e^{-iL_{\infty}t} \quad (B7)$$

$$= e^{\left( \eta \epsilon + \frac{1}{2} \sum_r \Gamma_{r \sigma} \right) t} G^+_{\eta \sigma}. \quad (B8)$$

These transformed superfermions still anticommute \{ $G^+_{\eta_1 \sigma_1}(t_1), G^+_{\eta_2 \sigma_2}(t_2)$ \} = 0. We now rewrite $A_1(t)$ using the $G^+_{\eta \sigma}$ as
By comparison we thus see that

\[
A_1(t) = e^{-iL_\infty t} \int dt_1 dt_2 dt_3 \left[ \gamma_{n_1 \sigma_1}(t-t_3) \gamma_{n_2 \sigma_2}(t_1-t_2) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) \right. \\
+ \gamma_{n_1 \sigma_1}(t-t_2) \gamma_{n_2 \sigma_2}(t_1-t_3) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) \\
\left. e^{iL_\infty t} \right] (B9)
\]

\[
e^{-iL_\infty t} \int dt_1 dt_2 dt_3 \left[ \gamma_{n_1 \sigma_1}(t-t_3) \gamma_{n_2 \sigma_2}(t_1-t_2) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) \right. \\
+ \gamma_{n_1 \sigma_1}(t-t_2) \gamma_{n_2 \sigma_2}(t_1-t_3) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) \\
\left. e^{iL_\infty t} \right] (B10)
\]

\[
e^{-iL_\infty t} \int dt_1 dt_2 dt_3 \left[ \gamma_{n_1 \sigma_1}(t-t_3) \gamma_{n_2 \sigma_2}(t_1-t_2) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) e^{iL_\infty t} \right] (B11)
\]

From Eq. (B9) to Eq. (B10) we used the anticommutation property of the \(G'_{\sigma} \). From Eq. (B10) to Eq. (B11) we relabeled the integration variables in the first term as \( t_1 \to t_2 \to t_3 \to t_1 \) and in the second term as \( t_1 \leftrightarrow t_2 \). But for \( A_2(t) \) we have similarly

\[
A_2(t) = e^{-iL_\infty t} \int dt_1 dt_2 dt_3 \gamma_{n_1 \sigma_1}(t-t_1) \gamma_{n_2 \sigma_2}(t_2-t_3) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) e^{iL_\infty t} (B13)
\]

\[
e^{-iL_\infty t} \int dt_1 dt_2 dt_3 \gamma_{n_1 \sigma_1}(t-t_1) \gamma_{n_2 \sigma_2}(t_2-t_3) G'_{n_1 \sigma_1}(t_1) G'_{n_2 \sigma_2}(t_2) G'_{n_3 \sigma_3}(t_3) e^{iL_\infty t} (B14)
\]

By comparison we thus see that \( A_1(t) = A_2(t) \). Hence \( \mathcal{G}^{(4)}_{\text{ren}} = 0 \).
