This letter presents an analytical framework to study the distortion effect of power amplifiers (PA) in a single-stream millimetre wave (mmWave) system with a radio-frequency beamforming architecture. A third-order nonlinearity PA model is used. The impact of PA nonlinearity on the transmitter performance is evaluated by means of its normalised mean square error. Also, the effect of PA compression on the system capacity in a line-of-sight channel is analysed. All analytical results are supported with Monte-Carlo simulations.

Introduction: In recent years millimetre wave (mmWave) communication has gained significant research interest. It is regarded as a pivotal technology to accommodate high data rates [1]. Although able to support high capacities thanks to large bandwidths, the mmWave frequencies exhibit a high path loss. Therefore, mmWave transceivers employ large phased-arrays to generate beamforming gains and to improve the link budget [2]. In addition, high capacities and large bandwidths pose stringent requirements, among others, on the tolerable amount of radio-frequency (RF) impairments.

The number of papers studying the effects of RF impairments on the performance of a single-stream mmWave RF beamforming system is sparse. The influence of phase noise and different local-oscillator (LO) architectures on the performance of mmWave systems with RF and hybrid beamforming architectures is investigated in [4]. For the former, an upper bound of capacity in a non-line-of-sight (NLOS) channel is provided. In [5], the influence of both transmitter and receiver residual distortion noises in a single-stream mmWave RF beamforming system is studied. The authors employ an equivalent single antenna model to derive a closed-form expression for ergodic capacity in both LOS and NLOS channels. While, in the latter systems, the effects of phase noise or IQ mismatch can be analysed similarly to a single antenna system, the same approach cannot be straightforwardly applied to the power amplifier (PA) compression effects. The main reason is that the signals in the branches of an antenna array cannot be considered uncorrelated.

Therefore, in this letter, we study the impact of PA nonlinearity in a multi-antenna system employing an RF beamforming transceiver architecture. Such an architecture is typical for mmWave transceivers. Using a third-order nonlinearity model, we investigate the effect of PA compression on transmitter performance. Furthermore, the same effect on the capacity of the system in an LOS channel is assessed.

A PA distortion-aware transmitter model: A block diagram of a mmWave phased-array transmitter is shown in Figure 1. The transmitter employs an RF beamforming architecture, having \( N_t \) antenna branches so that each branch comprises a phase shifter and a power amplifier. Furthermore, we assume that the signal at the input of the transmitter \( s \) is a zero-mean circular complex-Gaussian random variable with variance \( \mathbb{E}[s] = 0, \mathbb{E}[s^2] = \sigma_s^2 \). Note that this assumption holds for orthogonal frequency division multiplexing (OFDM) modulated signals. For beamforming, the transmitter employs a transmit beamforming vector \( f \) having the unit norm.

\[
\mathbf{f} = \left[ f_0 \ f_1 \ ... \ f_{N_t-1} \right]^T = \frac{1}{\sqrt{N_t}} \left[ 1 \ e^{j\phi} \ ... \ e^{j(N_t-1)\phi} \right]^T
\]  

where \( f_l = e^{j\phi_l}/\sqrt{N_t} \) with \( \phi \) being a phase shift. The factor \( N_t^{-1/2} \) allows \( \mathbf{f} \) having the unit norm.

The transmitted signal is given by

\[
x(t) = \sqrt{P} \mathbf{f}^H \mathbf{s} + \mathbf{n}_t,
\]

where \( \mathbf{s} = [s_0 \ s_1 \ ... \ s_{N_t-1}]^T \) is the transmitted signal vector, \( P \) is the total transmitted power, and \( \mathbf{n}_t = [n_0 \ n_1 \ ... \ n_{N_t-1}]^T \) is the thermal white noise vector.

The transmitter is driven by the signal \( s \), being first ideally up-converted, and then (power) divided into \( N_t \) copies, such that each copy feeds one branch of the phased-array. The input signal of the \( l \)-th branch is

\[
u_l(t) = \frac{\sqrt{P}}{\sqrt{N_t}} \mathbf{f}^H \mathbf{s} + \mathbf{n}_t,
\]

Hence, \( \mathbf{n}_t \sim \mathcal{CN}(0, \sigma_n^2) \). The signal \( v_l \) is then shifted in phase, yielding the signal \( v_l(t) = u_l(t) e^{j\phi_l} \), such that \( v_l = f l s \). Note that \( f_l \) is also a zero-mean circular complex-Gaussian random variable, having the same variance as \( u_l \), i.e. \( \mathbb{E}[v_l] = 0, \mathbb{E}[v_l^2] = \sigma_v^2 = \sigma_u^2/N_t \) [6].

After the phase shifting process, the signal \( v_l \) drives a PA yielding the output

\[
y_l = r(v_l) + n_l
\]

where \( r(\cdot) \) represents a nonlinear function used to describe PA nonlinearity (i.e. compression). The second term describes the output thermal noise that can be modelled as a zero-mean circular-Gaussian random variable with variance \( \mathbb{E}[n_l n_l^*] = \sigma_n^2 \).

Using Busgang’s theorem [8], the output of a circuit exhibiting nonlinearity can be expressed as a sum of the attenuated input signal replica and the distortion noise \( d_l \)

\[
y_l = \alpha v_l + d_l
\]

where \( \alpha \) is the PA compression parameter. Owing to [7], the 1-dB compression point is approximately equal to \( \sigma_v^2/\alpha^2 \approx 0.056/\alpha^2 \) or \( \sigma_v^2/\alpha^2 \approx 0.056/\alpha^2 \). From (3) and (4), the Busgang’s attenuation factor \( \alpha \) can be derived as

\[
\alpha = \frac{\mathbb{E}[v_l v_l^*]}{\mathbb{E}[v_l v_l^*]} = 1 + 2 \rho \mathbb{E}[v_l v_l^*] = 1 + 2 \rho \frac{\sigma_v^2}{N_t}
\]

The variance of the \( l \)-th branch distortion noise \( d_l \) can be expressed as

\[
\sigma_{d_l}^2 = \mathbb{E}[d_l d_l^*] = 2 \rho^2 \mathbb{E}[v_l v_l^*] = 2 \rho^2 \frac{\sigma_v^2}{N_t}
\]

For other PA models (SEL, TWTA, SSPA or memoryless polynomial), the attenuation factor and the variance of distortion noise can be found in [10–13]. The distortion noises between branches of the beamforming transceiver, which is a reasonable assumption for chip-integrated beamformers. For the above-mentioned PA model, the input-output relationship reads

\[
r(v_l) = v_l + r(v_l)
\]

\[
\mathbb{E}[r(v_l v_l^*)] = 2 \rho^2 \mathbb{E}[v_l v_l^*] = 2 \rho^2 \frac{\sigma_v^2}{N_t}
\]

Clearly, the correlation coefficient \( \rho \) has a unit-magnitude and phase \( \angle \zeta = \angle(1 - k) \phi \). Finally, by combining all the aforementioned, the signal emitted from the \( l \)-th antenna can be written as

\[
x_l = \frac{\alpha}{\sqrt{N_t}} e^{j\phi_l} s + d_l + n_l = \alpha f_l s + d_l + n_l
\]
and the total (power combined) transmitted signal reads
\[ x = a_0 \beta + \Delta + n, \]
where \( \Delta = [\delta_0, \delta_1, \ldots, \delta_{N-1}]^T \) is the distortion noise vector with covariance matrix given as \( \mathbb{E}[\Delta \Delta^H] = 2 \beta^2 \sigma_n^2 N^{-1} \mathbf{I} \). The variance of the transmitter noise vector is \( \mathbb{E}[n_n n_n^H] = \sigma_n^2 \mathbf{I}_N \). In the ideal case (no PA impairments), the signal reads \( x = f_0 \).

**NMSE of the transmitter:** The performance of a phased-array transmitter under PA impairments is evaluated by means of the normalised mean squared error (NMSE). The NMSE \( \beta \) of the \( l \)-th branch is defined as [7]
\[ \text{NMSE}_l \triangleq \frac{\mathbb{E}[e_l^2]}{\mathbb{E}[x_l x_l^H]} = N \sigma_n^2 \frac{\sigma_l^2}{\sigma_c^2} \]
where \( \sigma_l^2 \) is the variance of the error \( e_l = x_l - x_{l,i} = (\alpha - 1) f_s + \delta_l + n_l \) and \( \sigma_c^2 \) is the variance of the ideally transmitted signal. After finding the power of each term in the error signal, it can be shown that the final expression takes the following form
\[ \text{NMSE}_l = 2 \beta^2 \sigma_n^2/N + N \sigma_n^2 \sigma_l^2 = 2 \beta^2 N^{-1} \sigma_c^2 + N \text{SNR}^{-1} \]
where \( \text{SNR} = \sigma_c^2/\sigma_n^2 \) denotes the transmitter signal-to-noise ratio (SNR). Similar to [9], the optimal signal power, which minimises the NMSE, is found as
\[ \sigma_c^2 = \arg \min \text{NMSE}_l = N \sigma_n^2 / 12 \beta^2 \]
The NMSE in (11) can be related to the error-vector magnitude (EVM) as follows \( \text{EVM}^2 = \text{NMSE}_l \). The EVM is another figure of merit used to quantify the quality of an RF transceiver.

**Capacity:** Next, we investigate the impact of PA distortion noise on capacity. We assume that the communication takes place in an LOS channel, with the channel matrix expressed as
\[ \mathbf{H} = \mathbf{f}_a(\phi) \mathbf{a}(\phi) \]
where \( \mathbf{H} \) is the channel vector expressed as the receive beamforming vector aligned with AoD and AoA, then
\[ \eta = \frac{1}{N} \left( \frac{\sin \left( \frac{\pi \delta - \phi_N}{2} \right)}{\sin \left( \frac{\pi \delta - \mu_N}{2} \right)} \right)^2, \quad \eta = \frac{1}{N} \left( \frac{\sin \left( \frac{\pi \delta - \phi_N}{2} \right)}{\sin \left( \frac{\pi \delta - \mu_N}{2} \right)} \right)^2 \]
If AoA (or AoD) is uniformly distributed in the azimuth range of interest, it was shown in [5] that the expected value of the Fejer kernels can be approximated to 0.77935.

Finally, the capacity is obtained as \( C = \log_2 (1 + \text{SNDR}) \). It is maximised when \( \text{SNDR} \) in (18) has its maximum; the optimal power is found by
\[ \sigma_c^2 = \arg \max \text{SNDR} \]

The final expression is cumbersome and thus omitted, but it can be obtained using a symbolic solver, e.g. Mathematica. Another way to solve (20) is a one-dimensional numerical search. Having the optimal power signal \( \sigma_c^2 \), the optimal capacity is given by
\[ C_{\text{opt}} = \log_2 \left( 1 + \text{SNDR} \left( \sigma_c^2 \right) \right) \]
It should be noted that the capacity \( C \) can be zero when \( \sigma_c^2 = N_t/|\beta|^2 \).

Besides, it can be shown that, in the high power region (\( \sigma_c^2 \gg N_t/|\beta|^2 \)), \( \text{SNDR} \) tends to 2 and the capacity approaches \( C_{\text{eq}} = \log_2(3) \approx 1.59 \) b/s in 1 Hz of bandwidth. This behaviour is due to the nature of the used PA model.

**Numerical results:** A numerical example illustrates the effects of PA compression on the system performance. For that purpose, the compression parameter is set to \( \rho = 0.05 \), and the transmitter noise power is \( -50 \) dBm. The former can be obtained from large-signal gain parameters such as the third-order intercept and 1-dB compression points. The latter can be calculated from the output noise power spectral density integrated over channel bandwidth. For example, assuming a 2 GHz wide channel (e.g. in the 60 GHz band) and an optimistic output noise spectral density of \(-143 \) dBm/Hz, the noise power equals \(-50 \) dBm. We set \( D = 10 \) m and \( \lambda = 5 \) mm. The noise power is calculated as \( \sigma_n^2 = FkTB \) where \( F = 10 \) denotes the noise factor, \( k = 1.38 \times 10^{-23} \text{ J/K} \), \( T = 290 \text{ K} \) and \( B = 2 \) GHz. Moreover, we consider an equal number of antennas at both transmitter and receiver \( N_t = N_r = 16 \) [32, 64]. Besides, we set \( \sigma_f^2 = N_t/|\beta| \) to keep \( \| \mathbf{H} \|_2 = N_t \). We performed 10\(^3\) simulations per curve.

The NMSE of a single branch of the phased-array transmitter is shown in Figure 2. There is an optimal signal power that minimises the NMSE, which equals 0.45, 3.46, 6.47 dBm for \( N = 16, 32, 64 \), respectively. The optimal power increases when larger arrays are employed. Also, when the transmitter operates with higher signal powers \( \sigma_c^2 \), e.g. in the 1-dB compression region, the NMSE performance deteriorates.

The influence of PA compression on capacity is depicted in Figure 3. There is an optimal signal power that maximises the capacity, and this power is independent of the array size \( N \). Moreover, the capacity-optimal signal power is higher than the NMSE-optimal signal power, as shown in Figure 3, and is located in the 1-dB compression region (more precisely, in this example, near 1-dB compression point for \( N = 16 \), \( \approx 12.5 \) dBm). Hence, when the NMSE-optimal beamforming transmitter is used, the maximum system capacity is not reached. This means, in other words, that both figures of merit are not simultaneously optimised. In Figure 3,
we also compared the case when both transmitter and receiver can perfectly align their beams with respect to the channel AoD and AoA (solid curves) to the case when both have a finite number of beamforming directions (dashed curves), which would be the case in practice. To illustrate the difference, we employed an $N$-DFT beambook. In the latter case, the capacity has a "pulse-like" shape, which broadens and grows with bigger $N$ (because of higher beamforming gain). For $N = 64$, it reaches a peak of around 0.7 b/s in 1 Hz. In the high power region, the curves almost overlap, and the loss drops because of the dominant effect of PA compression.

**Conclusion**: We have derived some results on the effects of PA nonlinearity in mmWave phased-array systems employing a RF beamforming architecture. The transmitter has been analysed in terms of NMSE performance. The outcome implies, there is an optimal signal power for minimal NMSE, dependent on the array size. Furthermore, the impact of PA compression on the capacity performance has been investigated, showing an optimal signal power maximises the capacity but it differs from the optimal point for the NMSE. Hence, increasing the transmitter output power by a limited amount beyond the optimum NMSE point, can be useful to achieve higher or even optimum system capacity. Finally, we see the derived analytical expressions as a useful tool to evaluate the performance of phased-array systems under consideration of PA compression and to balance various parameters and design aspects effectively.
