ABSTRACT

GRB 050911, discovered by the Swift Burst Alert Telescope, was not seen 4.6 hr later by the Swift X-ray Telescope, making it one of the very few X-ray non-detections of a Gamma-Ray Burst (GRB) afterglow at early times. The γ-ray light-curve shows at least three peaks, the first two of which (∼T\textsubscript{0} – 0.8 and T\textsubscript{0} + 0.2 s, where T\textsubscript{0} is the trigger time) were short, each lasting 0.5 s. This was followed by later emission 10–20 s post-burst. The upper limit on the unabsorbed X-ray flux was 1.7 × 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1} (integrating 46 ks of data taken between 11 and 18 September), indicating that the decay must have been rapid. All but one of the long bursts detected by Swift were above this limit at ∼4.6 hr, whereas the afterglows of short bursts became undetectable more rapidly.

Deep observations with Gemini also revealed no optical afterglow 12 hr after the burst, down to \textit{r} = 24.0 (5\sigma limit). We speculate that GRB 050911 may have been formed through a compact object (black hole-neutron star) merger, with the later outbursts due to a longer disc lifetime linked to a large mass ratio between the merging objects. Alternatively, the burst may have occurred in a low density environment, leading to a weak, or non-existent, forward shock – the so-called ‘naked GRB’ model.

\textit{Subject headings:} gamma-rays: bursts

1. INTRODUCTION

The bimodality in Gamma-Ray Burst (GRB) durations has long been recognised (e.g. Kouveliotou et al. 1993) with the 90% γ-ray emission interval (T\textsubscript{90}) peaking around 0.3 and 30 s, with a minimum at two seconds. The short duration bursts also typically exhibit systematically harder emission than the longer ones (Kouveliotou et al. 1993). The revolution which transformed the study of long duration bursts via the identification of afterglows and host galaxies at cosmological redshifts has only just reached the short bursts. The recent discoveries of short burst afterglows in several cases (e.g. GRB 050509B: Gehrels et al. 2005, Bloom et al. 2005; GRB 050709: Covino et al. 2005, Fox et al. 2005b, Hjorth et al. 2005a, Villasenor et al. 2005; GRB 050724: Barthelmy et al. 2005b; GRB 050813: Fox et al. 2005c) and the association of these with host galaxies of various morphological types (including ellipticals) indicate that short GRBs have a different origin from the longer duration bursts. They are typically found at lower redshifts (e.g. Bloom et al. 2005; Berger et al. 2005; Tanvir et al. 2005) and have isotropic energies three orders of magnitude below those of the long GRBs. The definitive lack of detection of a supernova related to GRB 050509B (Hjorth et al. 2005b) supports the difference between long and short bursts. The observations to date are in line with what may be expected from GRBs occurring via compact object mergers [neutron star-neutron star (NS-NS) or black hole-neutron star (BH-NS)].

The two burst populations clearly overlap in the hardness duration parameter space and it is interesting to ask what distinguishes the different classes for the cases where classification simply via T\textsubscript{90} is ambiguous. At least one of the short GRBs found by Swift – GRB 050724; Barthelmy et al. 2005b – has softer emission beyond the expected T\textsubscript{90} of 2 s. In fact, these data showed that the distinction between long and short bursts is partly instrument-dependent. Using Swift data, the γ-ray light-curve of that burst was found to consist of an initial hard spike (lasting about 0.25 s), followed by another peak at T\textsubscript{0} + 1.1 s; this section of the light-curve would have classified GRB 050724 as a short burst. However, faint, softer emission was detected by the Swift Burst Alert Telescope (BAT) out to 140 s after the trigger. Simulations showed that BATSE (the Burst And Transient Source Experiment) would not have detected this softer pulse at more than 0.3σ, obtaining T\textsubscript{90} ∼ 0.43 s. Similar behaviour was seen for GRB 050709 (Fox et al. 2005b) and both Lazzati, Ramirez-Ruiz & Ghisellini (2001) and Connaughton (2002) investigated such ‘tails’ in BATSE short burst data. Norris & Bonnell (2005) have looked at short bursts with extended emission, finding that they can be differentiated from long bursts by having spectral lags consistent with zero for their initial spike emission. Huang et al. (2005) discuss GRB 040924. The duration of this burst (T\textsubscript{90} ∼ 1.2 s) places it in the short category, but the authors conclude that it might belong at the short end of the long GRB distribution. The presence of a supernova signature in this burst strengthens their as-
table:content:0

2. SWIFT OBSERVATIONS

The SWIFT Gamma-Ray Burst Explorer (Gehrels et al. 2004) is a multi-wavelength mission designed to detect and study GRBs. The observatory consists of three instruments – the wide-field γ-ray BAT (Barthelmy et al. 2005a) and the two narrow-field instruments: the X-ray and Ultraviolet/Optical telescopes (XRT; Burrows et al. 2005 and UVOT; Roming et al. 2005).

GRB 050911 was located by the BAT (trigger number 154630) on 11 September 2005 at 15:59:34 UT (Page et al. 2005a). The ground-calculated BAT position (Tueller et al. 2005) was RA = 00h54m52.4's, Dec = −38°51'42.8" (J2000), with an uncertainty of 2.8" (radius, 90% containment). The 90% upper limit was determined to be 16 s, while T90 = 17.3 s; the T90 fluence over 15–150 keV is ~3 × 10⁻⁷ erg cm⁻², placing it at the lower end of the BAT distribution.

Due to a combination of the Earth-limb observing constraint and a temporary problem with the star trackers, the first XRT and UVOT observations of the position of GRB 050911 started 4.6 hr after the burst trigger, when a 0.3 ks exposure was obtained. Table 1 gives the details of this and the subsequent X-ray observations of the burst. Throughout this Letter, errors are given at the 90% significance level unless otherwise stated.

2.1. γ-ray data

Fig. 1 plots the BAT light-curve, showing two short spikes, each about 0.5 s in duration, close to T0 = 0.8 s and T0 + 0.2 s (where T0 is the burst trigger time), followed by a slow rise and fall between T0 + 10 and T0 + 20 s.

The T90 BAT spectrum can be well fitted over 15–150 keV with a simple power-law, of photon index Γ = 1.90±0.33 (χ²/dof = 54/56). Fitting either a Band function (Band et al. 1993) or a cut-off power-law does not improve the fit.

Separate spectra for the time periods covering the first two spikes in the light-curve (T0 − 4 to T0 + 6 s) and the longer, broader peak (T0 + 6 to T0 + 26 s) were extracted, to determine whether the later emission appeared softer, as was the case for the two short bursts GRB 050709 and GRB 050724 (Barthelmy et al. 2005b; Boer et al. 2005). Although there is some evidence for spectral softening with time (Γearly = 1.82±0.11, Γlater = 2.29±0.49), within the errors the photon indices are consistent. However, as Barthelmy et al. (2005b) found for GRB 050724, simulations show it is likely that the later, weaker peak would not have been detected significantly by BATSE (<1σ); it should be noted, though, that the first peak would also have been marginal (<3.5σ), so BATSE may not have triggered on the event at all.

The hardness ratio [S(50–100 keV)]/[S(25–50 keV)] is consistent with the ranges observed for both short and long bursts detected by BATSE and SWIFT. Following Norris & Bonnell (2005), the spectral lag measurement for the initial peak is consistent with zero, as found for short bursts.

2.2. X-ray data

Only one source was detected in the BAT error circle by the XRT (Page et al. 2005b), but this was found to be constant over time and therefore was discounted as the afterglow of GRB 050911 (Page et al. 2005c). For any other object in the BAT error circle, the 3σ upper limit for the count-rate is 4 × 10⁻⁴ count s⁻¹ evaluated over the entire 46 ks exposure (see Table 1). The corresponding unabsorbed flux limit is 1.7 × 10⁻¹⁴ erg cm⁻² s⁻¹ over 0.3–10 keV, assuming a Crab-like spectrum with a Galactic absorbing column of 2.7 × 10²⁰ cm⁻² (Dickey & Lockman 1990). Considering just the initial 6.3 ks exposure at 4.6 hr after the trigger, the upper limit is 1.25 × 10⁻³ count s⁻¹ (5.2 × 10⁻¹⁴ erg cm⁻² s⁻¹), unabsorbed, over 0.3–10 keV.

Fig. 2 shows the BAT light-curve extrapolated into the 0.3–10 keV band (assuming a slope of Γ = 1.9) compared to the XRT upper limit. Fitting a power-law decay to the later peak in the BAT light-curve gives a slope of α = 2.2±0.4; the solid and dashed lines show α = 2.2 and the upper and lower limits respectively. The X-ray upper limit is consistent with the extrapolation of the fit to the end of the BAT data.

2.3. Optical and UV data

No new sources were found in the field by the UVOT, with 3σ upper limits on the magnitude of between 20–
21 for the optical and UV filters; the exposures were between 600 and 900 s in duration (Breeveld et al. 2005).

3. GROUND-BASED OPTICAL OBSERVATIONS

We observed the BAT position (Tueller et al. 2005) with the Gemini South Telescope and GMOS instrument over two epochs (midpoint times of 2005-09-12 04:05:14 UT and 2005-09-15 05:33:18 UT). Images were obtained in the r-band, with exposure times of 1500s (5x300s) and 3000s (10x300s); 5″ dithers were made between subsequent exposures to cover the chip gaps in the GMOS detectors, and the field of view of 5.5′ covered the complete refined BAT error circle. Note that the conditions were sub-optimal, with relatively poor seeing (∼1.2 ″). No new sources were seen in the GMOS images in comparison to the Digitized Sky Survey; however, as the Gemini observations are significantly deeper, a further search for variability was conducted by performing a point spread function matched image subtraction of the two epochs using the ISIS-II code of Alard & Lupton (1998). To estimate the sensitivity to variable objects, a set of artificial stars were created in the first epoch image based on a zeropoint obtained from comparison to the USNO catalogue, and the FWHM equal to that of stellar objects within the field, and the difference image investigated. Using this technique a conservative 5σ limiting magnitude of r = 24.0 was determined for any variable object within the BAT error circle 12 hr after the trigger.

No follow-up detections of GRB 050911 were reported through the GCN (Tristram et al. 2005; Castro-Tirado et al. 2005; Berger & Boss 2005).

4. DISCUSSION

The non-detection of an X-ray afterglow is very unusual for Swift bursts. Before GRB 050911, only four other GRBs (050416B, 050502A, 050709 and 050509C) had been observed with the XRT with no afterglow detection; however, these were first observed with the XRT after 86 hr, 11 days, 39 hr and 9 days respectively, all significantly later than for GRB 050911. As of 1 November 2005, Swift slewed to GRBs 050603, 050714A and 050827 with a greater delay than that for GRB 050911, yet X-ray afterglows were detected in these cases.

Swift bursts which were detected by the XRT before quickly fading below its sensitivity level (i.e., afterglows which would not have been located at 4.6 hr) were all short. (GRB 050421 is the exception to this rule and is discussed below.) GRB 050509B (T90 ∼ 30 ms; Hurkett et al. 2005; Barthelmy et al. 2005c; Gehrels et al. 2005) and GRB 050813 (T90 ∼ 0.6 s; Sato et al. 2005; Fox et al. 2005c) both showed no X-ray emission after a few thousand seconds. For GRB 050906 (T90 ∼ 128 ms; Parsons et al. 2005) only a possible, extremely faint X-ray counterpart was identified (Fox et al. 2005a). Likewise, GRB 050925 (T90 ∼ 72 ms; Holland et al 2005; Beardmore et al. 2005) was not detected after a prompt slew, although there is a possibility that this BAT trigger was due to a new soft γ-ray repeater.

Comparison of our stringent early X-ray upper limit for GRB 050911 of 5.2 × 10^{-14} erg cm^{-2} s^{-1} with the light-curves of other Swift bursts (e.g., fig. 2 of Nousek et al. 2005) shows that the afterglow must have been an order of magnitude or more fainter than all of the other long bursts at 4.6 hr, with the possible exception of GRB 050421. The light-curve of that burst (Goad et al. 2005) appears to be only the tail-end of the prompt emission, with no evidence for an afterglow (probably due to the burst occurring in a low density environment: a ‘naked’ GRB).

The ratio between the 4.6 hr-XRT and T90-BAT fluxes was measured for a large number of bursts and the lowest value found to be ∼ 4 × 10^{-6}. Considering the GRB 050911 BAT flux (1.86 × 10^{-8} erg cm^{-2} s^{-1}), this lowest observed ratio would predict an X-ray flux of ∼ 7 × 10^{-14} erg cm^{-2} s^{-1} at 4.6 hr, higher than the upper limit determined. Thus, GRB 050911 was particularly X-ray faint for the measured γ-ray flux.

Our Gemini limit on the optical flux of GRB 050911 is amongst the deepest obtained for a long duration Swift burst; only the afterglow of GRB 050412 was apparently fainter than this, with a limit of Rc = 24.9 only two hr after the burst (Kosugi et al. 2005). However optical afterglows for the recent short bursts GRBs 050509B and 050813 were undetected to deep limits via Keck, Gemini and VLT observations (e.g. Bloom et al. 2005; Hjorth et al. 2005b; Bloom 2005; Berger & Gladders 2005). Deep observations of the handful of short bursts which were localised prior to Swift also failed to locate any afterglow candidates (e.g. Hurley et al. 2003; Klotz et al. 2003).

4.1. Long or short?

From the discussion above, there are at least two possibilities for GRB 050911: either the light-curve is similar to GRB 050421, showing no sign of emission due to a forward shock, or it is akin to those in the short burst class. The calculated T90 for GRB 050911 falls within the long burst category, although the initial two peaks in the BAT light-curve are both short (∼ 0.5 s each).

The BAT spectrum is not particularly hard. Short bursts tend to be spectroscopically harder than the long bursts; the spectral distinction not strong, though, and the photon index measured for GRB 050911 is within the range observed for both populations (e.g. Ghirlanda, Ghisellini & Celotti 2004). However, any X-ray emission was unusually faint, more in keeping with measurements of short bursts (Fox et al. 2005b), which tend to fade below the XRT sensitivity within a few thousand seconds.

Both the short bursts GRBs 050509B and 050724 (Gehrels et al. 2005; Barthelmy et al. 2005) were found to be associated with non-star-forming elliptical galaxies (thus a compact binary merger origin is more likely than...
a hypernova). In the case of GRB 050911, the cluster EDCC 493 (Lumsden et al. 1992; \(z = 0.16\)) is in the line of sight (Berger 2005) although without a more refined position than that from the BAT, it cannot be claimed with any certainty that the burst is associated with any of the galaxies within the cluster. EDCC 493 is not a rich cluster and a rough estimate suggests that, with a radius of \(\sim 0.2^\circ\), the chance of such a cluster intersecting the line of sight is a few percent, so the alignment may just be due to chance. No information about the star-formation rate in this cluster is known.

If GRB 050911 is, as \(T_{90}\) suggests, a long burst, then it is unusually X-ray faint. It could be due to a collapsar, with the progenitor initially in a binary system. Assuming the progenitor to be the secondary star in the system, it could receive a kick into a low-density environment when the primary star undergoes a supernova explosion. If a GRB forms with very little surrounding interstellar material, only a weak forward shock will occur and therefore little afterglow emission will result.

If, instead, GRB 050911 is interpreted as a compact object merger, the \(\gamma\)-ray emission out beyond 10 s has to be explained; as discussed earlier, the burst is not unique in this respect. Models involving two neutron stars are unlikely to produce the long and structured emission seen in GRB 050911, because the mass ratio in a NS-NS merger is inevitably close to unity. The disruption of both neutron stars occurs as a single event and the light-curve is controlled by the properties of the resulting neutron torus. However, if the mass ratio is far from unity, the disruption event can be more complex. Davies, Levan & King (2005) consider a BH-NS merger with a mass ratio of 10:1. They find that mass transfer from the neutron star occurs in spurts, with instantaneous rates exceeding 100 \(M_\odot\) s\(^{-1}\). Between these spurts the neutron star remnant travels in a wider, eccentric orbit with an initial size dependent on how much of the angular momentum of the transferred mass is returned to the remnant. The orbits decay by gravitational radiation, causing subsequent bursts. For returned angular momentum fractions \(\sim 0.5\), these intervals can be several seconds. If the black hole is formed relatively early on in this process, delayed accretion events could then cause later outbursts. When the neutron star remnant reaches a mass of \(\sim 0.2 M_\odot\) it is completely disrupted, effectively terminating the accretion. Evidently more work is needed to model in detail the light-curve predicted by this pattern of mass transfer, but the luminosities and timescales produced from a BH-NS merger resemble those in GRB 050911.

5. CONCLUSIONS

No X-ray afterglow emission was detected for GRB 050911, starting 4.6 hr after the burst trigger. Comparison of the upper limit of the emission with other \textit{Swift}-detected bursts (Nousek et al. 2005) demonstrates that any afterglow was at least an order of magnitude fainter than for any other long burst, with the possible exception of GRB 050421. The behaviour could be due to either a BH-NS merger, or by a collapsar occurring in a region of low density, thus forming a ‘naked’ GRB. Whatever mechanism produced GRB 050911, it was an unusual, X-ray dark, burst.

6. ACKNOWLEDGMENTS

The authors acknowledge support for this work at the University of Leicester by PPARC, at PSU by NASA and in Italy by ASI. AJL and NRT acknowledge receipt of PPARC fellowships. We also thank the referee for useful comments and J. Norris for the spectral lag calculation.
