Abstract

The statistical study of the coronal mass ejections (CMEs) is a hot topic in solar physics. To further reveal the temporal and spatial behaviors of the CMEs at different latitudes and heights, we analyzed the correlation and phase relationships between the occurrence rate of CMEs, the coronal brightness index (CBI), and the 10.7 cm solar radio flux (F10.7). We found that the occurrence rate of the CMEs correlates with the CBI relatively stronger at high latitudes (≥60°) than at low latitudes (≤50°). At low latitudes, the occurrence rate of the CMEs correlates relatively weaker with the CBI than the F10.7. There is a relatively stronger correlation relationship between CMEs, the F10.7, and the CBI during Solar Cycle 24 (SC24) than Solar Cycle 23 (SC23). During SC23, the high-latitude CME occurrence rate lags behind the F10.7 by 3 months, and during SC24, the low-latitude CME occurrence rate leads the low-latitude CBI by 1 month. The correlation coefficient values turn out to be larger when the very faint CMEs are removed from the samples of the CDAW catalog. Based on our results, we may speculate that the source regions of the high/low-latitude CMEs may vary in height, and the process of magnetic energy accumulation and dissipation is from the lower to the upper atmosphere of the Sun. The temporal offsets between different indicators could help us better understand the physical processes responsible for the solar-terrestrial interactions.

Unified Astronomy Thesaurus concepts: Solar coronal mass ejections (310); Solar activity (1475); Magnetic fields (994)

1. Introduction

Coronal mass ejections (CMEs), the large-scale bursts of plasma and magnetic fields in the Sun, are the primary sources of catastrophic space weather, which causes many moderate to intense geomagnetic storms (Gosling 1990; Webb et al. 2000; Gopalswamy et al. 2000; Wang et al. 2003).

Since the successful launch of the Solar and Heliospheric Observatory (SOHO; Brueckner et al. 1995) as an onboarding instrument, the Large Angle Spectrometric Coronagraph (LASCO) has observed more than 30,000 samples of CMEs. Based on these data, scientists have extensively studied various physical properties of CMEs, such as their speed (Yurchyshyn et al. 2005; Gao & Li 2008; Mittal & Narain 2009), acceleration (Gopalswamy et al. 2000; Mittal & Narain 2009), occurrence (Cremades & Bothmer 2004; Lamy et al. 2019), latitude (Gopalswamy 2004; Mittal & Narain 2009), mass (Mittal & Narain 2009; Lamy et al. 2019), and so on. These studies have significantly advanced our understanding about CMEs.

The statistical study of the temporal and spatial behaviors of CMEs helps to understand the characteristics, formation process, and origin of CMEs, which is essential for us to understand solar activities and predict catastrophic space weather. Webb & Howard (1994) found that the occurrence rate of CMEs tends to track the solar cycle in both amplitude and phase by analyzing the variation of CME rate over time from 1973 to 1989. Gopalswamy et al. (2003a) analyzed the relationship between the occurrence rate of CMEs and the sunspot number from 1996 to 2002. They found that the occurrence rate of CMEs is highly correlated with the sunspot number (the coefficient value is 0.86). At the same time, for Solar Cycle 23 (SC23), their peaks are not at the same position but are 2 yr apart. Furthermore, Gopalswamy (2004) showed that a fraction of CMEs originates in spot-free areas. Lamy et al. (2019) analyzed the difference of the CME occurrence rate between the northern and southern hemisphere and confirmed that there exists asymmetry between the two hemispheres. Gopalswamy et al. (2015a), Winter et al. (2016), Compagnino et al. (2017), and Bilenko (2020) found that the number of CMEs during Solar Cycle 24 (SC24) is larger than that during SC23. Bilenko (2020) noted that the high-latitude CMEs contribute more to the increase of the number of CMEs during SC24.

Several studies have found some differences between the high-latitude and low-latitude CMEs. The high-latitude CMEs are closely related to polar crown filaments, while the low-latitude CMEs mainly to sunspots (Gopalswamy et al. 2003a, 2010). Moreover, there exist differences in statistical properties between them. Gao & Li (2008) found that during SC23, the speed of the low-latitude CMEs is slightly larger than the high-latitude CMEs. Gopalswamy et al. (2015b) found that during SC24, the low-latitude CMEs own larger speeds, wider angular widths, and smaller accelerations than the high-latitude CMEs. Gao & Li (2008), Jung et al. (2009), and Gopalswamy et al. (2015b) concluded that the main factor that causes the CMEs to have a larger speed is the magnetic field. Compared to the high-latitude CMEs, the source regions of low-latitude CMEs have higher magnetic-field strength and thus provide higher free energy to power the CMEs. Furthermore, Kilcik et al. (2011, 2017) pointed out that the maximum CME speed index (MCMESI) is a useful indicator of geomagnetic activities. The MCMESI represents CMEs with a larger speed. Statistically,
CMEs with larger speeds are often observed at low latitudes (Gao & Li 2008; Gopalswamy et al. 2015b). It indicates that the low-latitude CMEs may be a better indicator of geomagnetic activities than the high-latitude CMEs. Therefore, studying the temporal and spatial behaviors of CMEs at different latitudes is instructive for understanding their differences.

Usually, the temporal and spatial behaviors of the CMEs can be studied by comparing the relationship between the CME occurrence rate and solar activity indicators (Lamy et al. 2019). It is well known that the occurrence rate of CMEs varies with the solar cycle. The study of the relationship between CMEs and different solar activity indicators is helpful for connecting the variation of CMEs with the variation of solar activities, which would provide some enlightenment to the source region of CMEs. Cremades & Cyr (2007) pointed out that the 10.7 cm solar radio flux (F10.7) is a more reliable indicator of solar activities than the number of sunspots because the number of sunspots is determined by observers. The F10.7 is directly related to the total amount of magnetic flux that is supposed to come from the lower solar corona which is about 60,000 km above the surface atmosphere (Vats et al. 2001; Greenkorn 2012; Bhatt et al. 2017). Therefore, the F10.7 can be considered a low coronal activity index (Tapping & Detracey 1990; Greenkorn 2012). The CBI (Battams et al. 2020), a new white-light coronal brightness index, constructed from the LASCO C2 coronagraphs from 1996 to 2017, can be used to explore the spatial relationships between coronal structure and other geophysical indices. The CBI contains coronal brightnesses from 2.5 to 6.2 \( R_\odot \) coronal heights, which can represent the high coronal activity index.

We analyzed the correlation and phase relationships between the occurrence rate of CMEs, the CBI, and the F10.7 to study the temporal and spatial behaviors of CME occurrence rate at high/low latitudes. In the rest of this paper, we introduce data preparation in Section 2. Section 3 compares the occurrence rate of the low/high-latitude CME occurrence rate with the F10.7 and CBI, and studies the correlation relationship and phase relationship between CMEs and the F10.7, CMEs and the CBI, respectively. Section 4 presents conclusions and discussions.

2. Data Source and Preprocessing

2.1. CME Data Preparation

There are a total of five catalogs of CMEs from SOHO/LASCO (Brueckner et al. 1995) observations, i.e., CDAW (Yashiro et al. 2004, 2008), ARTEMIS (Boursier et al. 2009), CACTus (Robbrecht & Berghmans 2004; Robbrecht et al. 2009), SEEDS (Olmedo et al. 2008), and CORIMP (Byrne et al. 2009). CDAW is manually maintained and verified, whereas the other four are automatically generated. Therefore, most statistical analyses on CMEs used the CDAW catalog. We also used the CDAW catalog for our research work. There are 31,310 CMEs in the catalog we used, covering from 1996 January to 2021 August. CDAW records the physical characteristics of each CME, including the time, date, central position angle (CPA), angular width, the second-order speed at final height, accelerated speed, etc.

To study the CMEs at high/low latitudes, respectively, we converted the CPA to the projected heliographic latitude (i.e., the apparent latitude; Gopalswamy et al. 2003b; Yashiro et al. 2004; Gao & Li 2008; Li et al. 2009; Gao et al. 2009). For example, CPAs of 0°, 90°, 180°, and 270° correspond to the apparent latitudes of 90°, 0°, −90°, and 0°, respectively. According to the general division of high/low latitudes from the previous study (Sakurai 1998; Li et al. 2009), we grouped the CMEs whose apparent latitudes were \( \leq 50° \) into high-latitude CMEs, those whose apparent latitudes were \( \geq 60° \) into high-latitude CMEs, and did not research the CMEs whose latitudes are between 50° and 60°, considering the projection effect and the magnetic-field mixing effect. Since the apparent latitudes of the halo CMEs (the angular width is 360°) cannot be determined, we did not use the halo CMEs (the amount is 734, accounting for 2.34% of the total) for our work.

We finally obtained 4964 high-latitude CMEs (accounting for 15.9%) and 23,789 low-latitude CMEs (accounting for 76.0%). Figure 1 shows the time series of the monthly occurrence rate of CMEs for all/high/low latitudes. As can be

---

**Figure 1.** The monthly occurrence rate of CMEs derived from the CDAW catalog. The black line represents all CMEs, the red line represents the high-latitude CMEs, and the blue line represents the low-latitude CMEs.
seen from Figure 1, compared with the high-latitude CMEs, the low-latitude CMEs account for the vast majority.

2.2. CBI Data Preparation

The CBI data is obtained from the website5 generated by Battams et al. (2020). The time is from 1996 April 16 to 2017 July 31, including 7777 days. There are two data sets of CBIs: the raw data set (the data is not continuous because there are some days that have no CBI values) and the interpolated data set (those days without values have been assigned values through linear interpolation). We used the interpolated data set for our research. The data cube is $360 \times 38 \times 7777$ (the blue gray part in Figure 2).

The first dimension (i.e., 360) is the position angle (along the limb of the Sun), which starts at a position angle of $0^\circ$ (corresponding to solar north), then passes counterclockwise through the LASCO field of view so that $90^\circ$ corresponds to the eastern limb, $180^\circ$ to the solar south, $270^\circ$ to the western limb, and goes back to $0^\circ$ in the end. The second dimension (i.e., 38) represents the height in the corona that is from 2.5 to 6.2 $R_\odot$ with a step of 0.1 $R_\odot$.

The third dimension (i.e., 7777) represents the days from 1996 April 16 to 2017 July 31, with a step of 1 day.

To find out a proper height of the CBI for our research, we first summed the CBI values along the position angle to obtain a time series of the CBI at different heights, i.e., a two-dimensional array ($38 \times 7777$, the yellow-green part in Figure 2), then calculated the correlation coefficients (CCs) between the CME occurrence rate (with all-latitude CMEs) and the CBI from different heights to find out the height with the maximum correlation coefficient (MCC), i.e., the 4.5 $R_\odot$ height. The result is shown in Figure 3. We used the CBI data at the 4.5 $R_\odot$ height for our work.

Like the CMEs, the CBI also needs to be divided into three groups, i.e., all CBI, high-latitude ($\geq60^\circ$) CBI, and low-latitude ($\leq50^\circ$) CBI. Because the CBI data from the website provides position angle rather than latitude, we should also transform position angles into latitudes with the same way used for CMEs. Figure 4 shows the time series of monthly averaged CBI for all latitude, high latitude, and low latitude.

2.3. Data Source of F10.7

The F10.7, one of the most widely used indicators of solar activity (Tapping 2013), is the measurement of the integrated

---

5 https://lasco-www.nrl.navy.mil/CBI
emission at 10.7 cm from all the sources on the disk. Compared to the CBI, the F10.7 reflects more of the lower solar corona (about 60,000 km above the solar surface). The data of the F10.7 used in our work comes from the Canadian Solar Radio Monitoring Program (Ottawa) that gives three types of F10.7 flux: the observed, the adjusted, and the absolute. The absolute F10.7 flux eliminates the fluctuation caused by the variation of Sun–Earth distance and suppresses the antenna gain and ground reflected radiation. We used the absolute flux of F10.7 for our research, which covers from 1996 January to 2021 August (see the monthly average F10.7 in Figure 5). The unit of the F10.7 is the solar flux unit (sfu), where 1 sfu = 10^{-22} \text{W m}^{-2} \text{Hz}^{-1}.

3. Analyses and Results

3.1. Correlation Analysis between CME Occurrence Rate, F10.7, and CBI

We explored the correlation relationship between the monthly CME occurrence rate and monthly averaged F10.7 from 1996 January to 2021 August, and the correlation relationship between the monthly CME occurrence rate and monthly averaged CBI from 1996 April to 2017 July. The results are shown in Figure 6 and Table 1. The monthly CME occurrence rate, the monthly F10.7, and the monthly CBI are all normalized. In Figure 6, the “CC” in red color represents the correlation coefficient (CC). The left panels are for the CMEs and the F10.7, and the right panels are for the CMEs and the CBI.

From Figure 6 and Table 1, we can find that the CME occurrence rate is correlated with the F10.7 and the CBI. Their
correlation relationships at high latitudes are stronger than at low latitudes. For the high latitude, the coefficient value of $CC$ between CMEs and the CBI is 0.63, whereas for the low latitude, the value is 0.41. The correlation between high-latitude CMEs and the CBI ($CC = 0.63$) is stronger than that between CMEs and the $F_{10.7}$ ($CC = 0.54$). In contrast, at low latitudes, the correlation between CMEs and the CBI ($CC = 0.41$) is weaker than that between CMEs and the $F_{10.7}$ ($CC = 0.51$).

According to previous research, the number of the CMEs during SC24 is larger than that during SC23 (Gopalswamy et al. 2015a; Winter et al. 2016; Compagnino et al. 2017; Bilenko 2020), and the CMEs during SC24 have lower velocities (Lamy et al. 2019; Bilenko 2020) and weaker photospheric magnetic fields (Tripathy et al. 2015), which suggests that the characteristics of the source regions of CMEs during SC24 may be different from those during SC23 (Gao et al. 2014a). Therefore, we calculated the CCs for SC23 and SC24, respectively. The calculation results are listed in Table 1. From Table 1, we can find that their correlation relationship during SC24 is stronger than during SC23. It is worth noting that, at low latitudes during SC23, the three indices are all weakly correlated ($CC = 0.43$ and 0.39, respectively).

### Table 1

|                  | All High-latitude Low-latitude |
|------------------|------------------------------|
| 1996.1-2021.8    | F10.7 0.58(0.79) 0.54(0.75) 0.51(0.75) |
| 1996.4-2017.7    | CBI 0.52(0.70) 0.63(0.81) 0.41(0.59) |
| SC23             | F10.7 0.58(0.84) 0.60(0.80) 0.43(0.77) |
| SC24             | CBI 0.51(0.78) 0.65(0.83) 0.39(0.71) |
|                  | SC23 F10.7 0.58(0.84) 0.60(0.80) 0.43(0.77) |
|                  | CBI 0.51(0.78) 0.65(0.83) 0.39(0.71) |
|                  | SC24 F10.7 0.89(0.91) 0.82(0.87) 0.84(0.87) |
|                  | CBI 0.67(0.63) 0.80(0.83) 0.51(0.46) |

Note. The values in parentheses are the correlation coefficients without the “very poor” CMEs.

3.2. Phase Relationship between CME Occurrence Rate, $F_{10.7}$, and CBI

We used the cross-correlation analysis (CCA)\(^7\) to analyze the phase relationship between the monthly CME occurrence rate, monthly averaged $F_{10.7}$, and monthly averaged CBI at high latitudes, low latitudes, and all latitudes, respectively. In the CCA method, the leading or lagging relationship of two time series is determined by the phase lag position of the MCC (Hagino et al. 2004; Kilcik et al. 2017, 2018; Deng et al. 2019, 2020).

The values of the MCC and its corresponding phase lag time are listed in Table 2. To estimate the error level of these MCCs, we applied the Fisher’s test to calculate their confidence intervals at 95% significance (Kilcik et al. 2011, 2017, 2018; Ozguc & Kilcik 2021; Tirnakci & Kilcik 2021) and the results are listed in Table 2.

From Figure 7 and Table 2, we can find that in the whole time, the occurrence rate of the high-latitude CMEs is in phase with the high-latitude CBI and the $F_{10.7}$. The occurrence rate of the low-latitude CMEs is in phase with the $F_{10.7}$, whereas leads the low-latitude CBI by 5 months. During SC23, the occurrence rate of the high-latitude CMEs lags behind the $F_{10.7}$ by 3 months. During SC24, the occurrence rate of the

\(^7\) https://www.statsmodels.org/dev/generated/statsmodels.tsa.stattools.ccf.html
low-latitude CMEs leads the low-latitude CBI by 1 month. These results further indicate that the high-latitude CMEs correlate better with the high-latitude CBI. In contrast, the low-latitude CMEs correlate better with the F10.7.

4. Conclusions and Discussions

To reveal the temporal and spatial behaviors of the CMEs at different latitudes, we investigated the correlation and phase relationships of their occurrence rate with the F10.7 and CBI, and obtained the following results:

1. The high-latitude CME occurrence rate has a relatively stronger correlation relationship with the high-latitude CBI than the F10.7 (lower corona);
2. The low-latitude CME occurrence rate has a relatively stronger correlation relationship with the F10.7 than the low-latitude CBI;
3. There is a relatively stronger correlation relationship between CMEs, the F10.7, and the CBI for SC24 than SC23;
4. For SC23, the high-latitude CME occurrence rate lags behind the F10.7 by 3 months, whereas for SC24, they are in phase. For SC24, the low-latitude CME occurrence rate leads the low-latitude CBI by 1 month, whereas for SC23, they are in phase.

The occurrence rate of the high-latitude CMEs correlates more strongly with the high-latitude CBI. In contrast, the occurrence rate of the low-latitude CMEs is more correlated with the F10.7. The F10.7 is a low corona activity index and reflects the global variation of the Sun. The CBI is an index that reflects the high corona activities. Therefore, we could speculate that the source regions of high/low-latitude CMEs may vary in height: the source regions of high-latitude CMEs are closer to high coronas, and the source regions of low-latitude CMEs are closer to low coronas.

It is generally accepted that due to the upward evolution of solar activities, the cycles of upper activity indices commonly lag behind the lower activity indices by several months (Ozguc & Atac 2003; Du 2011; Du & Wang 2012). Bachmann & White (1994) found that six solar activity indicators (F10.7, Ca II K index, equivalent width of He I 1083 nm, Mg II 280 nm core-to-wing ratio, extreme ultraviolet radiation, and Lo emission) significantly lag behind the sunspot number by 1 month to several months during Solar Cycles 21 and 22. Deng et al. (2012) found that the sunspot number appears 1 month earlier than the coronal index. Tang & Deng (2013) found that the flare index lags behind the sunspot number and sunspot area. In our work, we find that the CME occurrence rate leads the CBI at low latitudes and lags behind the F10.7 at high latitudes. Since the CBI reflects the high corona activities and the F10.7 reflects the low corona activities, our results further indicate that the process of magnetic energy accumulation and dissipation is from the lower to the upper atmosphere of the Sun.

The existing literature shows that the phase relationships between solar activity indices are different during different solar cycles. Temmer et al. (2003) found that there exist significant time lags between flare activities (X-ray flare, Hα flare) and sunspot activities (sunspot number, sunspot area) during SC19, SC21, and SC23, whereas they are in phase during SC20 and SC22. Gao et al. (2014b) found that the flare index lags behind the sunspot number during SC21, the flare index is in phase with the sunspot number during SC22, and the flare index leads the sunspot number during SC23. In our work, we find that during SC23, the high-latitude CME occurrence rate lags behind the F10.7 by 3 months, whereas during SC24, the two indices are in phase. During SC23, the CME occurrence rate is in phase with the CBI, whereas during SC24, it leads the CBI by 1 month. Our results support that the leading/lagging relationship changes from one cycle to another.

Based on the ARTEMIS catalog, Lamy et al. (2019) investigated the correlation relationships between the CME occurrence rate and the F10.7 and other four solar activity indicators (sunspot number, sunspot area, X-ray, total photospheric magnetic flux). They found that their correlation relationships are stronger during SC24 than SC23. Based on the CDAW catalog, we also find that the correlation relationships of CME occurrence rate, the F10.7, and the CBI are stronger during SC24 than SC23, which agrees with their findings. The difference in the correlation degree during different cycles might be associated with the real differences in the behaviors of strong and weak photospheric magnetic fields in Cycles 23 and 24, as pointed out by Bilenko (2020).

However, our coefficient values (0.58 in SC23, 0.89 in SC24) based on CDAW are smaller than their values (0.93 in SC23, 0.95 in SC24) based on ARTEMIS. We think the reason is that the CDAW catalog is manually maintained, in which some small and faint ejections are included (marked with “Very Poor Event”). In contrast, the ARTEMIS catalog is automatically generated based on a preset threshold, in which those small and faint ejections have been dropped. The small and faint ejections in the CDAW catalog are marked since the middle of SC23, which accounts for 28% of the total CMEs. We also computed the CCs without these “Very Poor Events.” The results are shown in Table 1 (the values in parentheses).

Table 2

|            | All (MCC) | High-latitude (MCC) | Low-latitude (MCC) |
|------------|-----------|---------------------|--------------------|
|            | MCC       | Phase Lag (months)  | MCC                |
| 1996.1-2021.8 | CMEs-F10.7 | 0.58 ± 0.07         | 0.54 ± 0.08        |
| 1996.4-2017.7 | CMEs-CBI | 0.52 ± 0.09         | 0.63 ± 0.08        |
| SC23       | CMEs-F10.7 | 0.58 ± 0.11         | 0.61 ± 0.11        |
|            | CMEs-CBI | 0.51 ± 0.13         | 0.65 ± 0.10        |
| SC24       | CMEs-F10.7 | 0.89 ± 0.04         | 0.82 ± 0.06        |
|            | CMEs-CBI | 0.69 ± 0.11         | 0.80 ± 0.08        |

Note. Negative values indicate that the CME occurrence rate leads the F10.7/CBI, and positive values mean lagging.
We can easily notice that almost all of the CCs without the “Very Poor Event” increase. The coefficient values of SC23 (0.84) and SC24 (0.91) get close to the results of Lamy et al. (2019).
