Ontology Matching with Knowledge Rules

Shangpu Jiang and Daniel Lowd and Dejing Dou

{shangpu,lowd,dou}@cs.uoregon.edu

Abstract
Ontology matching is the process of automatically determining the semantic equivalences between the concepts of two ontologies. Most ontology matching algorithms are based on two types of strategies: terminology-based strategies, which align concepts based on their names or descriptions, and structure-based strategies, which exploit concept hierarchies to find the alignment. In many domains, there is additional information about the relationships of concepts represented in various ways, such as Bayesian networks, decision trees, and association rules. We propose to use the similarities between these relationships to find more accurate alignments. We accomplish this by defining soft constraints that prefer alignments where corresponding concepts have the same local relationships encoded as knowledge rules. We use a probabilistic framework to integrate this new knowledge-based strategy with standard terminology-based and structure-based strategies. Furthermore, our method is particularly effective in identifying correspondences between complex concepts. Our method achieves substantially better F-score than the previous state-of-the-art on three ontology matching domains.

Introduction
Ontology matching is the process of aligning two semantically related ontologies. Traditionally, this task is performed by human experts. Since the task is tedious and error prone, especially in larger ontologies, there has been substantial work on developing automated or semi-automated ontology matching systems (Shvaiko and Euzenat 2011). While some automated matching systems make use of data instances, in this paper we focus on the schema-level ontology matching task, in which no data instances are used.

Previous schema-level ontology matching systems mainly use two classes of strategies. Terminology-based strategies discover corresponding concepts with similar names or descriptions. Structure-based strategies discover corresponding groups of concepts with similar hierarchies. In many cases, additional information about the relationships among the concepts is available through domain models, such as Bayesian networks, decision trees, and association rules. A domain model can be represented as a collection of knowledge rules, each of which denotes a semantic relationship among several concepts. These relationships may be complex, uncertain, and rely on imprecise numeric values. In this paper, we introduce a new knowledge-based strategy which uses the structure of these knowledge rules as (soft) constraints on the alignment.

As a motivating example, consider two ontologies about basketball games. One has datatype properties height, weight and a binary property center for players, while the other has the corresponding datatype properties h, w, and position. Terminology-based strategies may not identify these correspondences. However, if we know that a large value of height implies center is true in the first ontology, and the same relationship holds for h and position = center in the second ontology, then we tend to believe that height maps to h and center maps to position = center.

We use Markov logic networks (MLNs) (Domingos and Lowd 2009) as a probabilistic language to combine the knowledge-based strategy with other strategies, in a formalism similar to that of (Niepert, Mellicke, and Stuckenschmidt 2010). In particular, we encode the knowledge-based strategy with weighted formulas that increase the probability of alignments where corresponding concepts have isomorphic relationships. We use an MLN inference engine to find the most likely alignment. We name our method Knowledge-Aware Ontology Matching (KAOM).

Our approach is also capable of identifying complex correspondences, an extremely difficult task in ontology matching. A complex correspondence is a correspondence between a simple concept and a complex concept (e.g., grad_student maps to the union of PhD and Masters). This can be achieved by constructing a set of complex concepts (e.g., unions) in each ontology, subsequently generating candidate complex correspondences, and using multiple strategies – including the knowledge-based strategy – to find the correct complex correspondences.

The contributions of this work are as follows:

- We show how to represent common types of domain models as knowledge rules, and how to use these knowledge rules to guide the ontology matching process, leading to more accurate alignments. Our approach is especially effective in identifying the correspondences of numerical or nominal datatype properties. By incorporating complex concepts, our approach is also capable of discovering complex correspondences, which is a very difficult scenario in the ontology matching task.
We evaluate the effectiveness of KAOM in three domains with different types of knowledge rules, and show that our approach not only outperforms the state-of-the-art approaches for ontology matching in one-to-one matching, but also discovers complex correspondences successfully.

The rest of the paper is organized as follows. First we review pervious work on ontology matching. We then introduce the concept of “knowledge rules” with a definition and examples. Next, we show our approach of using Markov logic to incorporate multiple strategies, including a knowledge-based strategy and the treatment of complex correspondences. Finally we present experimental results and conclude.

Ontology Matching

We begin by formally defining ontology matching.

Definition 1 (Ontology Matching (Euzenat and Shvaiko 2007)). Given two ontologies $O_1$ and $O_2$, a correspondence is a 3-tuple $(e_1, e_2, r)$ where $e_1$ and $e_2$ are entities of the first and second ontologies respectively, and $r$ is a semantic relation such as equivalence ($\equiv$) and subsumptions ($\subseteq$ or $\supseteq$). An alignment is a set of correspondences. Ontology matching is the task or process of identifying the correct semantic alignment between the two ontologies. In most cases, ontology matching focuses on equivalence relationships only.

Most existing schema-level ontology matching systems use two types of strategies: terminology-based and structure-based. Terminology-based strategies are based on terminological similarity, such as string-based or linguistic similarity measures. Structure-based strategies are based on the assumption that two matching ontologies should have similar local or global structures, where the structure is represented by subsumption relationships of classes and properties, and domains and ranges of properties. Advanced ontology matching systems often combine the two types of strategies (Euzenat and Shvaiko 2011). See (Shvaiko and Euzenat 2011) for a survey of ontology matching systems and algorithms. Recently, a probabilistic framework based on Markov logic was proposed to combine multiple strategies (Niepert, Meilicke, and Stuckenschmidt 2010).

Definition 2 (Complex Correspondences). A complex concept is a composition (e.g., unions, complements) of one or more simple concepts. In OWL (R) there are several constructors for creating complex classes and properties (see the top part of Table 1 for an incomplete list of constructors). A complex correspondence is an equivalence relation between a simple class or property and a complex class or property in two ontologies (Ritze et al. 2008).

Previous work takes several different approaches to finding complex correspondences (i.e., complex matching). One is to construct candidates for complex correspondences using operators for primitive classes, such as string concatenation or arithmetic operations on numbers (Dhamankar et al. 2004). (Ritze et al. 2008) introduce four specific patterns for complex correspondences: Class by Attribute Type (CAT), Class by Inverse Attribute Type (CIAT), Class by Attribute Value (CAV), and Property Chain pattern (PC). Finally, when aligned or overlapping data is available, inductive logic programming (ILP) techniques can be used as well (Hu et al. 2011) (Qin, Dou, and LePendu 2007).

Table 1: Syntax and semantics of DL symbols (top), DL axioms (middle), and other knowledge rules used in the examples of the paper (bottom).

| Syntax | Semantics |
|--------|-----------|
| $C \sqcap D$ | $C^I \sqcap D^I$ |
| $C \sqcup D$ | $C^I \sqcup D^I$ |
| $\neg C$ | $D \setminus C^I$ |
| $\exists R.C$ | $\{ (x \in D) \exists y((x, y) \in R^T \land y \in C^T) \}$ |
| $R \circ S$ | $\{ (x, y) \mid \exists z((x, z) \in R^T \land (z, y) \in S^T) \}$ |
| $R \mid C$ | $\{ (x, y) \in R^T \mid y \in C^T \}$ |

We illustrate a few forms of knowledge rules with the following examples.

Example 1. The submission deadline precedes the camera ready deadline: paperDueOn ≺ manuscriptDueOn. This is represented as $R_1($paperDueOn, manuscriptDueOn) with $R_1(a, b): a < b$.

Example 2. A basketball player taller than 81 inches and heavier than 245 pounds is likely to be a center: $h > 81 \land w > 245 \Rightarrow \text{pos} = \text{Center}$. This rule can be viewed as a branch of a decision tree or an association rule. It can be represented as $R_2(h, w, \text{pos}=\text{Center}, [81, 245])$, with $R_2(a, b, c, \theta): a > \theta_1 \land b > \theta_2 \Rightarrow c$.

Example 3. A smoker’s friend is likely to be a smoker as well: Smokes(x) ∧ Friend(x, y) ⇒ Smokes(y). This rule can be represented as $R_3($Smoke, Friend) with $R_3(a, b): a(x) \land b(x, y) \Rightarrow a(y)$.

Knowledge Aware Ontology Matching

In this section, we present our approach, Knowledge Aware Ontology Matching (KAOM). KAOM uses Markov logic networks (Domingos and Lowd 2009) to solve the ontology matching task. The MLN formulation is similar to (Niepert, Meilicke, and Stuckenschmidt 2010) but incorporates the knowledge-based matching strategy and treatment of complex correspondences.

In the ontology matching problem, we represent a correspondence with a binary relation, match(a, a′), which is true if concept a from the first ontology is semantically equivalent to concept a′ from the second ontology (e.g., match(writePaper, writes) means writePaper ≡ writes).

We define three components of the MLN of the ontology matching problem: constants, evidence and formulas. The logical constants are the entities in both ontologies. The evidence includes the complete set of OWL-supported relationships among all concepts in each ontology (e.g., subsumptions and disjointness, we use an OWL reasoner to create the complete set of OWL axioms.), and rules converted to first-order atoms as described in the previous section.

For the formulas, we begin with a set of formulas adapted from (Niepert, Meilicke, and Stuckenschmidt 2010). The numbers preceding the formulas are the weights. A missing weight means a formula with infinity weight.

1. A-priori similarity is the string similarity between all pairs of concepts:

$$s_{a,a'} \cdot \text{match}(a, a')$$ (1)

where $s_{a,a'}$ is the string similarity between $a$ and $a'$, which also serves as the weight of the formula. We use the Levenshtein measure (Levenshtein 1966) for simple correspondences. This atomic formula increases the probability of matching pairs of concepts with similar strings, all other things being equal.

2. Cardinality constraints enforce one-to-one simple (or complex) correspondences:

$$\text{match}(a, a') \land \text{match}(a, a'') \Rightarrow a' = a''$$ (2)

3. Coherence constraints enforce consistency of subclass relationships:

$$a \subseteq b \land a' \subseteq \neg b' \Rightarrow \neg(\text{match}(a, a') \land \text{match}(b, b'))$$ (3)

Knowledge-based Strategy

We propose a new knowledge-based strategy for ontology matching that uses the similarity of knowledge rules in the two ontologies. It is inspired by the structure-based strategy in many ontology matching algorithms (e.g., (Melnik, García-Molina, and Rahm 2002)). The strategy favors the alignments that preserve the same types of knowledge rules, which extends the subsumption relationship of entities in structure-based strategies to sub-property, disjoint properties, and user-defined relations such as ordering of dates, and non-deterministic relationships such as correlation and anti-correlation. The strategy can be represented as the Markov logic formulas:

$$-w_k R_k(a, b, ..., \neg \text{match}(a', b', ..., k) = 1, ..., m \hspace{1cm} (4)$$

$$+w'_k R_k(a, b, ..., \text{match}(a', b', ..., k) = 1, ..., m \hspace{1cm} (5)$$

where $R_k$ is a rule pattern.

Example 4. A reviewer of a paper cannot be the paper’s author. In the confOf ontology we have $R_4($writePaper, write) and in the confOf ontology we have $R_4($write, review) where $R_3(a, b): a \subseteq \neg b$ is the disjoint relationship of properties. Applying the constraint formulas defined above, we increase the score of all alignments containing the two correct correspondences: writePaper ≡ writes and readPaper ≡ reviews.

Rules involving continuous numerical attributes often include parameters (e.g., thresholds in Example 2) that do not match between different ontologies. In order to apply the knowledge-based strategy to numerical attributes, we make the assumption that corresponding numerical attributes roughly have a positive linear transformation. This assumption is often true in real applications, for instance, when an imperial measure of height matches to a metric measure of height. We propose two methods to handle numerical attributes. The first method is to compute a distance measure (e.g., Kullback-Leibler divergence) between the distributions of the corresponding attributes in a candidate alignment. Specifically, we replace Formulas 4 and 5 with:

$$d_0 - d \cdot \text{match}(a, a') \land \text{match}(b, b') ... , k = 1, ..., m \hspace{1cm} (6)$$

where $d$ is a distance measure of the two rules $R_k(a, b, ...) \land R_k'(a', b', ...)$ and $d_0$ is a threshold.

Example 5. In the nba-os ontology, we have conditional rules converted from a decision tree, such as

$$h > 81 \land w > 245 \Rightarrow \text{Center}$$
Similarly, in the nbayahoo ontology, we have
\[ h' > 2.06 \land w' > 112.5 \Rightarrow \text{Center}' \]

Here the knowledge rules represent the conditional distributions of multiple entities. We define the distance between the two conditional distributions as
\[
d(h, w, \text{Center}; h', w', \text{Center}') = \mathbb{E}_p(h, w) \cdot \mathbb{E}_p(h', w')
\]

where \( \mathbb{E}(\cdot) \) is expectation and \( \mathbb{E}(p|p') \) is a distance measure (Because Center and Center' are binary attributes, we simply use \( |p - p'| \) as the distance measure. For numerical attributes, we can use the difference of two distribution histograms as the distance measure). We assume the attribute correspondences \( h, h', w, w' \) are linear mappings, and the linear relation can be roughly estimated (e.g., by matching the minimum and maximum numbers in these rules). When computing the expectation over \( h \) and \( w \), we apply the linear mapping to generate corresponding values of \( h' \) and \( w' \). The distribution of the conditional attributes \( p(h, w) \) can be roughly estimated as independent and uniform over the ranges of the attributes.

The second method for handling continuous attributes is to discretize them, reducing the continuous attribute problem to the discrete problem described earlier. For example, suppose each continuous attribute \( x \) is replaced with a discrete attribute \( x_d \), indicating the quartile of \( x \) rather than its original value. Then we have \( R_5(h', a, w', \text{Center}) \) and \( R_5(h', b, w', \text{Center}) \) with relation \( R_5(a, b, c) : a = 4 \land b = 4 \Rightarrow c \), and the discrete value of 4 indicates that both \( a \) and \( b \) are in the top quartile. Other discretization methods are also possible, as long as the discretization is done the same way (e.g., equal-width) in both domains.

Our method does not rely on the forms of knowledge rules, nor does it rely on the algorithms used to learn these rules. As long as similar data mining techniques or tools are used on both sides of ontologies, we would always be able to find interesting knowledge-similarity between the two ontologies.

Complex Correspondences

Our approach can also find complex correspondences, which contain complex concepts in either or both of the ontologies. We add the complex concepts into consideration and treat them the same way as simple concepts, and all the simple and complex correspondences will be solved jointly by considering terminology, structure, and knowledge-based strategies in a single probabilistic formulation.

First, because complex concepts are recursively defined and potentially infinite, we need to select a finite subset of complex concepts and use them to generate the candidate correspondences. We will only include the complex concepts occurring in the ontology axioms or in the knowledge rules.

Second, we need to define a string similarity measure for each type of complex correspondence. For example, \( \text{Example 6} \) requires two conditions for a Class by Attribute Type (CAT) matching pattern \( O_1 : a \equiv O_2 : \exists p.b \) (e.g., \( a = \text{Accepted Paper}, p = \text{hasDecision}, b = \text{Acceptance} \)): \( a \) and \( b \) are terminologically similar, and the domain of \( p \) in the example is a superclass of \( a \). We can therefore define the string similarity of \( a \) and \( b \) which coincides with the first condition, and the second condition is encoded in the structure stability constraints. The string similarity measure of many other types of correspondences can be defined similarly based on the heuristic method in \( \text{Ritze et al. 2008} \).

If there does not exist a straightforward way to define the string similarity for a certain type of complex correspondences, we can simply set it to 0 and rely on other strategies to identify such correspondences.

Lastly, we need constraints for the correspondence of two complex concepts. The corresponding component concepts and same constructor always implies the corresponding complex concepts, while in the other direction, it is a soft constraint.

\[
\begin{align*}
\text{match}(a, a') \land \text{match}(b, b') \land \ldots \Rightarrow \text{match}(c, c') \\
\text{match}(a, a') \land \text{match}(b, b') \land \ldots \Leftarrow \text{match}(c, c')
\end{align*}
\]

where \( c = \text{cons}_k(a, b, \ldots), c' = \text{cons}_k(a', b', \ldots) \) for each constructor \( \text{cons}_k \) (e.g., union, \( \exists p.b \)).

Some complex correspondences are almost impossible to be identified with traditional strategies. With the knowledge-based strategy, it becomes possible.

\[\text{Example 6.} \] A reviewer of a paper cannot be the paper’s author. In the cnt ontology we have
\[
\text{writePaper} \subseteq \neg \text{readPaper}
\]

and in the conference ontology we have
\[
\text{contributes} \mid \text{Reviewed} \equiv \neg (\text{contributes} \circ \text{reviews})
\]

We first build two complex concepts \( \text{contributes} \mid \text{Reviewed} \equiv \neg (\text{contributes} \circ \text{reviews}) \). With \( R_1(a, b) = a \subseteq \neg b \) (disjoint properties), the score function would favor the correspondences
\[
\text{writePaper} \equiv \text{contributes} \mid \text{Reviewed} \equiv \neg (\text{contributes} \circ \text{reviews})
\]

Experiments

We test our KAOM approach on three domains: NBA, census and conference. The sizes of the ontologies of these domains are listed in Table 2. These domains contain very different forms of ontologies and knowledge rules, so we can examine the generality and robustness of our approach.

We use Pellet \( \text{Sirin et al. 2007} \) for logical inference of the ontological axioms and TheBeast\( ^2 \) \( \text{Riedel 2008} \) and RockIt\( ^1 \) \( \text{Noessner, Niepert, and Stuckenschmidt 2013} \) for Markov logic inference. We compare our system (KAOM) with three others: KAOM without the knowledge-based

\[\text{http://code.google.com/p/thebeast/}, \text{http://code.google.com/p/rockit/}\]
strategy (MLOM), CODI (Huber et al. 2011) (a new version of (Niepert, Melicke, and Stuckenschmidt 2010), which is essentially a different implementation of MLOM), and logmap2 (Jiménez-Ruiz, Grau, and Zhou 2012), a top performing system in OAEI 2014.

We manually specify the weights of the Markov logic formulas in KAOM and MLOM. The weights of stability constraints for subclass relationships are set with values same as the ones used in (Niepert, Melicke, and Stuckenschmidt 2010), i.e., the weight for subclass is -0.5, and those for sub-domain and range are -0.25. In KAOM, we also set the weights for different types of similarity rules based on our assessment of their relative importance and kept these weights fixed during the experiments.

**NBA**

The NBA domain is a simple setting that we use to demonstrate the effectiveness of our approach. We collected data from the NBA official website and the Yahoo NBA website. For each ontology, we used the WinMine toolkit to learn a decision tree for each attribute using the other attributes as inputs.

For each pair of conditional distributions based on decision tree with up to three attributes, we calculate their similarity based on the distance measure described in Example 5. We use the Markov logic formula (6) with the threshold $d_0 = 0.2$. To make the task more challenging, we did not use any name similarity measures. Our method successfully identified the correspondence of all the numerical and nominal attributes, including height, weight and positions (center, forward and guard) of players. In contrast, without a name similarity measure, no other method can solve the matching problem at all.

**Census**

We consider two census datasets and their ontologies from UC Irvine data repository. Both datasets represent census data but are sampled and post-processed differently. These two census ontologies are flat with a single concept but many datatype properties and nominal values. For this domain, we use association rules as the knowledge. We first discretize each numerical attribute into five intervals, and then generate association rules for each ontology using the Apriori algorithm with a minimum confidence of 0.9 and minimum support of 0.001. For example, one generated rule is:

```latex
\text{age} = ('(-inf-25.5)', education = '11th'), \text{hours-per-week} = ('(-inf-35.5)'), \Rightarrow \text{gross-income} = '<=50K' \text{ conf: } (1)
```

This is represented as

$$R_6(\text{age}^d, \text{11th}, \text{hours-per-week}^d, \text{gross-income}^d)$$

where $x^d$ refers to the discretized value of $x$, split into one fifth percentile intervals, and $R_6(a, b, c, d) : a = 1 \land b \land c = 1 \Rightarrow d = 1$. For scalability reasons, we consider up to three concepts in a knowledge rule, i.e., association rules with up to three attributes. We set the weight of knowledge similarity constraints for the association rules to 0.25.

![Figure 1: Precision, recall and F1 on the census domain as a function of the string similarity threshold $\tau$.](image)

In the Markov logic formulation in (Niepert, Melicke, and Stuckenschmidt 2010), only the correspondences with apriori similarity measure larger than a threshold $\tau$ are added as evidence. In the experiments, we set $\tau$ with different values from 0.50 to 0.90. When $\tau$ is large, we deliberately discard the string similarity information for some correspondences. MLOM for this task is an extension of (Niepert, Melicke, and Stuckenschmidt 2010) by adding correspondences of nominal values and their dependencies with the related attributes. The results are shown in Figure 1. We can see that KAOM always gets better recall and F1, with only a slight degradation in precision. This means our approach fully leverages the knowledge rule information and thus does not rely too much on the names of the concepts to determine the mapping. For example, when $\tau = 0.70$, KAOM finds 6 out of 8 correspondences of values of adult:workclass and income:class_of_worker, while MLOM finds none. The other two systems were not designed for nominal value correspondences, but CODI only identified 7 and logmap2 only identified 3 attribute correspondences, while KAOM and MLOM find all the 12 attribute correspondences.

OntoFarm

In order to show how our system can use manually created expert knowledge bases, we use OntoFarm, a standard ontology matching benchmark for an academic conference domain as the third domain in our experiments. As part of OAEI, it has been widely used in the evaluation of ontology matching systems. The process of manually knowledge rule creation is time consuming, so we only used 5 of the OntoFarm ontologies (cmt, conference, confOf, edas, ekaw). Using their knowledge of computer science conferences and the structure of just one ontology, two individuals listed a number of rules (e.g., Example 1). We then translated these rules into each of the five ontologies. Thus, the same knowledge was added to each of the ontologies, but its representation depended on the specific ontology. For some ontologies, some of the rules were not representable with the concepts in them and thus had to be omitted. This manually constructed knowledge base was developed before running any experiments and kept fixed throughout our experiments. Among the 5 ontologies, we have 10 pairs of matching tasks in total. We set \( \tau \) to 0.70, and the weight for the knowledge similarity constraints to 1.0.

We first compare the four methods to the reference one-to-one alignment from the benchmark (Figure 2). KAOM achieves similar precision and F1, and better recall than other systems. It was able to identify correspondences in which the concept names are very different, for instance, cmt:readPaper \equiv \text{confOf:reviews}. Note that the similarity constraints work in concert with other constraints. For instance, in Example 4, since disjointness is a symmetric knowledge rule, domain and range constraints could be helpful to identify whether cmt:writePaper should match to confOf:writesOf\text{confOf:reviews}.

To evaluate our approach on complex correspondences, we extended the reference alignment with hand-labeled complex correspondences (Figure 3). MLOM does not perform well in this task because the complex correspondences require a good similarity measure to become candidates (such as the linguistic features in Ritze et al. 2008). KAOM, however, uses the structure of the rules to find many complex correspondences without relying on complex similarity measures. For this task we also tried learning the weights of the formulas (KAOM-learn). For each of the 10 pairs of ontologies, we used the rest 9 pairs as training data. KAOM-learn performs slightly better than KAOM.

With the hand-picked or automatically learned weights, KAOM produces a single most-likely alignment. However, we can further tune KAOM to produce alignments with higher recall or higher precision. We accomplish this by adding the MLN formula \( \text{match}(a, a') \) with weight \( w \). When \( w \) is positive, alignments with more matches are more likely, and when \( w \) is negative, alignments with fewer matches are more likely (all other things being equal). We adjusted this weight to produce the precision-recall curve shown in Figure 4. KAOM dominates CODI and provides much higher recall values than logmap2, although logmap2’s best precision remains slightly above KAOM’s.

Conclusion

We proposed a new ontology matching algorithm KAOM. The key component of KAOM is the knowledge-based strategy, which is based on the intuition that ontologies about the same domain should contain similar knowledge rules, in spite of the different terminologies they use. KAOM is also capable of discovering complex correspondences, by treating complex concepts the same way as simple ones. We encode the knowledge-based strategy and other strategies in Markov logic and find the best alignment with its inference tools. Experiments on the datasets and ontologies from three different domains show that our method effectively uses knowledge rules of different forms to outperform several state-of-the-art ontology matching methods.
