First-principles theory of extending the spin qubit coherence time in hexagonal boron nitride

Jaewook Lee, Huijin Park and Hosung Seo

Negatively charged boron vacancies (VB−) in hexagonal boron nitride (h-BN) are a rapidly developing qubit platform in two-dimensional materials for solid-state quantum applications. However, their spin coherence time (T2) is very short, limited to a few microseconds owing to the inherently dense nuclear spin bath of the h-BN host. As the coherence time is one of the most fundamental properties of spin qubits, the short T2 time of VB− could significantly limit its potential as a promising spin qubit candidate. In this study, we theoretically proposed two materials engineering methods, which can substantially extend the T2 time of the VB− spin by four times more than its intrinsic T2. We performed quantum many-body computations by combining density functional theory and cluster correlation expansion and showed that replacing all the boron atoms in h-BN with the 10B isotope leads to the coherence enhancement of the VB− spin by a factor of three. In addition, the T2 time of the VB− can be enhanced by a factor of 1.3 by inducing a curvature around VB−. Herein, we elucidate that the curvature-induced inhomogeneous strain creates spatially varying quadrupole nuclear interactions, which effectively suppress the nuclear spin flip-flop dynamics in the bath. Importantly, we find that the combination of isotopic enrichment and strain engineering can maximize the T2 time of VB−, yielding 207.2 μs and 161.9 μs for single- and multi-layer h-10BN, respectively. Furthermore, our results can be applied to any spin qubit in h-BN, strengthening their potential as material platforms to realize high-precision quantum sensors, quantum spin registers, and atomically thin quantum magnets.

INTRODUCTION

Optically addressable spin defects in wide band-gap materials are promising solid-state qubit platforms that enable cutting-edge quantum applications such as quantum computation1, quantum sensing2, and quantum network3,4. Spin defects in diamond5, which show long spin coherence times and many other attractive features such as high-temperature quantum functionality6 and spin-to-photon interfaces7, is one of the leading qubit systems for quantum applications. Progresses made in the research on diamond have inspired several pioneering studies, wherein quantum spin defects have been developed in silicon carbide and nitrides, broadening the palette of spin qubits in materials8–11. Notably, the spin qubits in non-diamond hosts provide unique opportunities for building advanced platforms for quantum systems by taking advantage of the well-established material technologies developed for their hosts12,13. Recently, the search for qubit systems in two-dimensional (2D) van der Waals (vdW) materials has gained significant attention owing to their potential superiority in light extraction, heterostructuring, defect positioning, strain engineering, and nano-photonic integration14–17. Among the 2D vdW materials, quantum spin defects in hexagonal boron nitride (h-BN) are gaining prominence for the development of optically active spin qubits. Owing to its wide bandgap of ~6 eV, h-BN hosts a variety of color centers from near infrared to ultraviolet15,16,18. Some of the color centers have been found to emit bright single photons even at room temperature, and these findings have sparked worldwide research efforts in this direction19–25. Subsequently, the search for optically addressable spin qubits in h-BN has become the focus of materials research, and several breakthroughs have been made recently. Notably, negatively charged boron vacancies (VB−) were discovered as optically addressable spin qubits in h-BN26–28. Since the first report by Gottscholl et al.26, several important achievements have been made29, including the realization of coherent Rabi oscillations30, deterministic defect generations31–33, nano-scale quantum sensing34, and coupling to nano-photonic structures35. In addition, carbon-related defects36–38 and boron vacancy complexes have also been recently identified as optically accessible spin qubits in h-BN. Overall, significant advances have been made in the development of defect-based spin qubits in h-BN and their use in quantum applications. Nonetheless, further research is required to realize robust spin qubits in h-BN.

One of the most compelling issues for h-BN spin qubits is their short spin coherence time (T2) due to the dense nuclear spin bath in the h-BN lattice26,39. For VB−, the Hahn-echo T2 time has been measured to be several microseconds26. Notably, several well-known schemes, such as isotopic purification40, dynamical decoupling (DD)41, and clock transitions (CT)42,43, are available to extend the spin coherence times in materials. However, in h-BN, a conventional isotopic purification is impossible because all the naturally occurring boron (10B and 11B) and nitrogen (14N and 15N) isotopes exhibit non-zero nuclear spins. In addition, the coherence protection schemes such as DD and CT are often limited by the intrinsic Hahn-echo T2 time. When the T2 time is extremely short like in h-BN, pulse requirements in the DD and CT schemes become considerably challenging11. Considering the fundamental role of the coherence time in determining the retention time of the quantum information, the short T2 time of the h-BN spin qubits is one of the most pressing problems that needs to be solved for advancing these platforms in h-BN. In this study, by taking the VB− spin as a representative spin qubit system in h-BN, we developed two unconventional methods to enhance the T2 time of spin qubits significantly in h-BN via...
isotopic enrichment and strain engineering. We combined density functional theory (DFT) and cluster correlation expansion (CCE) to compute the theoretical T₂ time of V₃⁺ in h-BN single layer and multiple layers to be 45.9 μs and 26.6 μs, respectively, in the presence of an intrinsic nuclear spin bath in natural h-BN. Subsequently, we showed that the T₂ times increased to 143.4 and 81.1 μs in the single- and multi-layer h-BN, respectively, which is enriched with the ¹⁰B isotope. This result is somewhat counterintuitive as the ¹⁰B isotope has a larger nuclear spin (I = 3) than that of the ¹⁴B isotope (I = 3/2). We found that this T₂ enhancement by a factor of three resulted from the smaller gyromagnetic ratio of ¹⁰B than that of ¹⁴B, despite the much larger nuclear spin of ¹⁰B. In addition, we demonstrated that the T₂ time could be further increased to 207.2 μs and 161.9 μs for the single- and multi-layer h-BN, respectively, by inducing inhomogeneous strain around the V₃⁺. We considered a Gaussian-shaped bubble around V₃⁺ as a representative inhomogeneous strain and showed that the T₂ increased in proportion to the Gaussian width and height, demonstrating the impact of the local inhomogeneous strain on the T₂ time. We found that a spatial inhomogeneity in the nuclear spin quadrupole interaction effect, induced by the inhomogeneous strain, plays a crucial role in suppressing the nuclear spin flip-flop dynamics, thus enhancing the V₃⁺ spin coherence. Our results pave the way for effective protection of the spin coherence in h-BN, and this method should be applicable to V₅⁺ as well as to any potential spin qubits in h-BN. Improved spin coherence of V₅⁺ would also open possibilities of further coherence extension using DD or CT, thereby advancing spin qubits in h-BN as promising platforms for quantum information science and technology.

RESULTS
Spin decoherence of V₃⁺ in natural h-BN

We considered a central spin model to compute the decoherence dynamics of a V₃⁺ spin interacting with the nuclear spin bath in the h-BN lattice. Figure 1a shows a schematic of the spin model, in which a V₃⁺ defect is created in the middle of a large h-BN supercell. The ground state of V₃⁺ is a spin-triplet state, and the spin density is highly localized at the vacancy site (see inset of Fig. 1a). In our model, we assumed a localized S = 1 at the vacancy site and treated its +1 and 0 spin sublevels as qubit states. The nuclear spin bath, which strongly interacts with the V₃⁺ spin via hyperfine interaction, is derived from the spin-bearing boron and nitrogen nuclei in h-BN. Notably, all the naturally occurring boron and nitrogen isotopes exhibit non-zero nuclear spins: 19.9% of ¹⁰B with I = 3, 80.1% of ¹⁰B with I = 3/2, 99.6% of ¹⁴N with I = 1, and 0.4% of ¹⁵N with I = 5/2. In our model, we randomly distributed the nuclear spins in the h-BN lattice according to their natural abundance. To compute the homogeneous dephasing time (T₂) of the V₃⁺ spin, we considered the Hahn-echo pulse sequence and used the CCE method to expand the many-body nuclear-spin correlation effects systematically on the V₃⁺ spin decoherence. Notably, the CCE method combined with DFT calculations enables the quantum many-body computation of T₂ without the assumption of any adjustable theoretical parameter. Owing to its predictive power, the CCE method was successfully applied to a wide range of solid-state qubit systems, yielding excellent agreement with the experimental results (further details on the theoretical methods and the system’s spin Hamiltonian are provided in the Method and Supplementary Information sections; see Supplementary Note 1 and 2, and Supplementary Fig. 1).

Figure 1b presents the computed spin coherence of V₃⁺ in the bulk of natural h-BN. Evidently, the spin coherence rapidly decays during the free evolution time, within tens of microseconds. By fitting the coherence with a stretched exponential function (exp(-t/τ)^n), we computed the T₂ time and stretching exponent (n) of the decay to be 26.64 μs and 2.64, respectively. In addition, we determined T₂ and n of the V₃⁺ spin in the single-layer h-BN to be 45.85 μs and 2.27, respectively, owing to the reduced number of nuclear spins surrounding V₃⁺ (see Supplementary Fig. 2). Notably, the computed T₂ time corresponds to the upper limit of T₂ set by the intrinsic nuclear spin bath of h-BN. The experimentally measured T₂ time can be smaller than the theoretical T₂, if other decoherence sources such as other paramagnetic defects are present in h-BN.

To examine the nuclear bath dynamics generating the intracrystalline magnetic noise, we analyzed the impact of the spin Hamiltonian terms on the V₃⁺ spin decoherence. Importantly, we find that the nuclear quadrupole interaction plays an important role in determining the bath dynamics in h-BN. Figure 1b shows the V₃⁺ decoherence computed with a partial spin Hamiltonian in which the magnetic Hamiltonian terms are excluded from the model. We observe that the spin coherence decays much faster in the “without-the-quadrupole” model than in the “with-the-quadrupole” model. Without the quadrupole interaction effect in the model, the T₂ time of V₃⁺ is reduced to 17.92 μs and 34.98 μs for the multi- and single-layer h-BN, respectively. Notably, the nuclear spin flip-flop transitions, driven by the magnetic dipolar coupling between the nuclear spins, are the dominant sources of intracrystalline magnetic noise in a nuclear spin bath. Our results show that the quadrupole interaction in h-BN plays a significant role in suppressing such nuclear flip-flop transitions in the h-BN.

To understand the role of quadrupole interaction in the pairwise nuclear spin transitions, we show the energy levels of two ¹⁰B nuclear spins, defined as |m_i, m_j⟩, where m_i = 3, 2, 1, 0, −1, −2, −3, in Fig. 1c–e. Figure 1c shows the energy level splitting due to the Zeeman interaction (H₂) and hyperfine field imposed by the V₃⁺ spin (H₁). The Zeeman splitting yields spin manifolds, which are separated from each other in energy by 13.7 MHz in the presence of an external magnetic field of 3 T. Each manifold contains certain number of two-spin states such as |−3, −1⟩, |−2, −2⟩, |−1, −3⟩, which have the same Zeeman energy, as shown in Fig. 1d. These states in a manifold are split by a small energy of the order of hundreds of Hz because of the hyperfine field (denoted as ΔHF in Fig. 1d). In the “without-the-quadrupole” decoherence model, the magnetic dipolar interaction drives the flip-flop transitions between the states, confined in each manifold, with a transition rate of hundreds of Hz because of the hyperfine field (denoted as ΔΩ HF in Fig. 1d). However, the transitions are strongly suppressed between the states belonging to different manifolds because of a large Zeeman energy mismatch. Remarkably, the energy levels in a manifold exhibit significant splitting in the presence of the quadrupole interaction, as shown in Fig. 1e. We found that the quadrupole-induced splitting (ΔΩ Q in Fig. 1e) ranges from tens of kHz to a few MHz, owing to the large nuclear quadrupole interaction in h-BN (see Table 1). Thus, the flip-flop transitions within a Zeeman manifold are significantly suppressed, compared to those evaluated using the “without-the-quadrupole” model, because of the large quadrupole-driven energy mismatch. Our analysis reveals the importance of the quadrupole interaction in determining the nuclear bath dynamics, which in turn governs the spin decoherence of the spin qubits in h-BN.

Isotopic enrichment of h-BN to increase T₂

Figure 2 depicts the computed T₂ of V₃⁺ in h-BN as a function of the composition ratio of ¹⁰B and ¹⁴N in h-BN. Surprisingly, we find that the T₂ time substantially increases as the ratio of ¹⁰B and ¹⁴N increases toward 100% in the lattice, despite their larger nuclear spins than those of ¹¹B and ¹⁵N. When h-BN is 100% enriched with ¹⁰B and ¹⁴N (i.e., h-¹⁰B¹⁴N), the T₂ time is increased to 143.39 μs and 81.11 μs in the single- and multi-layer h-¹⁰B¹⁴N, respectively. These values are three times larger than those in natural h-BN.
In contrast, the $T_2$ times in single- and multi-layer h-10B are 45.85 μs and 26.64 μs, respectively, which are unanticipated, because a smaller nuclear spin (e.g., $I_{10B} = 1/2$ vs. $I_{11B} = 3/2$ of 10B) results in a smaller number of flip-flop transition channels in the nuclear spin–spin interaction as well as lower intracrystalline magnetic noise in h-11B than in h-10B. However, our results show that the opposite is true—the intracrystalline magnetic noise is significantly reduced in h-10B.

To elucidate the microscopic origin of the enhanced $T_2$ in h-10B, we consider a hypothetical central spin model, where the magnetic dipolar coupling strength is proportional to $(r_{ij})^3$, the magnetic dipolar interactions (denoted as $\Delta_{HF}$), whereas it is given by both the hyperfine and quadrupole interactions (denoted as $\Delta_{HF+Q}$).

**Table 1.** Electric field gradients in h-BN, and the corresponding quadrupole coupling constants ($eQ_{Vzz}$) computed using DFT.

| Isotopes | $V_{xx}$ (eV/Å$^2$) | $V_{zz}$ (eV/Å$^2$) | $eQ_{Vzz}$ (MHz) | $eQ_{Vzz}$ (Exp.) (MHz) |
|----------|---------------------|---------------------|-----------------|---------------------|
| $^{10B}$ | -15.450             | 30.901              | 6.260           | 6.1                 |
| $^{11B}$ | -15.450             | 30.901              | 3.004           | 2.9                 |
| $^{15N}$ | -2.478              |                     | 0.23            | 0.2                 |

respectively, we consider the range of $y_B$ to be from 1 to 10 rad G$^{-1}$ ms$^{-1}$, and that of $I_B$ from 1/2 to 3 in Fig. 3. We find that for a given $y_B$, the $T_2$ time decreases as $I_B$ increases, indicating that the intracrystalline magnetic noise increases as the total number of nuclear spin flip-flop channels in the bath (proportional to $(I_B)^2$) increases. In addition, $T_2$ increases quadratically as $y_B$ decreases. For instance, for $I_B = 3/2$, the $T_2$ changes from 24 μs to 695 μs when $y_B$ changes from 10 to 1 rad G$^{-1}$ ms$^{-1}$. The $y_B$-dependent change in $T_2$ observed mainly because the magnetic dipolar coupling strength is proportional to $(y_B)^2$. Thus, decreasing $y_B$ reduces the flip-flop transition rate quadratically in the nuclear spin bath. In h-10B, the total number of flip-flop transitions is increased by four times, but the flip-flop transition rate is substantially decreased by approximately nine times compared to those in h-11B.

In the case of $^{14N}$ isotope, the same analysis yields four times larger number of flip-flop transition channels and approximately two times smaller flip-flop transition rates in h-B$^{14N}$ compared to those in h-B$^{15N}$. Therefore, based on the result shown in Fig. 3, we can conclude that in h-BN, the spin coherence of VB is much more sensitive to the change in $y_B$ than that in $I_B$, and the increased $T_2$ in h-B$^{14N}$ stems from the smaller $y_B$ of the $^{10B}$ and $^{14N}$ nuclear spins despite their larger nuclear spin numbers.
**Effects of inhomogeneous lattice strain on spin coherence**

Next, we investigate the impact of inhomogeneous lattice strain on the $T_2$ of $V_{B^-}$ spin in h-BN. We consider a curved h-BN to create an inhomogeneous strain around $V_{B^-}$. Reportedly, various feasible methods have been developed to study the curvature-induced phenomena in h-BN by creating bubbles, pillars, folds, and wrinkles. As a representative model of the local curvature and inhomogeneous strain, we consider a Gaussian lattice deformation as illustrated in Fig. 4a. The lattice deformation can be described in terms of the full width at half maximum (FWHM) and height of the Gaussian function, and the $V_{B^-}$ defect is created on top of the Gaussian deformation. To cross-check the dependence of our results on the shape of lattice deformation, we also considered two other types of lattice deformations, which are Lorentzian-shape and pillar-shape deformations (see Supplementary Fig. 3). We employed DFT to compute the spin Hamiltonian parameters in the deformed h-BN lattice. The computed effects were subsequently included into the spin Hamiltonian to examine the effect of the inhomogeneous lattice strain on the spin coherence of $V_{B^-}$.

**Fig. 3** Hypothetical $T_2$ of $V_{B^-}$ in h-BN. Computed $T_2$ as a function of the gyromagnetic ratio and nuclear spin number of $^{10}$B in h-$^{10}$B-$^{14}$N. An external magnetic field of 3 T is applied.

**Fig. 2** Enhancement of $T_2$ in h-BN via isotopic engineering. a, b Computed $T_2$ of the $V_{B^-}$ spin in a monolayer h-BN and b multi-layer h-BN as a function of the ratio of $^{14}$N and $^{10}$B nuclei in the lattice. An external magnetic field of 3 T is applied. The maximum $T_2$ time is obtained when h-BN is 100% enriched with $^{10}$B both in the single- and multi-layer configurations, yielding a $T_2$ of 143 µs and 81 µs, respectively.

Figure 4b shows the computed $T_2$ time of the $V_{B^-}$ in natural h-BN (no isotopic modification) as a function of the FWHM and height of the Gaussian lattice deformation. Evidently, the $T_2$ time increases significantly with the increasing function height and FWHM. At a Gaussian height of 3.5 Å, the $T_2$ in the single- and multi-layer h-BN is 58.7 µs and 34.2 µs, respectively, as shown in Fig. 4b. These values are 12.9 µs and 7.5 µs greater than those in natural and flat h-BN. In Supplementary Fig. 4, we computed the $V_{B^-}$ spin decoherence in the presence of the Lorentzian-shape and pillar-shape lattice deformations. We found that the $V_{B^-}$ spin coherence is consistently enhanced in these situations: when the deformation height is 3.5 Å, the $T_2$ time in the single-layer h-BN reaches 54.6 µs and 72.2 µs in the presence of the Lorentzian- and pillar-shape deformations, respectively. This result shows that the $T_2$ enhancement due to inhomogeneous strain is valid regardless of lattice deformation shapes.

To understand the curvature-induced enhancement of the $T_2$ time, we analyze the impact of the lattice deformation on the $V_{B^-}$ spin decoherence in terms of two factors: modification of the nuclear spin–spin distances and spatial inhomogeneity induced in the nuclear spin quadrupole interaction in the deformed h-BN lattice. In Supplementary Fig. 6, we consider a model that does not include the nuclear spin quadrupole interaction, and compute $T_2$ as a function of FWHM and function height same as before (Fig. 4). We find that the $T_2$ time shows negligible changes, as shown in Supplementary Fig. 6, implying that the enhanced $V_{B^-}$ spin coherence, obtained using the Gaussian lattice deformation, is not derived from the mere modification of the nuclear spin–spin distances; instead, it is mediated by the modified nuclear quadrupole interaction produced by the inhomogeneous strain.

To visualize the role of nuclear quadrupole interaction in determining the strain-driven enhancement of $T_2$, we compute the first-order quadrupole-interaction-induced energy shift ($\xi$) of a nuclear spin in h-BN. As described in Supplementary Note 3, the energy shift is calculated as $Q_c \times \xi \times (3m^2 - I(I+1))$, where $Q_c$ is the coefficient of quadrupole interaction (6), and $\xi = V_{zz} - (V_{xx} + V_{yy})/2$, where $V_{ii}$ ($i = x, y, z$) is the electric field gradient computed using DFT. Figure 5a–c shows $\xi$ as a function of position with respect to the $V_{B^-}$ site, indicating that a difference of $\xi$ between two different points, shown in Fig. 5a–c, is proportional to the difference between the quadrupole-induced energy shifts of the two nuclear spins at these two different points. As shown in Fig. 5a–c, the inhomogeneity of $\xi$ becomes broader and larger as the Gaussian lattice deformation increases. In Supplementary Fig. 7, we also show...
the quadrupole coupling constant ($C_q = eQV_{zz}/\hbar$) and the asymmetry parameter ($\eta_{As} = (V_{xx} - V_{yy})/V_{zz}$) in the presence of the lattice deformation. In terms of the $^{10}\text{B}-^{11}\text{B}$ two-spin energy levels presented in Fig. 1e, a larger difference of $\zeta$ between two $^{10}\text{B}$ spins results in a larger level splitting in their two-spin energy levels.

Nuclear spin flip-flop transitions are well understood in terms of a pseudospin model\textsuperscript{48,52}, which can model a flip-flop transition between any two $^{10}\text{B}$ nuclear spin states having the same Zeeman energy. The two states of a pseudospin are separated by an energy gap ($\Delta$), and the transition between them is mediated by the magnetic dipolar interaction with a flip-flop transition rate ($\Omega$) (see Supplementary Note 4). Figure 5d, e shows the histogram of (log($\Omega/\Delta$)) for all the possible pseudospins in the Gaussian-deformed h-BN. Notably, a small log($\Omega/\Delta$) indicates a high suppression in the flip-flop transition. Furthermore, a large Gaussian deformation around the $V_{8^-}$ defect produces a large number of pseudospins with small log($\Omega/\Delta$) values appearing in the histogram. Our results demonstrate that the energy gap between numerous $^{10}\text{B}-^{11}\text{B}$ pseudospins in h-BN increases as the Gaussian lattice deformation becomes larger, which in turn produces a larger inhomogeneous strain around $V_{8^-}$. This results in a considerable suppression of the nuclear flip-flop transitions in h-BN, leading to the enhancement of the $T_2$ time of $V_{8^-}$.

**Maximizing the spin coherence time**

The two methods suggested in this study can be combined to maximize the $T_2$ time. Figure 6a, b presents the computed $T_2$ as a function of the Gaussian height and FWHM for the $V_{8^-}$ in the Gaussian-deformed $^{10}\text{B}-^{11}\text{B}14\text{N}$. Evidently, the maximum achievable $T_2$ is 207.17 $\mu$s and 161.92 $\mu$s in the single- (Fig. 6c) and multi-layer h-BN (Fig. 6d), respectively. These values are approximately six times larger than that in natural and flat h-BN. Supplementary Fig. 5 shows the $V_{8^-}$ spin decoherence in the Lorentzian-deformed single-layer $^{10}\text{B}-^{11}\text{B}14\text{N}$ and in the presence of pillar-shaped lattice deformation as well. We found that $T_2$ time reaches 188.9 $\mu$s and 308.4 $\mu$s for the Lorentzian- and the pillar-shaped deformation, respectively, in the single-layer $^{10}\text{B}-^{11}\text{B}14\text{N}$. We remark that the combined effect of the smaller gyromagnetic ratio of $^{11}\text{B}$ and the inhomogeneous quadrupole interaction induced by the inhomogeneous strain leads to the enhancement of $T_2$ of the $V_{8^-}$ spin.

**DISCUSSION**

In summary, we proposed two theoretically effective methods to extend the spin coherence time of the $V_{8^-}$ spin qubit in h-BN. The spin coherence time is otherwise limited to a few microseconds because of the strong intracrystalline magnetic noise caused by the dense nuclear spin bath in the h-BN lattice. To predict the $T_2$ time of the spin qubit accurately, we performed first-principles calculations by combining the DFT and CCE theory. In a natural h-BN host, the theoretical upper limit of the $V_{8^-}$ $T_2$ time is 45.85 $\mu$s and 26.64 $\mu$s in single- and multi-layer h-BN, respectively. Next, we demonstrated that the $T_2$ time can be increased to 143.39 $\mu$s and 81.11 $\mu$s in single- and multi-layer h-BN, respectively, in which all the boron atoms in the lattice are replaced by the $^{10}\text{B}$ isotope. It is evident that such an isotopic enrichment technique has been already developed and applied to h-BN\textsuperscript{59,60}. By analyzing the magnetic dipolar interaction between the boron nuclear spins, we showed that the smaller gyromagnetic ratio of $^{10}\text{B}$ plays a key role in suppressing the nuclear flip-flop dynamics, despite its large nuclear spin compared to that of $^{11}\text{B}$. Then, we showed that the $T_2$ time of $V_{8^-}$ can be further increased by introducing an inhomogeneous strain around the $V_{8^-}$ defect. Applying a Gaussian-type lattice deformation (as a representative model of the inhomogeneous strain), we identified that the inhomogeneous strain contributes to the suppression of the nuclear spin flip-flop dynamics in the bath by producing spatially varying nuclear quadrupole interactions in h-BN. We found that applying both the isotopic enrichment and inhomogeneous strain could increase the $T_2$ time of $V_{8^-}$ by six times that in a pristine h-BN.
FWHW = the possible pseudospins in h-BN with Gaussian lattice deformation, where FWHW = 2.5 Å and FWHW = 4 Å, and the structures used for (a), (b), and (c) are the same as those shown in Fig. 4a, characterized by a Z = 1.5 Å and FWHW = 4 Å, b Z = 2.5 Å and FWHW = 8 Å, and c Z = 3.5 Å and FWHW = 10 Å. e, f Histogram of log(Ω/Δ) of all the possible pseudospins in h-BN with Gaussian lattice deformation, where Ω is the flip-flop transition rate, and Δ is the energy gap of a pseudospin (see Supplementary Note 4). The h-BN structures used are characterized by d Z = 3.5 Å and FWHW = 10 Å, e Z = 1.5 Å and FWHW = 4 Å, and f Z = 2.5 Å and FWHW = 8 Å, which are schematically shown in Fig. 4a.

Our study on V_{6}^{−} not only provides a fundamental understanding of the decoherence of V_{6}^{−} spins in h-BN but paves the way to engineer their T2 times. With an increased T2 time, the V_{6}^{−} spin coherence could be further enhanced by combining other active quantum control schemes such as DD or CTs. In addition, the essential physics developed in this study can be applied to any localized spin in any 2D vdW material. Thus, the proposed approach provides a universal tool for engineering the coherence of potential spin qubits in 2D vdW materials. Combining these engineering schemes with the unique characteristics of 2D vdW materials would be a promising strategy for the development of robust low-dimensional quantum systems.

**METHODS**

**Quantum-bath approach for decoherence and CCE**

According to the quantum-bath theory, the spin qubit decoherence occurs because of the entanglement between the qubit and its environment\({eq}^{60}\. In our spin model, the V_{6}^{−} spin serves as a qubit, and the main environmental degrees of freedom are the nuclear spins residing in the h-BN lattice. The nuclear spins are coupled to each other via magnetic dipolar coupling, and the nuclear spin bath interacts with the qubit through hyperfine interactions. The full spin Hamiltonian for the entire quantum many-body system is described in Supplementary Note 1. To compute the homogeneous dephasing time\(T_{2}^\text{h}\) of the V_{6}^{−} ensembles, the Hahn-echo pulse sequence, which features a π pulse between two free evolution time t, is considered. The decoherence of the qubit is obtained by computing the off-diagonal elements of the reduced density matrix of the qubit after tracing out the bath degrees of freedom at the end of the 2π free evolution time, as: \(\mathcal{L}(2\tau) = \frac{\text{Tr}[S_{z}(2\tau)]}{\langle S_{z}(0) \rangle}\), where \(S_{z}\) is the electron spin raising operator, and \(\rho\) is the density operator of the entire system. To compute the coherence function, we employed the CCE method\(^{47,62}\), which systematically expands the coherence function. We find that the CCE expansion converges at the CCE-2 level of the theory, implying that the nuclear spin–spin pairwise correlation effect is the dominant source of decoherence. Extensive numerical convergence tests were performed in terms of the CCE order, bath size, and coupling radius, and the corresponding results are summarized in Supplementary Note 2 and Supplementary Fig. 1.

**DFT calculations**

We performed DFT calculations using plane-wave basis functions with an energy cutoff of 85 Ry, as implemented in the Quantum Espresso (QE) code\(^{63}\) and the GIPAW module\(^{64,65}\), to compute the nuclear quadrupole interaction and the hyperfine interaction in h-BN containing V_{6}^{−} with a Gaussian lattice deformation. We used the Perdew–Burke–Ernzerhof exchange-correlation functional along with the projector-augmented wave (PAW) pseudopotentials\(^{16,67}\). To simulate an isolated V_{6}^{−} defect in the h-BN, we used large supercells containing either single- or multi-layer h-BN. For the single-layer h-BN calculations, we built a 336-atom supercell starting from a 4-atom orthorhombic unit cell. The h-BN layer in the supercell was separated from its periodic images in the out-of-plane direction by a 10-Å-thick vacuum space. For the multi-layer h-BN, a 672-atom supercell was used.

To cross-check our results obtained with the orthorhombic supercell, we computed the spin Hamiltonian parameters and the V_{6}^{−} spin decoherence by using a 450-atom hexagonal supercell for h-BN. We show the results in Supplementary Tables 1, 2, 3, and Supplementary Figs. 8, 9 in Supplementary Information. We found that the computed EFG and hyperfine parameters obtained with the hexagonal supercell are consistent with the orthorhombic supercell results except for a few atoms near the V_{6}^{−} defect.

---

**Fig. 5 Inhomogeneous nuclear quadrupole interaction of \(^{10}\)B, induced by an inhomogeneous strain.** A Spatial map of the coefficient of first-order energy shift of the nuclear spins in curved h-BN, due to the quadrupole interaction, which is defined as \(\zeta = V_{zz} - (V_{xx} + V_{yy})/2\). Gaussian deformation is applied around the VB defect in the h-BN, with a spatial map of the coefficient of first-order energy shift of the nuclear spins in curved h-BN, due to the quadrupole interaction, which is defined as \(\zeta = V_{zz} - (V_{xx} + V_{yy})/2\). Gaussian deformation is applied around the VB defect in the h-BN.
In particular, the EFG parameters show a noticeable difference for a few N atoms near the VB− due to a slight difference in the atomic relaxation depending on the supercell shape (see Supplementary Fig. 8 and Supplementary Table 2). We found, however, that this difference did not affect the main conclusion of this study. In Supplementary Fig. 9, we compare the VB− spin decoherence in multi-layer h-BN, with Gaussian lattice deformation, as a function of FWHM and height of the Gaussian deformation function. Nitrogen in the lattice is 100% 14N. An external magnetic field of 3 T is applied.
