Cyclic Cold Stresses before Transplanting
Influence Tomato Seedling Growth, but Not Fruit
Earliness, Fresh-market Yield, or Quality

Clemson University, Coastal Research and Education Center, 2865 Savannah Highway, Charleston, SC 29414

Abstract. Tomato seedlings (Lycopersicon esculentum Mill. ‘Sunny’) were exposed to cyclic cold stress at 2 ± 1C, then to 29 ± 6C in a greenhouse before being transplanted to the field. Cold-stressed seedlings were transplanted when the risk of ambient cold stress was negligible. In the first year of a 2-year study, transplants were exposed to 2C for 3, 6, or 12 hours for 1, 3, or 6 days before field planting. In the second year, transplants were exposed to 2C for 6, 12, or 18 hours for 4, 7, or 10 days before field planting. In the first year, cold stress generally stimulated increases in seedling height, leaf area, and shoot and root dry weights but decreased chlorophyll content. In the second year, all seedling growth characteristics except leaf area and plant height were diminished in response to longer cold-stress treatment. In both years, earliness, total productivity, and quality were unaffected by any stress treatment. Therefore, cold stress occurring before transplanting has a negligible effect on earliness, yield, or quality.

Tomatoes are established in coastal South Carolina in the field by transplanting. The major benefit of transplant use is earlier production. However, stresses during the stand-establishment phase may delay plant development and may negate any benefit to earliness. Normally, many successive hand-harvests are required for acceptable yields. Because of high labor costs, methods to reduce harvest costs are desired. It is imperative, therefore, that transplanted tomatoes become established rapidly and uniformly to ensure maximum yield with few harvests.

To time the production to maximize returns, tomatoes in coastal South Carolina are transplanted near the last killing frosts. In some cases, late-season frosts may kill newly planted fields, or periods of cold weather may stagnate growth and establishment. It is not known whether cold stress occurring during the seedling phase retards growth and development over the course of the season. Previous studies with cotton (Christiansen and Thomas, 1969), carrots and lettuce (Currah, 1978), red beets (Hegarty and Thompson, 1974), and onions (Henriksen, 1978) have confirmed that stress incurred early in crop development reduced yield. Little research has been done on the long-term effects of short-term stresses on transplantable vegetable crops.

Customary methods of reducing stress in the field may involve proper acclimation of transplants by witholding water or exposing the transplants in holding areas to low temperatures. However, these techniques may inhibit tomato growth and development. The earliness of hardened tomato transplants in cold frames can be reduced in contrast to nonhardened plants (Brasher and Westover, 1937; Porter, 1936) that reported earliness and quality.

The cold-stress treatments consisted of factorial combinations of stress duration and frequency. In the first year, seedlings were exposed to 2C for 3, 6, or 12 hr (duration) for 1, 3, or 6 days (frequency) before field planting. In the second year, seedlings were exposed to 2C for 6, 12, or 18 hr for 4, 7, or 10 days before field planting. A non-stressed control was included each year. A 3 × 3 factorial combination of cold-stress duration and frequency treatments produced nine unique cold-stress regimes plus a nonstressed control. Speedling cell trays were cut into quarts and each quarter, representing one replication, contained six plants for transplant growth analysis and 10 plants.
for field planting. The experimental treatments were replicated four times, and the trays arranged in a randomized complete-block design in the greenhouse. Cold stress was accomplished by repeatedly moving the trays into an empty walk-in cooler (2 ± 1°C), using a schedule described in Table 1, and then back into a greenhouse (29 ± 6°C) after the prescribed time. All cold-stress treatments were planned to terminate at the same time for uniform transplant data collection and subsequent field planting.

The greenhouse growth period and cold-stress treatments were terminated 41 and 38 days after seeding in 1987 and 1988, respectively. The following growth variables were quantified: leaf area/seedling (including petioles) with a leaf area meter (Model LI-3000, LI-COR, Lincoln, Neb.); stem diameter (measured at cotyledon attachment); seedling height (measured from the medium surface to the approximate apical meristem tip); number of expanded true leaves (considered expanded if petiole easily visible); shoot and washed-root dry weights (dried at 65°C for 24 hr). Leaf disks (0.3 cm²) were removed from the second true leaf above the cotyledons and composed from five randomly selected plants per treatment and total chlorophyll was determined (Moran, 1982). Growth data were tested by analysis of variance (ANOVA) and mean separation performed using least significant difference. Orthogonal contrasts were performed comparing the effect of cold stress (pooled over all stress treatments) to the non-cold-stressed control. The relative importance of cold-stress duration and frequency was determined by partitioning the total sum of squares for treatments into main and interaction effects and expressing these individual contributions to variation as a percentage of the sum of squares for the model (composed of only those sources of variation in the ANOVA).

Cold stress vs. transplant shock, earliness, yield, and quality. The seedlings from the 10 temperature treatments were planted on 22 Apr. 1987 and 18 Apr. 1988 after all risk of ambient cold stress had passed at the Clemson Univ. Coastal Research and Education Center in Charleston, S.C. The soil type was a Yauhannah loamy fine sand, an aquic hapudults (pH 7.2). Before planting in 1987, the field was fertilized with 77N-55P-100K-39Ca kg·ha⁻¹; in 1988, the field was treated with 181N-69P-175K-36Ca kg fertilizer/ha and 355 kg dolomitic lime/ha. In both years, the beds were fumigated with methyl bromide and mulched with black plastic mulch. In 1987, overhead irrigation was used; in 1988, drip irrigation tubing was buried on the east shoulder of the beds before mulching. Plants were spaced 46 cm apart within rows on 1.8-m beds (≈ 27,000 plants/ha). A treatment plot consisted of one row, 4.6 m long, and contained 10 plants. Each treatment plot was replicated four times in a randomized complete-block design. The plots were irrigated when needed as indicated by tensiometers. The plants were staked, tied up with 'strings, and all lateral shoots were removed below the first flower cluster, except the first lateral directly below this cluster.

The long-term effects of cold stress on transplant growth and development in the field were monitored. In this study, transplant shock was defined as the percentage of all leaves on a plant exhibiting serious necrosis, chlorosis, or damage. Transplant shock data were collected on 1 May 1987 and 29 Apr. 1988. The number of days to first flower and to first fruit on the first fruit cluster (≈10-cm diameter) was evaluated weekly.

All fruit showing a slight pink coloration were hand-harvested on 2, 8, 15, and 23 July 1987 or 28 June, 5, 12, 19 July 1988. Fruit was graded into diameter categories as large (>70 mm), medium (55 to 69 mm), and small (<55 mm). Cull fruit was graded according to quality defects, such as blossom-end rot, corky blossom end (callus >5 mm in diameter), catface, seams, and rough fruit.

Statistical analysis of the field data was performed as described above.

Table 1. Schedule of 2°C cold-stress treatments imposed on 'Sunny' tomato seedlings before field planting in 1987 and 1988.

| Stress duration (hr) | Cold-stress frequency (No. of days) | Clock hours | Days before planting in the field’ |
|---------------------|------------------------------------|-------------|-----------------------------------|

Results

Cold stress vs. seedling growth. Seedling response to cold-stress duration and frequency differed between the first (1987) and second (1988) experiments. In the first experiment, the main effect of cold-stress duration did not affect any growth variables (Table 2). Similarly, cold-stress frequency did not affect any growth variables except total chlorophyll content. As cold-stress frequency increased progressively from 1 to 6 days, the chlorophyll content decreased. The major sources of variation in plant height, leaf area, stem diameter, and shoot and root dry weights were attributable to the interaction between duration and frequency and to uncontrolled error. The number of leaves produced on seedlings was unaffected by any cold-stress frequency, duration, or their interaction; unexplained error was the major source of variation in leaf number. Generally, even though plant growth varied differentially as cold-stress frequency interacted with duration, tomato seedling growth was similar between the nonstressed control and seedlings exposed to 6 days of 12-hr cold stress (Table 3). Orthogonal contrasts comparing the unstressed control to the pooled mean of all cold-stress treatments indicated that cold stress stimulated an increase in plant height, leaf area, and shoot and root dry weights, but a decrease in chlorophyll content (Table 2).

In the second experiment, the levels of cold-stress duration and frequency were increased to determine if seedlings can withstand even greater low temperature extremes. Uncontrolled error tended to account for more of the variation in all these variables than either stress duration or frequency (Table 2). Cold-stress duration accounted for major portions of variation in stem diameter, leaf number, shoot and root dry weights, and total chlorophyll content. Root and shoot dry weights increased as cold-stress duration increased from 6 to 12 hr, but as exposure increased to 18 hr, root dry weight decreased and shoot dry weight was equivalent to weights after 6 hr of cold-stress duration. Leaf number remained stable for up to 12 hr of cold-stress duration, but leaf number decreased as duration increased to 18 hr. However, chlorophyll content decreased as duration increased from 6 to 12 hr with no further decrease at longer durations. Cold-stress frequency did not affect plant height, leaf number, shoot dry weight, or chlorophyll content. In contrast, as cold-stress frequency increased, leaf area, stem diameter, and root dry weights decreased. Generally, as frequency increased from 7 to 10 days, these growth variables decreased. Unlike in the first experiment, the interaction between duration and frequency was not significant, except with shoot and root dry weights. However, this variation was considered minor. Converse to the first experiment, orthogonal contrasts comparing the unstressed control to the pooled mean of all cold-stress treatments in the second year indicated that all seedling growth variables except leaf area were reduced in response to cold stress. The milder cold stress in the first year seemed to be stimulatory, but the more extreme cold stresses in the second year were deleterious.

Cold stress vs. field performance. Orthogonal contrasts comparing the unstressed control to the pooled mean of all cold-stress treatments indicated, as expected, that cold-stressed plants exhibited more transplant shock, as expressed by leaf death, than nonstressed (Table 4). In both experiments, the major source of variation in the incidence of transplant shock was cold-stress duration and, to a lesser extent, cold-stress frequency. In the first experiment, the number of dead or necrotic leaves (counted on seedlings =11 days after transplanting) was not affected by cold stress lasting only 6 hr. However, increasing the duration

*Mean separation within rows and columns by least significant difference test at P = 0.05.
2C, since heat from the light units increased the temperature of the cooler to a minimum of 4.4C. Hence, cold-stress imposition was planned to occur in darkness, commencing as early as late afternoon and throughout the evening and early morning hours to reduce the number of hours of light deprivation. Therefore, it is unknown what effect the increased periods of darkness imposed during cold stress had on seedling growth.

We found that, although short-term cold stresses affected gross seedling growth and appearance, these aberrations were not detrimental to the yielding capacity of 'Sunny' tomatoes. There were no long-term effects to short-term cold stresses that occurred before transplanting; thus, 'Sunny' can be considered relatively cold tolerant during this developmental period. In the first experiment, the stress levels evaluated were chosen to approximate those potential stresses common in the field in coastal South Carolina. Since tomato earliness, yield, and quality were unaffected, more-rigorous cold stress regimes were used in the second experiment with cumulative cold stresses ranging from as short as 24 hr at 2C to as much as 180 hr. Even though these regimes were unrealistic, the second experiment confirmed that cold stresses occurring during transplant hardening of 'Sunny' tomato were not detrimental, but may be considered an enhancement of total productivity. The marketable yield of all cold-stress treatments pooled compared to that of the non-cold-stressed treatment indicated a higher yield for the former. This study implies that transplanting the cultivar Sunny into the field may occur under very cool field conditions and will not likely cause significant reductions in yield potential.
