We present a pair of coupled partial differential equations to describe the evolution of the average total intensity and intensity flux of a wave field inside a randomly layered medium. These equations represent a modification of the Kubelka-Munk equations, or radiative transfer. Our modification accounts for wave interference (e.g., localization), which is neglected in radiative transfer. We numerically solve the modified Kubelka-Munk equations and compare the results to radiative transfer as well as to simulations of the wave equation with randomly located thin layers.

I. INTRODUCTION

The most basic mesoscopic theory that attempts to explain multiply scattered wave energy is the theory of radiative transfer (RT). In a one-dimensional (1D) layered medium, RT is equivalent to the well-known Kubelka-Munk (KM) equations [1,2] because the KM equations are in essence a two-flux theory and in 1D there are only two directions (up and down). However, due to the inevitability of wave interference in 1D [3], RT is unable to accurately predict all aspects of energy transport in randomly layered media. Wave interference is explicitly ignored in RT [2,4] and leads to the phenomenon of wave localization, as described by many authors previously [3,5–7]. Wave localization is of primary importance for topics such as the interaction of electrons with disorder [8] (e.g., the metal-to-insulator transition), the transmission of light through randomly layered structures (such as a stack of transparencies [6]), and the late-time behavior of seismic recordings at volcanoes [9].

Previous studies have been devoted to understanding RT in layered media, despite its neglect of wave interference. Hemmer [10] may have been the first to solve for the Green’s function of RT in 1D, as pointed out by Paaschens [11]. The application of 1D RT to vertical seismic profiles has been the subject of work by Wu [12,13] and Wu and Xie [14]. Sato and Fehler [15] have discussed 1D RT, and Sato [16] has derived the solution of the Green’s function of RT in 1D using the integral form, instead of the differential form used by Hemmer [10]. Building upon the work of Wu and Xie [14], which centered on stationary RT in layered media, the time-dependent case has been recently considered [17]. Bakut et al. [18] have generalized the Green’s function of 1D RT in homogeneous media to a medium composed of piecewise homogeneous layers. Though 1D RT has been thoroughly understood in the course of these studies, how wave interference changes the picture—from the point of view of RT—has so far not been covered. It is the aim of the present work to properly incorporate wave interference, and hence the phenomenon of wave localization, within the framework of RT for the case of layered media.

Wave localization in 1D systems has received considerable attention, both theoretically and experimentally. As a result, several different techniques have been applied. Among the most widely used is random matrix theory coupled with Fürstenberg’s theorem [6,19–21]. This approach deals with the wave field itself for a single realization of randomness by using “self-averaging” quantities [22]. Given an ensemble of random realizations, these quantities converge (closely) to their average in a single realization, provided the realization includes enough scatterers. In spite of its ability to model the wave field itself, random matrix theory is basically a stationary theory and it relies on a limiting procedure, Fürstenberg’s theorem, which takes the limit as the number of matrix products (i.e., scatterers) becomes infinite. Furthermore, random matrix theory is primarily limited to 1D systems. Historically, this fact has led to a disconnect in the prevailing theoretical treatment of multiple scattering in 1D (random matrix theory) versus 2D and 3D (RT).

Significant progress has been made recently toward incorporating wave interference into RT (at least within the diffusion approximation) using the self-consistent (SC) theory of Anderson localization. In fact, a 1D version of the SC theory has been studied analytically [23]. The SC theory is different from random matrix theory in that it predicts the late-time spatial and temporal evolution of the mean wave field intensity (the squared wave field) for an ensemble of random realizations. The crux of the SC theory is that it attempts to include the effects of wave interference by using a “self-consistent” expression for the diffusion constant, an idea originally popularized by Vollhardt and Wolfle [8].

Here, we include the effects of wave interference by deriving the 1D RT equations from a fundamental level, using a procedure first demonstrated by Goedecke [2]. We find that once properly modified, the 1D RT equations (also known as the KM equations [2]) can account for interference effects such as wave localization. We call these new equations modified KM equations. Thus, we are able to correctly account for wave interference within the framework of RT, at least in 1D. We also show that the predictions of the modi-

*Present address: Alaska Volcano Observatory, Anchorage, Alaska 99508, USA
fied KM equations agree with predictions of random matrix theory: namely, the expected exponential decay of the steady-state transmission coefficient with sample size. We finish by testing and verifying the modified KM equations through a comparison with numerical simulations of the wave equation. In contrast to the 1D version of the SC theory [23], the modified KM equations hold for all times and model both the total intensity and the intensity flux. At the end, we comment on the prospects of generalizing the 1D theory to higher dimensions, especially 3D where the notorious and interesting transition from extended to localized wave propagation occurs.

II. SCATTERING MATRIX WITH INTERFERENCE TERMS

We aim to derive equations similar to the 1D RT equations, or KM equations, but with the explicit inclusion of wave interference. Although it is not necessary, we assume in the following that there is no absorption for simplicity. For a layered medium made up of thin layers, or 1D scatterers, embedded in a homogeneous background medium, the scattering matrix relating incident and scattered waves at scatterer $n$ is

$$
\begin{bmatrix}
\tilde{S}_n \\
\tilde{S}_{n+1}
\end{bmatrix} =
\begin{bmatrix}
r & t \\
t & r
\end{bmatrix}
\begin{bmatrix}
\tilde{S}_n \\
\tilde{S}_{n+1}
\end{bmatrix},
$$

(1)

where $r$ and $t$ are the reflection and transmission coefficients of a scatterer, $\tilde{S}_{n+1}$ and $\tilde{S}_n$ are the downward and upward propagating complex wave amplitudes at the base of scatterer $n$, and $\tilde{S}_n$ and $\tilde{S}_{n+1}$ are the downward and upward propagating complex wave amplitudes at the top of scatterer $n$, as shown in Fig. 1. Note that the complex wave amplitudes at the top of scatterer $n$, $\tilde{S}_n$ and $\tilde{S}_{n+1}$, are related to the complex wave amplitudes at the base of scatterer $n-1$, $\tilde{S}_n$ and $\tilde{S}_{n-1}$, by simple phase advance or delay

$$
\tilde{S}_n = \tilde{S}_{n-1} e^{i \Delta Z},
$$

$$
\tilde{S}_{n+1} = \tilde{S}_{n} e^{i \Delta Z},
$$

(2)

where $\Delta Z$ is the delay operator associated with the propagation time between scatterers $n$ and $n-1$ [24]. From Eq. (2), it follows that $|\tilde{S}_n|^2 = |\tilde{S}_{n-1}|^2$ and $|\tilde{S}_{n+1}|^2 = |\tilde{S}_n|^2$. By taking the squared magnitude of the two equations making up the scattering matrix, Eq. (1), and adding and subtracting them, we thus arrive at the equations

$$
|\tilde{S}_n|^2 + |\tilde{S}_{n+1}|^2 = (|r|^2 + |t|^2)(|\tilde{S}_n|^2 + |\tilde{S}_{n+1}|^2) + (r T + r T')(\tilde{S}_n^*\tilde{S}_{n-1} + \tilde{S}_{n-1}^*\tilde{S}_n).
$$

(3)

$$
|\tilde{S}_n|^2 - |\tilde{S}_{n+1}|^2 = (|r|^2 - |t|^2)(|\tilde{S}_n|^2 - |\tilde{S}_{n+1}|^2) + (r T - r T')(\tilde{S}_n^*\tilde{S}_{n-1} - \tilde{S}_{n-1}^*\tilde{S}_n).
$$

(4)

For a 1D scatterer embedded in a homogeneous medium, two identities exist: $|r|^2 + |t|^2 = 1$, or conservation of energy, and $r T + r T' = 0$, as shown by Ursin [25]. With these identities, expressions (3) and (4) can be simplified as

$$
|\tilde{S}_{n+1}|^2 - |\tilde{S}_n|^2 = |\tilde{S}_n|^2 - |\tilde{S}_{n+1}|^2,
$$

(5)

$$
(|\tilde{S}_{n+1}|^2 + |\tilde{S}_n|^2) - (|\tilde{S}_n|^2 + |\tilde{S}_{n+1}|^2) = -2 |r|^2 (|\tilde{S}_n|^2 - |\tilde{S}_{n+1}|^2) - 4 \text{Im}(r T) |t|^2 \text{Im}(\tilde{S}_n^*\tilde{S}_{n+1}).
$$

(6)

Note that the interference terms are not present in Eq. (5). This equation states that the energy flux between scatterers $n$ and $n-1$ equals that between scatterers $n$ and $n-1$. The principle of energy flux conservation in layered media has been used by Claerbout to derive the method of “acoustic daylight imaging” ([24] in Chap. 8). In contrast, Eq. (6), which describes the local change in total intensity on either side of a scatterer, contains an interference term. This term depends on the correlation between the downward propagating wave field at the top of scatterer $n$ ($\tilde{S}_n$) and the upward propagating wave field at the base of scatterer $n$ ($\tilde{S}_{n+1}$).

We continue by averaging Eqs. (5) and (6) over ensembles of randomly placed scatterers. We denote ensemble averages with brackets $\langle \cdot \rangle$ and thus the ensemble average of the squared magnitude of the down-going wave field between scatterers $n-1$ and $n$ by $\langle |\tilde{S}_n|^2 \rangle = I_n$, and so on for other wave field quantities. With ensemble averaging, we obtain from Eqs. (5) and (6) that

$$
\langle \tilde{I}_{n+1} - \tilde{I}_n \rangle - \langle \tilde{I}_n - \tilde{I}_{n-1} \rangle = 0,
$$

(7)

$$
\langle \tilde{I}_{n+1} + \tilde{I}_n \rangle - \langle \tilde{I}_n + \tilde{I}_{n-1} \rangle = -2 \frac{|r|^2}{|t|^2} \langle \tilde{I}_n - \tilde{I}_{n-1} \rangle
$$

$$
- 4 \text{Im}(r T) \frac{|t|^2}{|t|^2} \langle \text{Im}(\tilde{S}_n^*\tilde{S}_{n+1}) \rangle.
$$

(8)

The stationary 1D RT equations result from these equations by first assuming zero correlation in phase between wave fields propagating in opposite directions at scatterer $n$, $\langle \tilde{S}_n^*\tilde{S}_{n+1} \rangle = 0$, followed by taking a limiting procedure to move from discrete to continuous variables, as shown by Goedecke [2].
It is well known, however, that wave interference causes
the term \( \langle \hat{S}_n \hat{S}_{n+1} \rangle \) to be nonzero, especially in 1D. We thus
include the term containing \( \langle \hat{S}_n \hat{S}_{n+1} \rangle \), and therefore account
for interference effects, by considering the directional wave
fields on either side of a planar source within a 1D random
medium. We take the depth axis \((z)\) positive downward.
First, consider the situation above the source depth \(z\). There,
the up-going wave field \( \hat{S}_n \) is the wave field incident from
the source direction and it can be related to the down-going
wave field \( \hat{S}_n \) using the reflection coefficient \( R_1 \) for the entire
random medium above scatterer \( n \) as [26]

\[
R_1 \hat{S}_n = \hat{S}_n.
\]

Moreover, the up-going wave field \( \hat{S}_{n+1} \) can be related to the
up-going wave field on the other side of scatterer \( n \), \( \hat{S}_n \), using
the reflection and transmission coefficients of a single scat-
er, \( r \) and \( t \), and the reflection coefficient for the entire
random medium below scatterer \( n \), denoted \( R_2 \), as

\[
\hat{S}_n = \frac{t \hat{S}_{n+1}}{1 - rR_2}.
\]

Equations (9) and (10) relate the wave fields \( \hat{S}_{n+1} \) and \( \hat{S}_n \):

\[
\hat{I}_n = \frac{R_1 t}{1 - rR_2} \hat{I}_{n+1}.
\]

Substituting this relationship for \( \hat{S}_n \) into Eq. (8) and assuming
the ensemble averaging can be distributed as

\[
\text{Im} \left( \frac{R_1 t}{1 - rR_2} |\hat{S}_{n+1}|^2 \right) = \langle |\hat{S}_{n+1}|^2 \rangle \text{Im} \left( \frac{R_1 t}{1 - rR_2} \right),
\]

Eq. (8) above the source becomes

\[
(\hat{I}_{n+1} + \hat{I}_n) - (\hat{I}_n + \hat{I}_n) = -2 \frac{|r|^2}{|t|^2} (\hat{I}_n - \hat{I}_n) - 4 \hat{I}_{n+1} \frac{\text{Im}(r^*)}{|t|^2} \text{Im} \left( \frac{R_1 t}{1 - rR_2} \right).
\]

Applying the same considerations to the situation below
the source depth \(z\) means that the direction of the wave field
incident from the source is the opposite of the case just
shown. In addition, the roles of the terms \( R_1 \) and \( R_2 \) are
different: \( R_1 \) is now the reflection coefficient for the entire
random medium beneath scatterer \( n \) and \( R_2 \) is the reflection
coefficient for the entire random medium above scatterer \( n \).
This convention maintains the same relation between \( R_1 \) and
\( R_2 \) and the direction of the incident wave field as was used
previously. Thus, starting with \( R_1 \hat{S}_{n+1} = \hat{S}_n \), Eq. (8) below
the source is

\[
(\hat{I}_{n+1} + \hat{I}_n) - (\hat{I}_n + \hat{I}_n) = -2 \frac{|r|^2}{|t|^2} (\hat{I}_n - \hat{I}_n) - 4 \hat{I}_{n+1} \frac{\text{Im}(r^*)}{|t|^2} \text{Im} \left( \frac{R_1 t}{1 - rR_2} \right).
\]

As pointed out by Goedecke [2], the term on the left-hand
side of Eq. (15) becomes a spatial derivative when making
the transition to a continuous depth variable \( n \rightarrow z \). Therefore,
the directional wave fields become functions of \( z \)—that is,
\( \hat{I}_d = I_d(z) \) and \( \hat{I}_u = I_u(z) \) where \( I_d \) and \( I_u \) are the ensemble-
averaged down-going and up-going intensities. Therefore, Eq. (15) becomes

\[
\frac{d(I_d + I_u)}{dz} = -2 \rho \frac{|r|^2}{|t|^2} (I_d - I_u) - 4 \rho I_d \frac{\text{Im}(r^*)}{|t|^2} \text{Im} \left( \frac{R_1 t}{1 - rR_2} \right).
\]

We further simplify Eq. (16) by defining the ensemble-
averaged total intensity \( I = I_d + I_u \) and the ensemble-averaged
intensity flux \( I_f = I_d - I_u \). This simplifies Eq. (16) as

\[
\langle \hat{I}_{n+1} + \hat{I}_n \rangle - \langle \hat{I}_n + \hat{I}_n \rangle = -2 \frac{|r|^2}{|t|^2} \langle \hat{I}_n - \hat{I}_n \rangle - 4 \hat{I}_{n+1} \frac{\text{Im}(r^*)}{|t|^2} \text{Im} \left( \frac{R_1 t}{1 - rR_2} \right).
\]
\[
\frac{dI_{\ell}}{dz} = -2B \frac{|r|^{2}}{|r|^{2} + |t-1|^{2}} I_{\ell} - \frac{2}{\ell_{\text{loc}}} I_{d}.
\]  
(19)

We have chosen the definitions in Eq. (18) in a manner consistent with the usual definitions for these quantities [2,3]. For instance, regarding the quantity \( \rho |r|^{2}/|r|^{2} \), in the weak-scattering limit (\( |r|^{2} \approx 1 \)) we find that

\[ B = \frac{|r|^{2}}{|r|^{2} + |t-1|^{2}}. \]  
(21)

Thus, \( B \) is a dimensionless parameter describing the directionality of the scattering [17]. For isotropic scattering, \( B = 1/2 \). In addition we define

\[ \frac{1}{\ell_{s}} = \rho (|r|^{2} + |t-1|^{2}), \]  
(22)

consistent with what we know for the 1D scattering cross section from Sheng [3]: \( \sigma_s = |r|^{2} + |t-1|^{2} \). Therefore, from Eq. (22), we can identify the factor \( \rho (|r|^{2} + |t-1|^{2}) = \rho \sigma_s \). In the weak-scattering limit, it is well known that \( \ell_{s} = 1/\rho \sigma_s \). Thus, our definition for \( \ell_{s} \) in Eq. (22) is consistent with the usual definition of \( \ell_{s} \) in the weak-scattering limit. The appendix demonstrates the consistency of the definition for \( \ell_{\text{loc}} \) as it appears in Eq. (19) based on the relation in Eq. (18).

We have just shown how to apply the limiting procedure to Eq. (14). Applying the same limiting procedure to Eqs. (7) and (13) gives all of the necessary stationary transport equations, which we summarize here:

\[ \frac{dI_{\ell}}{dz} = 0, \]  
(23)

\[ \frac{dI_{\ell}}{dz} = -2B I_{\ell} + \frac{2}{\ell_{\text{loc}}} I_{d} \quad (\text{for } z < z_{s}), \]  
(24)

These equations comprise the modified KM equations in the stationary case. Equation (24) may be rewritten more concisely as

\[ \frac{dI_{\ell}}{dz} = -2 \left[ \frac{B}{\ell_{s}} + \frac{1}{\ell_{\text{loc}}} \right] I_{\ell} - \frac{\text{sgn}(z-z_{s})}{\ell_{\text{loc}}} (I_{r} - |I_{r}|), \]  
(25)

where the quantity \( I_{r} - |I_{r}| \) is either \( 2I_{u} \) for \( z > z_{s} \), or \( 2I_{d} \) for \( z < z_{s} \): it is twice the intensity propagating back toward the source. Equation (25) shows that the inclusion of wave interference in the KM (or RT) equations leads to two additional terms which affect the average total intensity in different ways. The first term containing \( 1/\ell_{\text{loc}} \) on the right-hand side (RHS) of Eq. (25) causes the coherent intensity to decay more rapidly than when wave interference is neglected. Furthermore, the second term containing \( 1/\ell_{\text{loc}} \) on the RHS causes the spatial distribution of the incoherent intensity to be entirely different than in the case of no interference (as demonstrated later in a numerical example). The form of Eq. (25) allows the identification of the extinction mean free path (the decay of the coherent intensity), \( 1/\ell_{\text{ext}} = B/\ell_{s} + 1/\ell_{\text{loc}} \). This insight is possible since the quantity \( I_{r} - |I_{r}| \) in Eq. (25) is zero for the coherent intensity. Note that the coherent intensity decays exponentially even without interference effects (\( \ell_{\text{loc}} \to \infty \), or RT) due to scattering out of the forward direction.

IV. MODIFIED KM THEORY: THE TIME-DEPENDENT CASE

Having derived the modified KM equations for the stationary case in Eqs. (25) and (23), we will turn our attention to the time-dependent (dynamic) case. Given the current coordinate system for \( z \), this is accomplished by noting that 

\[
\frac{dI_{u}}{dz} = \frac{\partial I_{u}}{\partial z} + v^{-1} \frac{\partial I_{u}}{\partial t} \quad \text{and} \quad \frac{dI_{d}}{dz} = \frac{\partial I_{d}}{\partial z} - v^{-1} \frac{\partial I_{d}}{\partial t},
\]

where \( v \) is the velocity of energy transport (the energy velocity). Including the presence of planar isotropic (zero net down-going component) sources [17], we obtain the following time-dependent equations

\[ \frac{\partial I_{\ell}}{\partial z} + \frac{1}{v} \frac{\partial I_{\ell}}{\partial t} = \frac{\Gamma}{v}, \]  
(26)

\[ \frac{\partial I_{\ell}}{\partial z} + \frac{1}{v} \frac{\partial I_{\ell}}{\partial t} = -2 \left[ \frac{B}{\ell_{s}} + \frac{1}{\ell_{\text{loc}}} \right] I_{\ell} - \frac{\text{sgn}(z-z_{s})}{\ell_{\text{loc}}} (I_{r} - |I_{r}|), \]  
(27)

where \( \Gamma \) is the isotropic (omnidirectional) source term [17]. Note that for \( \ell_{\text{loc}} \to \infty \) (no wave interference), Eqs. (26) and (27) are the same equations as have been studied previously by others within the context of RT in layered media [12–14,17].

With Eqs. (26) and (27), which are the modified KM equations in the time-dependent case, we proceed to numerically solve the equations for two cases: with interference and without (\( \ell_{\text{loc}} \to \infty \), or RT). These cases are compared to ensemble averages of simulations of the wave equation.

V. NUMERICAL SIMULATIONS

Our numerical solution of Eqs. (26) and (27) exploits staggered grid-finite-difference methods [27]. In this technique, we calculate the total intensity \( I_{\ell} \) and the intensity flux
Based simulation. Therefore, we also simulate the wave propagation in an ensemble-averaged wave propagation model, or RT, theory. We simulate different spatial grids shifted by half of a grid spacing and on different temporal grids shifted by half of a time step. Our purpose is to test whether the modified KM theory of a time step. Our purpose is to test whether the modified KM theory is zero phase and hence acausal.

The setup of our numerical simulation is as follows: for a single realization, we place 50 scatterers randomly over a depth range of $L = 200$ m. The scatterers are lower in propagation velocity (1000 m/s) than the background medium (2000 m/s) but have the same density. We excite a source in the center of the 200-m range at $z_s = 0$ m. At the ends of the 200-m range are absorbing boundaries. To obtain ensemble averages of the total intensity, we first bandpass-filter our numerical results from a single realization with a Gaussian filter peaked at 500 Hz. We filter in the frequency domain since the transport properties (i.e., $\ell_s$ and $\ell_{loc}$) are strongly dependent on frequency. In other words, Eqs. (26) and (27) model the wave experiment in a particular frequency band. After filtering, we square the wave field for each of 100 simulations with randomly placed scatterers and then add the squared wave fields. From the ensemble-averaged wave fields, we estimate the extinction mean free path $\ell_{ext}$ from the decay of the coherent intensity and the localization length $\ell_{loc}$ from the exponential decay of the incoherent intensity away from the source. We find $\ell_{ext} = 38.1 \pm 0.5$ m and $\ell_{loc} = 57.2 \pm 1.7$ m. These two parameters enter into Eqs. (26) and (27). We further find that the energy velocity of the coherent wave is only slightly altered from the phase velocity of the background medium (2000 m/s), which is expected since the scatterers we employ are 1D versions of Rayleigh scatterers ($B = 1/2$, with thickness $d$ much less than the dominant wavelength) [3], and hence are not resonant scatterers.

The thick black line in Fig. 2 is the total intensity from the numerical solution of the standard KM equations (RT, $\ell_{loc} \to \infty$), with the wave simulation shown as the thin blue line. Note that these snapshots are logarithmic in intensity. Strong localization effects are evident in the wave simulation as seen in the sharp exponential peak in the total intensity at the source position at later times. This behavior is not captured in the solution of the standard KM equations, which predict that the total intensity is flat around the source position. In addition, the standard KM equations significantly underpredict the decay of the coherent wave. The discrepancy between standard KM theory and the wave simulation is most evident at $t = 0.11$ s in Fig. 2(d), where the wave simulation shows a concentration of total intensity near the source position.

The simulation for the modified KM equations is the thick black line in Fig. 3. In contrast to the standard KM equations, the modified KM equations for normally incident plane waves in a layered medium, excited by a planar force source:

$$
\frac{1}{c^2} \frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial z^2} = \frac{1}{\rho c^2(z)} F_w(t) \delta(z),
$$

where $u$ is the displacement field as a function of time $t$ and spatial coordinate $z$, $c$ is the phase velocity, $\rho$ is the density of the medium, $F$ is a dimensionless constant related to the strength of the forcing function, $w(t)$ is the dimensionless source time function, and $\delta(z)$ is the spatial delta function. We simulate Eq. (28) by the finite-difference method using centered, second-order approximations for the derivatives. The details of the numerical implementation have been previously discussed in Haney et al. [17].

The various panels show (a) $t = 0$ s, (b) $t = 0.02$ s, (c) $t = 0.045$ s, and (d) $t = 0.11$ s. The source time function is zero phase and hence acausal (symmetric about $t = 0$ s).

$I_r$ on different spatial grids that have been shifted by half of a grid spacing and on different temporal grids shifted by half of a time step. Our purpose is to test whether the modified KM equations (26) and (27) predict the results of a wave-based simulation. Therefore, we also simulate the wave equation for normally incident plane waves in a layered medium, excited by a planar force source:

$\frac{1}{c^2} \frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial z^2} = \frac{1}{\rho c^2(z)} F_w(t) \delta(z),

$
With a proper modification to the well-known Kubelka-Munk equations, we are able to accurately describe the transport of wave intensity in a 1D layered medium at all times, even when interference effects dominate (e.g., wave localization). This is confirmed by numerical simulations comparing wave simulations and the modified Kubelka-Munk equations. In the future, we plan to extend our approach, which currently uses only two fluxes, to a theory valid for 2D and 3D disordered media. One approach to this extension would utilize higher-dimensional discrete flux theories as described by Cwilich [28]. Such a transport theory will be capable of simultaneously describing the propagating coherent intensity, the intensity flux, and the localization transition in 3D.

VI. CONCLUSION

We thank John Scales for many useful discussions. Partially supporting KvW are the NSF (Grant No. EAR-0337379) and ARO (Grant No. DAAD19-03-1-0292).

APPENDIX: VERIFICATION OF THE LOCALIZATION LENGTH

Here, we give credence to our use of the term localization length $\ell_{\text{loc}}$ as it appears in Eq. (19). By doing so, we justify the expression for $\ell_{\text{loc}}$ in Eq. (18). We proceed by finding the stationary transmission coefficient for a slab geometry in the case of interference. We adopt the approach shown by van Rossum and Nieuwenhuizen [29], wherein the authors derived the stationary transmission coefficient $T$ for the case of no interference. In that case, $T(L) = z_s/L$, where $z_s$ is the extrapolation length outside the slab and $L$ is the thickness of the slab [29]. In analogy to electronic systems, the behavior $T(L) = z_s/L$ is an expression of Ohm’s law.

We begin by taking the stationary version of Eqs. (26) and (27):

$$\frac{dI_i}{dz} = \frac{\Gamma}{v},$$  \hspace{1cm} (A1)

$$\frac{dI_f}{dz} = -2 \left[ \frac{B}{\ell_s} + \frac{1}{\ell_{\text{loc}}} \right] I_f - \frac{\text{sgn}(z-z_s)}{\ell_{\text{loc}}} (I_i - |I_f|),$$  \hspace{1cm} (A2)

where, as discussed before in reference to Eqs. (26) and (27), $\Gamma$ is the isotropic (omnidirectional) source term [17]. Let a single stationary (planar) source act at depth $z_s$, such that $\Gamma = \delta(z-z_s)$. Based on physical considerations, we know that $I_i$ is symmetric (even) about $z=z_s$ and $I_f$ is antisymmetric (odd). This, together with the fact that $\Gamma = \delta(z-z_s)$ in Eq. (A1), leads to the relation $I_f = \text{sgn}(z-z_s)/2v$ and therefore that $\text{sgn}(I_f) = \text{sgn}(z-z_s)$. Since $\text{sgn}(I_f)|I_f| = I_f$, Eq. (A2) may be written as

![Image](036601-6)
\[
\frac{dI_t}{dz} = - \left[ \frac{2B}{\ell_s + \ell_{loc}} + 1 \right] I_t - \frac{\text{sgn}(z - z_s)}{\ell_{loc}} I_r. \quad (A3)
\]

Solving this equation for \( I_t \) allows a substitution for \( I_t \) in Eq. (A1). At depths away from the source (for \( z \neq z_s \)), this gives an expression in terms of \( I_t \) only:

\[
\frac{d^2 I_t}{dz^2} + \frac{1}{\ell_{loc}} \frac{d}{dz} \left[ \text{sgn}(z - z_s) I_t \right] = 0. \quad (A4)
\]

For the case of no interference, \( \ell_{loc} \rightarrow \infty \), Eq. (A4) reduces to the Laplace equation (the diffusion equation in the stationary case). However, when interference is taken into account, the equation is a modified Laplace equation.

In preparation for an application of the standard approach shown by van Rossum and Nieuwenhuizen [29], we proceed by investigating how the extrapolation length outside of a slab of thickness \( L \) changes when interference is accounted for. We use the well-known approach of Morse and Feshbach [30] to define the extrapolation length. Consider a slab containing randomly located thin layers extending from \( z=0 \) to \( z=L \). Outside of this interval, the medium is homogeneous. Take a planar source of intensity at some \( z_s<0 \), outside of the slab. Since the entire slab extends over \( z=0 \) to \( z=L \), we have \( z_s<z \) and thus \( \text{sgn}(z - z_s) = 1 \) for all points \( z \) within the slab. In this case, Eqs. (A3) and (A4) are, for all points \( z \) inside of the slab, given by

\[
\frac{dI_t}{dz} = - \left[ \frac{2B}{\ell_s + \ell_{loc}} + 1 \right] I_t \quad (A5)
\]

and

\[
\frac{d^2 I_t}{dz^2} + \frac{1}{\ell_{loc}} \frac{dI_t}{dz} = 0. \quad (A6)
\]

At the far end of the slab \( z=L \), we require there be no up-going intensity \( I_u = (I_t - I_r)/2=0 \). Now using Eq. (A5), we substitute for \( I_t \) in the relation \( I_t - I_r = 0 \), giving an equation in terms of \( I_r \) only:

\[
I_r + \frac{\ell_{loc}}{\ell_r + \ell_{loc}} \left[ \frac{dI_r}{dz} + \frac{I_r}{\ell_{loc}} \right] = 0, \quad (A7)
\]

where we use the transport mean free path \( \ell_r = \ell_s/2B \) to make the notation concise [17]. We can rewrite Eq. (A7) as

\[
I_r + \frac{\alpha}{\ell_r} \frac{dI_r}{dz} = 0, \quad (A8)
\]

where \( \alpha = \ell_r \ell_{loc} / (\ell_{loc} + 2\ell_r) \). Equation (A8) means that, near \( z=L \), \( I_r = C(L + \alpha z) / \alpha \) where \( C \) is a dimensionless constant. Within this approximation, \( I_r = 0 \) at \( z=L+\alpha \); therefore, the extrapolation length \( z_e \)—the distance outside of the slab where \( I_r \) vanishes—is equal to \( \alpha \). That is, \( z_e = \ell_r \ell_{loc} / (\ell_{loc} + 2\ell_r) \). One can see in this expression that, for no interference \( (\ell_{loc} \rightarrow \infty) \), \( z_e = \ell_{tr} \) which is the usual extrapolation length encountered in 1D when interference is neglected [17].

At the side of the slab on which the source of intensity is incident, at \( z=0 \), we require the down-going intensity to be equal to the incident intensity \( I_t \). Thus, \( I_t = (I_r + I_f)/2 = I_0 \) at \( z=0 \). Using Eq. (A5), we substitute for \( I_t \) in the relation \( (I_r + I_f)/2 = I_0 \), giving

\[
I_r - \frac{\ell_{loc}}{\ell_r + \ell_{loc}} \frac{\partial I_r}{\partial z} + \frac{I_f}{\ell_{loc}} = 2I_0. \quad (A9)
\]

Equation (A9) may be rewritten as

\[
I_r - \frac{\partial I_r}{\partial z} = \frac{2I_0 (\ell_{loc} + \ell_r)}{\ell_{loc}}. \quad (A10)
\]

Near \( z=0 \), the solution is approximately given by

\[
I_r = \frac{2I_0}{\ell_{loc} (\ell_{loc} + 2\ell_r)} \left[ \frac{z}{\ell_{tr}} + 2 \right]. \quad (A11)
\]

Within this approximation, at a distance equal to the (interference adjusted) extrapolation length outside of the slab, \( z = -z_e \), \( I_r \) is therefore given by

\[
I_r = \frac{2I_0}{\ell_{loc} (\ell_{loc} + 2\ell_r)} \left[ \frac{z}{\ell_{tr}} + 2 \right] = 2I_0 \Delta, \quad (A12)
\]

where we represent the term containing \( \ell_{loc} \) and \( \ell_{tr} \) by \( \Delta \).

Following the method employed by van Rossum and Nieuwenhuizen [29], we seek to solve Eq. (A6) with the boundary conditions \( I_r = 0 \) and \( I_r = 2I_0 \Delta \) at the (interference adjusted) extrapolation lengths \( z = (L + z_e) \) and \( z = -z_e \), respectively. The solution is

\[
I_r(z) = 2I_0 \Delta \left[ \frac{e^{-z_{loc}} - e^{-(L + z_e)z_{loc}}}{e^{z_{loc}} - e^{-(L + z_e)z_{loc}}} \right]. \quad (A13)
\]

The steady-state transmission coefficient \( T(L) = I_r(z=L)/I_0 \) is

\[
T(L) = 2\Delta e^{-Lz_{loc}} \frac{1}{e^{z_{loc}} - e^{-(L + z_e)z_{loc}}} \approx 2\Delta e^{-Lz_{loc}} \frac{1 - e^{-z_{loc}}}{e^{z_{loc}}} \left[ \frac{1 - e^{-z_{loc}}}{e^{z_{loc}}} \right], \quad (A14)
\]

where the approximation is for \( z_e \leq L \). This expression shows that when interference is taken into account the steady-state transmission coefficient goes down exponentially as a function of the length of the slab \( L \)—a hallmark of localization in the stationary case. This behavior is in stark contrast to \( T(L) \approx z_e/L \) [29] obtained when interference is neglected \( (\ell_{loc} \rightarrow \infty) \). The fact that the length scale controlling the exponential decay with \( L \) in Eq. (A14) is \( \ell_{loc} \) supports the use of this term in Eq. (19) and, as a consequence, the expression for \( \ell_{loc} \) in Eq. (18).
