Fast and Efficient Compressive Sensing using Structurally Random Matrices

Thong T. Do, Student Member, IEEE, Lu Gan, Member, IEEE, Nam H. Nguyen and Trac D. Tran, Senior Member, IEEE

Abstract—This paper introduces a new framework of fast and efficient sensing matrices for practical compressive sensing, called Structurally Random Matrix (SRM). In the proposed framework, we pre-randomize a sensing signal by scrambling its samples or flipping its sample signs and then fast-transform the randomized samples and finally, subsample the transform coefficients as the final sensing measurements. SRM is highly relevant for large-scale, real-time compressive sensing applications as it has fast computation and supports block-based processing. In addition, we can show that SRM has theoretical sensing performance comparable with that of completely random sensing matrices. Numerical simulation results verify the validity of the theory as well as illustrate the promising potentials of the proposed sensing framework.

Index Terms—compressed sensing, compressive sensing, random projection, sparse reconstruction, fast and efficient algorithm

I. INTRODUCTION

Compressed sensing (CS) [1], [2] has attracted a lot of interests over the past few years as a revolutionary signal sampling paradigm. Suppose that \( x \) is a length-\( N \) signal. It is said to be \( K \)-sparse (or compressible) if \( x \) can be well approximated using only \( K \ll N \) coefficients under some linear transform:

\[
x = \Psi \alpha,
\]

where \( \Psi \) is the sparsifying basis and \( \alpha \) is the transform coefficient vector that has \( K \) (significant) nonzero entries.

According to the CS theory, such a signal can be acquired through the following random linear projection:

\[
y = \Phi x + e,
\]

where \( y \) is the sampled vector with \( M \ll N \) data points, \( \Phi \) represents a \( M \times N \) random matrix and \( e \) is the acquisition noise. The CS framework is attractive as it implies that \( x \) can be faithfully recovered from only \( M = O(K \log N) \) measurements, suggesting the potential of significant cost reduction in digital data acquisition.

While the sampling process is simply a random linear projection, the reconstruction to find the sparsest signal from the received measurements is highly non-linear process. More precisely, the reconstruction algorithm is to solve the \( l_1 \)-minimization of a transform coefficient vector:

\[
\min \| \alpha \|_1 \quad \text{s.t.} \quad y = \Phi \Psi \alpha.
\]

Linear programming [11], [2] and other convex optimization algorithms [3], [4], [5] have been proposed to solve the \( l_1 \) minimization. Furthermore, there also exists a family of greedy pursuit algorithms [6], [7], [8], [9], [10] offering another promising option for sparse reconstruction. These algorithms all need to compute \( \Phi \Psi \) and \( (\Phi \Psi)^T \) multiple times. Thus, computational complexity of the system depends on the structure of sensing matrix \( \Phi \) and its transpose \( \Phi^T \).

Preferably, the sensing matrix \( \Phi \) should be highly incoherent with sparsifying basis \( \Psi \), i.e., rows of \( \Phi \) do not have any sparse representation in the basis \( \Psi \). Incoherence between two matrices is mathematically quantified by the mutual coherence coefficient [11].

Definition I.1. The mutual coherence of an orthonormal matrix \( N \times N \) \( \Phi \) and another orthonormal matrix \( N \times N \) \( \Psi \) is defined as:

\[
\mu(\Phi, \Psi) = \max_{1 \leq i, j \leq N} |\langle \Phi_i, \Psi_j \rangle|,
\]

where \( \Phi_i \) are rows of \( \Phi \) and \( \Psi_j \) are columns of \( \Psi \), respectively.

If \( \Phi \) and \( \Psi \) are two orthonormal matrices, \( \| \Phi \Psi \|_2 = \| \Psi \|_2 = 1 \). Thus, it is easy to see that for two orthonormal matrices \( \Phi \) and \( \Psi \), \( 1/\sqrt{N} \leq \mu \leq 1 \). Incoherence implies that the mutual coherence or the maximum magnitude of entries of the product matrix \( \Phi \Psi \) is relatively small. Two matrices are completely incoherent if their mutual coherence coefficient approaches the lower bound value of \( 1/\sqrt{N} \).

A popular family of sensing matrices is a random projection or a random matrix of i.i.d random variables from a sub-Gaussian distribution such as Gaussian or Bernoulli [12], [13]. This family of sensing matrix is well-known as it is universally incoherent with all other sparsifying basis. For example, if \( \Phi \) is a random matrix of Gaussian i.i.d entries and \( \Psi \) is an arbitrary orthonormal sparsifying basis, the sensing matrix in the transform domain \( \Phi \Psi \) is also Gaussian i.i.d matrix. The universal property of a sensing matrix is important because it enables us to sense a signal directly in its original domain without significant loss of sensing efficiency and without any other prior knowledge. In addition, it can be shown that random projection approaches the optimal sensing performance of \( M = O(K \log N) \).

However, it is quite costly to realize random matrices in practical sensing applications as they require very high

computational complexity and huge memory buffering due to their completely unstructured nature [14]. For example, to process a $512 \times 512$ image with $64K$ measurements (i.e., 25% of the original sampling rate), a Bernoulli random matrix requires nearly gigabytes storage and giga-flop operations, which makes both the sampling and recovery processes very expensive and in many cases, unrealistic.

Another class of sensing matrices is a uniformly random subset of rows of an orthonormal matrix in which the partial Fourier matrix (or the partial FFT) is a special case [13], [14]. While the partial FFT is well known for having fast and efficient implementation, it only works well in the transform domain or in the case that the sparsifying basis is the identity matrix. More specifically, it is shown in [14, Theorem 1.1] that the minimal number of measurements required for exact recovery depends on the incoherence of $\Phi$ and $\Psi$:

$$M = O(\mu_n^2 K \log N)$$

where $\mu_n$ is the normalized mutual coherence: $\mu_n = \sqrt{N} \mu$ and $1 \leq \mu_n \leq \sqrt{N}$. With many well-known sparsifying bases such as wavelets, this mutual coherence coefficient might be large and thus, resulting in performance loss. Another approach is to design a sensing matrix to be incoherent with a given sparsifying basis. For example, Noiselets is designed to be incoherent with the Haar wavelet basis in [15], i.e. $\mu_n = 1$ when $\Phi$ is Noiselets transform and $\Psi$ is the Haar wavelet basis. Noiselets also has low-complexity implementation $O(N \log N)$ although it is unknown if noiselets is also incoherent with other bases.

II. COMPRESSIVE SENSING WITH STRUCTURALLY RANDOM MATRICES

A. Overview

One of remaining challenges for CS in practice is to design a CS framework that has the following features:

- **Optimal or near optimal sensing performance**: the number of measurements for exact recovery approaches the minimal bound, i.e. on the order of $O(K \log N)$;
- **Universality**: sensing performance is equally good with almost all sparsifying bases;
- **Low complexity, fast computation and block-based processing support**: these features of the sensing matrix are desired for large-scale, real-time sensing applications;
- **Hardware/Optics implementation friendliness**: entries of the sensing matrix only take values in the set \{0, 1, -1\}.

In this paper, we propose a framework that aims to satisfy the above wish-list, called Structurally Random Matrix (SRM) that is defined as a product of three matrices:

$$\Phi = \sqrt{\frac{N}{M}} DFR$$

where:

- $R \in N \times N$ is either a uniform random permutation matrix or a diagonal random matrix whose diagonal entries $R_{ii}$ are i.i.d Bernoulli random variables with identical distribution $P(R_{ii} = \pm 1) = 1/2$. A uniformly random permutation matrix scrambles signal’s sample locations globally while a diagonal matrix of Bernoulli random variables flips signal’s sample signs locally. Hence, we often refer the former as the **global randomizer** and the latter as the **local randomizer**.

- $F \in N \times N$ is an orthonormal matrix that, in practice, is selected to be fast computable such as popular fast transforms: FFT, DCT, WHT or their block diagonal versions. The purpose of the matrix $F$ is to spread information (or energy) of the signal’s samples over all measurements.

- $D \in M \times N$ is a subsampling matrix/operator. The operator $D$ selects a random subset of rows of the matrix $FR$. If the probability of selecting a row $P$ (a row is selected) is $M/N$, the number of rows selected would be $M$ in average. In matrix representation, $D$ is simply a random subset of $M$ rows of the identity matrix of size $N \times N$.

The scale coefficient $\sqrt{\frac{N}{M}}$ is to normalize the transform so that energy of the measurement vector is almost similar to that of the input signal vector.

Equivalently, the proposed sensing algorithm SRM contains 3 steps:

1. **Step 1 (Pre-randomize)**: Randomize a target signal by either flipping its sample signs or uniformly permuting its sample locations. This step corresponds to multiplying the signal with the matrix $R$.

2. **Step 2 (Transform)**: Apply a fast transform $F$ to the randomized signal.

3. **Step 3 (Subsample)**: Randomly pick up $M$ measurements out of $N$ transform coefficients. This step corresponds to multiplying the transform coefficients with the matrix $D$.

Conventional CS reconstruction algorithm is employed to recover the transform coefficient vector $\alpha$ by solving the $l_1$ minimization:

$$\hat{\alpha} = \arg\min_{\alpha} \|\alpha\|_1 \text{ s.t. } y = \Phi \Psi \alpha.$$  (3)

Finally, the signal is recovered as $\hat{x} = \Psi \hat{\alpha}$. The framework can achieve perfect reconstruction if $\hat{x} = x$.

From the best of our knowledge, the proposed sensing algorithm is distinct from currently existing methods such as random projection [16], random filters [17], structured Toeplitz [18] and random convolution [19] via the first step of pre-randomization. Its main purpose is to spread the structure of the signal, converting the sensing signal into a white noise-like one to achieve universally incoherent sensing.

Depending on specific applications, SRM can offer computational benefits either at the sensing process or at the signal reconstruction process. For applications that allow us to perform sensing operation by computing the complete transform $F$, we can exploit the fast computation of the matrix $F$ at the sensing side. However, if it is required to precompute $DFR$ (and then store it in the memory for future sensing operation), there would not be any computational benefit at the sensing side. In this case, we can still exploit the structure of SRM to speed up the signal recovery at the reconstruction side as in most $l_1$-minimization algorithms [3], majority of computational complexity is spent to compute matrix-vector multiplications $Au$ and $A^T u$, where $A = \Phi \Psi$. Note that
both \( A \) and \( A^T \) are fast computable if the sparsifying matrix \( \Psi \) is fast computable, i.e. their computational complexity on the order of \( O(N \log N) \). In addition, when \( F \) is selected to be the Walsh-Hadamard matrix, the SRM entries only take values in the set \( \{-1, 1\} \), which is friendly for hardware/optics implementation.

The remaining of the paper is organized as follows. We first discuss about incoherence between SRMs and sparsifying transforms in Section III. More specifically, Section III-A will give us a rough intuition of why SRM has sensing performance comparable with Gaussian random matrices. Detail quantitative analysis of the incoherence for SRMs with the local randomizer and the global randomizer is presented in Section III-B. Based on these incoherence results, theoretical performance of the proposed framework is analyzed in Section IV and then followed by experiment validation in Section V. Finally, Section VI concludes the paper with discussion of practical advantages of the proposed framework and relationship between the proposed framework and other related works.

### III. Incoherence Analysis

#### A. Asymptotical Distribution Analysis

If \( \Phi \) is an i.i.d Gaussian matrix \( \mathcal{N}(0, \frac{1}{N}) \) and \( \Psi \) is an arbitrarily orthonormal matrix, \( \Phi \Psi \) is also i.i.d Gaussian matrix \( \mathcal{N}(0, \frac{1}{N}) \), implying that with overwhelming probability, a Gaussian matrix is highly incoherent with all orthonormal \( \Psi \). In other words, the i.i.d Gaussian matrix is universally incoherent with fixed transforms (with overwhelming probability). In this section, we will argue that under some mild conditions, with \( \Phi = DFR \), where \( D, F, R \) are defined as in the previous section, entries of \( \Phi \Psi \) are asymptotically normally distributed \( \mathcal{N}(0, \sigma^2) \), where \( \sigma^2 \leq O(\frac{1}{N}) \). This claim is illustrated in Fig. II which depicts the quantile-quantile (QQ) plots of entries of \( \Phi \Psi \), where \( N = 256 \), \( F \) is the 256 \( \times \) 256 DCT matrix and \( \Psi \) is the Daubechies-8 orthogonal wavelet basis. Fig. II(a) and Fig. II(b) correspond to the case \( R \) is the local and global randomizer, respectively. In both cases, the QQ-plots appear straight, as the Gaussian model demands.

Note that \( \Phi \) is a submatrix of \( A = FR \). Thus, asymptotical distribution of the entries of \( A \Psi \) is similar to that of entries of \( \Phi \Psi \).

Before presenting the asymptotical theoretical analysis, we introduce the following assumptions for the local and global randomization models.

1) Assumptions for the Local Randomization Model:
- \( F \) is an \( N \times N \) unit-norm row matrix with absolute magnitude of all entries on the order of \( O(\frac{1}{\sqrt{N}}) \).
- \( \Psi \) is an \( N \times N \) unit-norm column matrix with the maximal absolute magnitude of entries on the order of \( o(1) \).

2) Assumptions for the Global Randomization Model:
- The global randomization model requires similar assumptions for the local randomization model plus the following extra assumptions.
  - The average sum of entries on each column of \( \Psi \) is on the order of \( o(\frac{1}{\sqrt{N}}) \).
  - Sum of entries on each row of \( F \) is zero.
  - Entries on each row of \( F \) and on each column of \( \Psi \) are not all equal.

**Theorem III.1.** Let \( A = FR \), where \( R \) is the local randomizer. Given the assumptions for the local randomization model, entries of \( A \Psi \) are asymptotically normally distributed \( \mathcal{N}(0, \sigma^2) \) with \( \sigma^2 \leq O(\frac{1}{N}) \).

**Proof.** With notations being defined in Section III-A, we have:

\[
S_{ij} = (A_i, \Psi_j) = \sum_{k=1}^{N} F_{ik} \Psi_{kj} R_{kk} 
\]  
(4)

Denote \( Z_k = F_{ik} \Psi_{kj} R_{kk} \). Because \( R_{kk} \) are i.i.d Bernoulli random variables, \( Z_k \) are i.i.d zero-mean random variables with \( E(Z_k) = 0 \). The assumption that \( |F_{ik}| \) are on the order of \( O(\frac{1}{\sqrt{N}}) \) implies that there exist two positive constants \( c_1 \) and \( c_2 \) such that:

\[
\frac{c_1}{N} \Psi_{kj}^2 \leq \text{Var}(Z_k) = F_{ik}^2 \Psi_{kj}^2 \leq \frac{c_2}{N} \Psi_{kj}^2.
\]

(5)
verify its convergence condition: for a given \( \{ ij \} \), assume there exists a counterproof method. Assume there exists \( \epsilon_0 \), such that \( \forall N \), there exists at least \( k_0 \in \{ 1, 2, \ldots, N \} \):

\[
\text{Var}(Z_{k_0}) > \epsilon_0 \sigma^2.
\]  

From (5), (6) and (8), we achieve:

\[
\epsilon_0 \frac{C_1}{N} \leq \text{Var}(Z_{k_0}) \leq \frac{C_2}{N} \Psi_{k_0j}^2.
\]  

This inequality cannot be true if \( \Psi_{k_0j} \) is on the order of \( o(1) \). The underlying intuition of the convergence condition is to guarantee that there is no random variable with dominant variance in the sum \( S_{ij} \). In this case, it simply requires that there is no dominant entry on each column of \( \Psi \).

Similarly, we can obtain a similar result when \( \mathbf{R} \) is a uniformly random permutation matrix.

**Theorem III.2. Let \( A = FR \), where \( \mathbf{R} \) is the global randomizer. Given the assumptions for the global randomization model, entries of \( A\Psi \) are asymptotically normally distributed \( N(0, \sigma^2) \), where \( \sigma^2 = \mathcal{O}(\frac{1}{N}) \).

*Proof.* Let \( \{ \omega_1, \omega_2, \ldots, \omega_N \} \) be a uniform random permutation of \( [1, 2, \ldots, N] \). Note that \( \{ \omega_k \}^N_{k=1} \) can be viewed as a sequence of random variables with identical distribution. In particular, for a fixed \( k \):

\[
P(\omega_k = i) = \frac{1}{N}, i = 1, 2, \ldots, N.
\]

Denote \( Z_k = F_{\omega_k} \Psi_{kj} \) (we omit the dependence of \( Z_k \) on \( i \) and \( j \) to simplify the notation), we have:

\[
S_{ij} = \langle A_i, \Psi_j \rangle = \sum_{k=1}^{N} F_{\omega_k} \Psi_{kj} = \sum_{k=1}^{N} Z_k.
\]

Using the assumption that the vector \( \mathbf{F}_i \) has zero average sum and unit norm, we derive:

\[
E(Z_k) = \Psi_{kj} E(F_{\omega_k}) = \frac{\Psi_{kj}}{N} \sum_{j=1}^{N} F_{ij} = 0.
\]

and also,

\[
E(Z_k^2) = \Psi_{kj}^2 E(F_{\omega_k}^2) = \frac{\Psi_{kj}^2}{N} \sum_{j=1}^{N} F_{ij}^2 = \frac{\Psi_{kj}^2}{N}.
\]

In addition, note that although \( \{ \omega_k \}^N_{k=1} \) have the identical distribution, they are correlated random variables because of the uniformly random permutation without replacement. Thus, with a pair of \( k \) and \( l \) such that \( 1 \leq k \neq l \leq N \), we have:

\[
E(Z_k Z_l) = \Psi_{kj} \Psi_{lj} E(F_{\omega_k} F_{\omega_l})
\]

\[
= \frac{\Psi_{kj} \Psi_{lj}}{N(N-1)} \sum_{1 \leq p \neq q \leq N} F_{ip} F_{jq}
\]

\[
= \frac{\Psi_{kj} \Psi_{lj}}{N(N-1)} \left( \frac{1}{N} \sum_{p=1}^{N} F_{ip}^2 - \frac{1}{N} \sum_{p=1}^{N} F_{ip}^2 \right)
\]

\[
= \frac{\Psi_{kj} \Psi_{lj}}{N(N-1)}.
\]

The last equation holds because the vector \( \mathbf{F}_i \) has zero average sum and unit-norm. Then, we derive the expectation and the variance of \( S_{ij} \) as follows:

\[
E(S_{ij}) = 0;
\]

\[
\text{Var}(S_{ij}) = \frac{\Psi_{kj}^2}{N(N-1)}.
\]
\[ \text{Var}(S_{ij}) = \sum_{k=1}^{N} E(Z_k^2) + \sum_{1 \leq k \neq l \leq N} E(Z_k Z_l) \]
\[ = \frac{1}{N} \sum_{k=1}^{N} \Psi_{kj}^2 - \frac{1}{N(N-1)} \sum_{1 \leq k \neq l \leq N} \Psi_{kj} \Psi_{lj} \]
\[ = \frac{1}{N} - \frac{1}{N(N-1)} \left( \left( \sum_{k=1}^{N} \Psi_{kj}^2 \right) - \sum_{k=1}^{N} \Psi_{kj}^2 \right) \]
\[ = \frac{1}{N} - \frac{1}{N(N-1)} \left( \sum_{k=1}^{N} \Psi_{kj}^2 \right) - 1 \]
\[ \leq \frac{1}{N} + \frac{1}{N(N-1)} = O(\frac{1}{N}). \]

The forth equations holds because the column \( \Psi_j \) has unit-norm. The theorem is then a simple corollary of the Combinatorial Central Limit Theorem [20] (see Appendix 1), provided that its convergence condition can be verified that:

\[ \lim_{N \to \infty} N \max_{1 \leq k \leq N} \left( \frac{1}{N} \sum_{i=1}^{N} \left| F_{ik} - F_i \right|^2 \right) = 0, \]

where

\[ F_i = \frac{1}{N} \sum_{k=1}^{N} F_{ik}; \quad \Psi_j = \frac{1}{N} \sum_{k=1}^{N} \Psi_{kj}. \]

Because \( F_i \) is zero, \( \left| F_i \right| = 1 \) and \( \max_{1 \leq k \leq N} F_{ik}^2 = O(\frac{1}{N}) \), the equation (10) holds if the following equation holds:

\[ \lim_{N \to \infty} \max_{1 \leq k \leq N} \left( \frac{1}{N} \sum_{i=1}^{N} \left| \Psi_{jk} - \Psi_j \right|^2 \right) = 0. \]

Because \( \left\{ \Psi_j \right\} \) are on the order of \( o(\frac{1}{\sqrt{N}}) \):

\[ \sum_{k=1}^{N} \left( \Psi_{jk} - \Psi_j \right)^2 = \left| \Psi_j \right|^2 - N\Psi_j^2 = 1 - N\Psi_j^2 = O(1). \]

Also, due to \( \left| \Psi_j \right| \leq \max_{1 \leq k \leq N} \left| \Psi_{jk} \right| \) and \( \left| \Psi_{jk} \right| \) are on the order of \( o(1) \):

\[ \max_{1 \leq k \leq N} \left( \Psi_{jk} - \Psi_j \right)^2 \leq 4 \max_{1 \leq k \leq N} \Psi_j^2 = o(1). \]

Combination of (12) and (13) implies (11) and thus the convergence condition of the Combinatorial Central Limit Theorem is verified.

The condition that each row of \( F \) has zero average sum is to guarantee that entries of \( F \Psi \) have zero mean while the condition that entries on each row of \( F \) and on each column of \( \Psi \) are not all equal is to prevent the degenerate case that entries of \( F \Psi \) might become a deterministic quantity. For example, when entries of a row \( F \), are all equal \( \frac{1}{\sqrt{N}} \), \( S_{ij} = \frac{1}{\sqrt{N}} \sum_{k=1}^{N} \Psi_{kj} \), which is a deterministic quantity, not a random variable. Note that these conditions are not needed when \( R \) is the local randomizer.

If \( F \) is a DCT matrix, a (normalized) WHT matrix or a (normalized) DFT matrix, all the rows (except for the first one) have zero average sum due to the symmetry in these matrices. The first row, whose entries are all equal \( \frac{1}{\sqrt{N}} \), can be considered as the averaging row, or a lowpass filtering operation. When the input signal is zero-mean, this row might be chosen or not without affecting quality of the reconstructed signal. Otherwise, it should be included in the chosen row set to encode the signal’s mean. Lastly, the condition that absolute average sum of every column of the sparsifying basis \( \Psi \) are on the order of \( o(\frac{1}{\sqrt{N}}) \) is also close to the reality because the majority of columns of the sparsifying basis \( \Psi \) can be roughly viewed as bandpass and highpass filters whose average sum of the coefficients are always zero. For example, if \( \Psi \) is a wavelet basis (with at least one vanishing moment), then all columns of \( \Psi \) (except one at DC) has column sum of zero.

The aforementioned theorems show that under certain conditions, the majority of entries of \( A\Psi \) (also \( \Phi \Psi \)) behave like Gaussian random variables \( N(0, \sigma^2) \), where \( \sigma^2 \leq O(\frac{1}{N}) \). Roughly speaking, this behavior constitutes to a good sensing performance for the proposed framework. However, these asymptotic results are not sufficient for establishing sensing performance analysis because in general, entries of \( A \Psi \) are not stochastically independent, violating a condition of a sensing Gaussian i.i.d matrix. In fact, the sensing performance might be quantitatively analyzed by employing a powerful analysis framework of a random subset of rows of an orthonormal matrix [14]. Note that \( A \) is also an orthonormal matrix when \( R \) is the local or the global randomizer.

Based on the Gaussian tail probability and a union bound for the maximum absolute value of a random sequence, the maximum absolute magnitude of \( A \Psi \) can be asymptotically bounded as follows:

\[ P\left( \max_{1 \leq i,j \leq N} |S_{ij}| \geq t \right) \leq 2N^2 \exp\left(-\frac{t^2}{2\sigma^2}\right) \]

where \( \sigma^2 \leq \frac{c}{N} \) and \( c \) is some positive constant and \( \leq \) stands for “asymptotically smaller or equal”, i.e., when \( N \) goes to infinity, \( \leq \) becomes \( \leq \).

If we choose \( t = \sqrt{\frac{2c \log(N/\delta)}{N}} \), the above inequality is equivalent to:

\[ P\left( \max_{1 \leq i,j \leq N} |S_{ij}| \leq \sqrt{\frac{c \log(N/\delta)}{N}} \right) \geq 1 - \delta \]

which implies that with probability at least \( 1 - \delta \), the mutual coherence of \( A \) and \( \Psi \) is upper bounded by \( O\left(\sqrt{\frac{\log(N/\delta)}{N}}\right) \), which is close to the optimal bound, except the \( \log N \) factor.

In the following section, we will employ a more powerful tool from the theory of concentration inequalities to analyze the coherence between \( A = FR \) and \( \Psi \) when \( N \) is finite. We also consider a more general case that \( F \) is a sparse matrix (e.g. a block-diagonal matrix).

B. Incoherence Analysis

Before presenting theoretical results for incoherence analysis, we introduce assumptions for block-based local and global randomization models.

1) Assumptions for the Block-based Local Randomization Model:

- \( F \) is an \( N \times N \) unit-norm row matrix with the maximal absolute magnitude of entries on the order of \( O(\frac{1}{\sqrt{N}}) \),
where $1 \leq B \leq N$, i.e. $\max_{1 \leq i,j \leq N} |F_{ij}| = \frac{c}{\sqrt{B}}$, where $c$ is some positive constant.

* $\Psi$ is an $N \times N$ unit-norm column matrix.

2) Assumptions for the Block-based Global Randomization Model: The block-based global randomization model requires similar assumptions for the block-based local randomization model plus the following assumption:

* All rows of $F$ have zero average sum.

**Theorem III.3.** Let $A = FR$, where $R$ is the local randomizer. Given the assumptions for the block-based local randomization model, then

- With probability at least $1 - \delta$, the mutual coherence of $A$ and $\Psi$ is upper bounded by $O(\sqrt{\frac{\log(N/\delta)}{B}})$.
- In addition, if the maximal absolute magnitude of entries of $\Psi$ is on the order of $O(\frac{1}{\sqrt{N}})$, the mutual coherence is upper bounded by $O(\sqrt{\frac{\log(N/\delta)}{N}})$, which is independent of $B$.

**Proof.** A common proof strategy for this theorem as well as for other theorems in this paper is to establish a large deviation inequality that implies the quantity of our interest is on the order of average sensing performance. In many cases, we are only interested in cumulative coherence between two matrices $A$ and $\Psi$ or $A$ and $\Psi_T$, where $T$ is the support of the transform coefficient vector. As will be shown in the following section, the cumulative coherence

where $c$ is some positive constant, then

$$\sigma^2 \leq \max_{1 \leq i,j \leq N} |F_{ij}|^2 \sum_{k \in \text{supp}(F_i)} F_{ik}^2 \leq \max_{1 \leq i,j \leq N} |F_{ij}|^2 = c \frac{1}{B}. \quad (15)$$

Finally, we derive an upper bound of the mutual coherence $\mu = \max_{1 \leq i,j \leq N} |S_{ij}|$ by taking a union bound for the maximum absolute value of a random sequence:

$$P(\max_{1 \leq i,j \leq N} |S_{ij}| \geq t) \leq 2N^2 \exp(-t^2/\sigma^2).$$

Choose $t = \sqrt{\sigma^2 \log(2N^2/\delta)}$, after simplifying the inequality, we get:

$$P(\max_{1 \leq i,j \leq N} |S_{ij}| \geq \sqrt{\sigma^2 \log(2N^2/\delta)}) \leq 1 - \delta.$$ 

Thus, with an arbitrarily $\Psi$, (14) holds and we achieve the first claim of the Theorem:

$$P(\max_{1 \leq i,j \leq N} |S_{ij}| \leq \sqrt{\sigma^2 \log(2N^2/\delta)}) \geq 1 - \delta.$$ 

In the case that (15) holds, we achieve the second claim of the Theorem:

$$P(\max_{1 \leq i,j \leq N} |S_{ij}| \leq \sqrt{c \log(2N^2/\delta)} \frac{1}{N}) \geq 1 - \delta.$$ 

**Remark III.1.** When $A$ is some popular transform such as the DCT or the normalized WHT, the maximal absolute magnitude of entries is on the order of $O(\frac{1}{\sqrt{N}})$. As a result, the mutual coherence of $A$ and an arbitrary $\Psi$ is upper bounded by $O(\sqrt{\frac{\log(N/\delta)}{N}})$, which is also consistent with our asymptotic analysis above. In other words, when at least $\Phi$ or $\Psi$ is a dense and uniform matrix, i.e. the maximal absolute magnitude of their entries is on the order of $O(\frac{1}{\sqrt{N}})$, their mutual coherence approaches the minimal bound, except for the log $N$ factor. In general, the mutual coherence between an arbitrary $\Phi$ and a sparse matrix $A$ (e.g. block diagonal matrix of block size $B$) might be $\frac{B}{N}$ times larger.

Cumulative coherence is another way to quantify incoherence between two matrices [21].

**Definition III.1.** The cumulative coherence of an $N \times N$ matrix $A$ and an $N \times K$ matrix $B$ is defined as:

$$\mu_c(A, B) = \max_{1 \leq i \leq N} \sqrt{\sum_{1 \leq j \leq K} (\langle A_i, B_j \rangle)^2}$$

where $A_i$ and $B_j$ are rows of $A$ and columns of $B$, respectively.

The cumulative coherence $\mu_c(A, B)$ measures the average incoherence between two matrices $A$ and $B$ while mutual coherence $\mu(A, B)$ measures the entry-wise incoherence. As a result, the cumulative coherence seems to be a better indicator of average sensing performance. In many cases, we are only interested in cumulative coherence between $A$ and $\Psi_T$, where $T$ is the support of the transform coefficient vector. As will be shown in the following section, the cumulative coherence...
provides a more powerful tool to obtain a tighter bound for the number of measurements required for exact recovery.

From the definition of cumulative coherence, it is easy to verify that \( \mu_c \leq \sqrt{K} \mu \). If we directly apply the result of the Theorem III.3 we obtain a trivial bound of the cumulative coherence: \( \mu_c = O(\sqrt{K \log N/B}) \) for an arbitrary basis \( \Psi \) and \( \mu_c = O(\sqrt{K \log N/B}) \) for a dense and uniform \( \Psi \). In fact, we can get rid of the factor \( \log N \) by directly measuring the cumulative coherence from its definition.

**Theorem III.4.** Let \( A = FR \), where \( R \) is the local randomizer. Given the assumptions for the block-based local randomization model, with probability at least \( 1 - \delta \), the cumulative coherence of \( A \) and \( \Psi_T \), where \( |T| = K \), is upper bounded by \( \frac{2c}{\sqrt{B}} \max(\sqrt{K}, 4\sqrt{\log(2N/\delta)}) \).

**Proof.** Denote \( U = \Psi_T \) and \( U_k \) are columns of \( U \). Let \( A_i \) and \( \Psi_j \) (\( j \in T \)) be rows of \( A \) and columns of \( \Psi_T \), respectively.

\[
S_i = \sum_{j \in T} (A_i, \Psi_j)^2 = \|A_i \Psi_T\|_2 = \| \sum_{k \in \text{supp}(F_i)} R_{kk} F_k U_k \|_2.
\]

Denote \( V_k = F_k U_k \) and \( V \) is the matrix of columns \( V_k \), \( k \in \text{supp}(F_i) \). First, we derive upper bound for the Frobenius norm of \( V \):

\[
\|V\|_F^2 \leq \max_{1 \leq i \leq N} \|F_{ij}\|_2^2 \leq \frac{c^2 K}{B}.
\]

The last equation holds because \( \|U\|_F^2 = K \). Also, the bound for the spectral norm is:

\[
\|V\|_2^2 = \sup_{\|\beta\|_2=1} \sum_{k \in \text{supp}(F_i)} |\langle \beta, V_k \rangle|^2 = \sup_{\|\beta\|_2=1} \sum_{j=1}^{K} F_{ij}^\dagger (\sum_{k \in \text{supp}(F_i)} |\beta_j U_{ij}|)^2 \leq \max_{1 \leq i \leq N} \|F_{ij}\|_2^2 \|\beta\|_2=1 \sum_{1 \leq k \leq N} |\langle \beta, U_k \rangle|^2 \leq \frac{c^2}{B} \|U\|_2^2 = \frac{c^2}{B}.
\]

The last equation holds because \( \|U\|_2^2 = 1 \). Now, we have:

\[
S_i = \| \sum_{k \in \text{supp}(F_i)} R_{kk} F_k U_k \|_2 = \| \sum_{k \in \text{supp}(F_i)} R_{kk} V_k \|_2.
\]

Let us denote \( Z = \sum_{k \in \text{supp}(F_i)} R_{kk} V_k \). \( Z \) is a Rademacher sum of vectors and \( S_i = \|Z\|_2 \) is a random variable. To show that \( S_i \) is concentrated around its expectation, we first derive bound of \( E(\|Z\|_2) \). It is easy to verify that for a random variable \( X \), \( E(X) \leq \sqrt{E(X^2)} \). Thus, we will derive the upper bound for the simpler quantity \( E(\|Z\|_2^2) \)

\[
E(\|Z\|_2^2) = E(\|Z^* Z\|_2) = \sum_{k, l \in \text{supp}(F_i)} E(R_{kk} R_{ll}) \langle V_k, V_l \rangle = \sum_{k \in \text{supp}(F_i)} \langle V_k, V_k \rangle = \|V\|_F^2 = \frac{c^2}{B} K.
\]

The third equality holds because \( R_{kk} \) are i.i.d Bernoulli random variables and thus, \( E(R_{kk} R_{ll}) = 0 \forall k \neq l \). As a result,

\[
E(S_i) = E(\|Z\|_2) \leq c\sqrt{\frac{K}{B}}.
\]

Applying Ledoux’s concentration inequality of the norm of a Rademacher sum of vectors [22] (see Appendix 2). Noting that \( \|V\|_2^2 \) can be viewed as the variance of \( S_i \), yields:

\[
\Pr(S_i \geq c\sqrt{\frac{K}{B} + t}) \leq 2 \exp(-t^2 \frac{B}{16c^2}).
\]

Finally, apply a union bound for the maximum absolute value of a random process, we obtain:

\[
\Pr(\max_{1 \leq i \leq N} S_i \geq c\sqrt{\frac{K}{B} + t}) \leq 2N \exp(-t^2 \frac{B}{16c^2}).
\]

Choose \( t = \frac{4c}{\sqrt{B}} \sqrt{\log(2N/\delta)} \), we get:

\[
\Pr(\max_{1 \leq i \leq N} S_i \geq \frac{c}{\sqrt{B}}(\sqrt{K} + 4\sqrt{\log(2N/\delta)})) \leq \delta.
\]

Finally, we derive:

\[
\Pr(\max_{1 \leq i \leq N} S_i \geq \frac{2c}{\sqrt{B}} \max(\sqrt{K}, 4\sqrt{\log(2N/\delta)})) \leq \delta.
\]

**Remark III.2.** When \( K \geq 16 \log(2N/\delta) \), the cumulative coherence is upper bounded by \( O(\sqrt{\frac{K}{B}}) \). When \( K \leq 16 \log(2N/\delta) \), the upper bound of the cumulative coherence is \( O(\sqrt{\frac{\log(N/\delta)}{B}}) \), which is similar to that of the mutual coherence in Theorem III.3.

**Remark III.3.** When \( F \) is some popular transform such as the DCT or the normalized WH, the maximum absolute magnitude of entries is on the order of \( O(\sqrt{\frac{1}{N}}) \). As a result, the cumulative coherence of \( A \) and any arbitrary \( \Psi_T \), where \( |T| = K \), is upper bounded by \( O(\sqrt{\frac{K}{N}}) \) if \( K > 16 \log(\frac{2N}{\delta}) \).

**Remark III.4.** The above theorem represents the worst-case analysis because \( \Psi \) can be an arbitrary matrix (the worst case corresponds to the case when \( \Psi \) is the identity matrix). When \( \Psi \) is known to be dense and uniform, the upper bound of cumulative coherence, according to the Theorem III.3 and the fact that \( \mu_c \leq \mu \sqrt{K} \), is \( O(\sqrt{\frac{K \log N}{B N}) \), which is, in general, better than \( O(\sqrt{\frac{K}{B}}) \).

The asymptotical distribution analysis in Section III-A reveals a significant technical difference required for two randomization models. With the local randomizer, entries of \( A\Psi \) are sums of independent random variables while with the global randomizer, they are sums of dependent random variables. Stochastic dependence among random variables makes it much harder to set up similar arguments of their sum’s concentration. In this case, we will show that the incoherence of \( A \) and \( \Psi \) might depend on an extra quantity, the heterogeneity coefficient of the matrix \( \Psi \).
Definition III.2. Assume $\Psi$ is an $N \times N$ matrix. Let $T_k$ be the support of the column $\Psi_k$. Define:

$$\rho_k = \frac{\max_{1 \leq i \leq N} |\Psi_{ki}|}{\sqrt{\frac{1}{|T_k|} \sum_{i \in T_k} |\Psi_{ki}|}}.$$  

(16)

The column-wise heterogeneity coefficient of the matrix $\Psi$ is defined as:

$$\rho_{\Psi} = \max_{1 \leq k \leq N} \rho_k.$$  

(17)

Obviously, $1 \leq \rho_k \leq \sqrt{|T_k|}$. $\rho_k$ illustrates the difference between the largest entry’s magnitude and the average energy of nonzero entries of the vector $\Psi_k$. Roughly speaking, it indicates heterogeneity of nonzero entries of the vector $\Psi_k$. If nonzero entries of a column $\Psi_k$ are homogeneous, i.e. they are on the same order of magnitude, $\rho_k$ is on the order of a constant. If all nonzero entries of a matrix are homogeneous, the heterogeneity coefficient is also on the order of a constant, $C_{\Psi} = O(1)$ and $\Psi$ is referred as a uniform matrix. Note that a uniform matrix is not necessarily dense, for example, a block-diagonal matrix of DCT or WHT blocks.

The following theorem indicates that when the global randomizer is employed, the mutual coherence between $A$ and $\Psi$ is upper-bounded by $O(\rho_{\Psi} \sqrt{\log(N)/B})$, where $B$ is the block size of $\Phi$ and $\Psi$ is an arbitrary matrix with the heterogeneity coefficient $\rho_{\Psi}$.

Theorem III.5. Let $A = FR$, where $R$ is the global randomizer. Assume that $\rho_k \geq 4 \log(2N^2/\delta) \forall k \in \{1, 2, \ldots, N\}$, where $\rho_k$ is defined as in (17). Given the assumptions for the block-based global randomization model, then

- With probability at least $1 - \delta$, the mutual coherence of $A$ and $\Psi$ is upper-bounded by $O(\rho_{\Psi} \sqrt{\log(N)/B})$, where $\rho_{\Psi}$ is defined as in (17).
- In addition, if $\Psi$ is dense and uniform, i.e. the maximum absolute magnitude of its entries is on the order of $O(\sqrt{N})$ and $B \geq 4 \log(2N^2/\delta)$, the mutual coherence is upper-bounded by $O(\sqrt{\log(N)/B})$, which is independent of $B$.

Proof. Let $[\omega_1, \omega_2, \ldots, \omega_N]$ be a uniformly random permutation of $\{1, 2, \ldots, N\}$.

$$S_{ij} = \langle A_i, \Psi_j \rangle = \sum_{k=1}^{N} F_{\omega_k} \Psi_{jk}.$$  

As in the proof of the Theorem III.2, $\{\omega_k\}_{k=1}^{N}$ can be viewed as a sequence of dependent random variables with identical distribution, i.e. for a fixed $k \in \{1, 2, \ldots, N\}$:

$$P(\omega_k = i) = \frac{1}{N}, \quad i \in \{1, 2, \ldots, N\}.$$  

The condition of $F$ is equivalent to $\max_{1 \leq i,j \leq N} |F_{ij}| = \frac{c}{\sqrt{B}}$, where $c$ is some positive constant. Define $\{q_{\omega_k}\}_{k=1}^{N}$ as the following:

$$q_{\omega_k} = \begin{cases} \frac{\sqrt{B}|T_k|}{2c\rho_{\Psi}} F_{\omega_k} \Psi_{jk} + \frac{1}{2} & \text{if } \Psi_{jk} \neq 0 \\ 0 & \text{if } \Psi_{jk} = 0. \end{cases}$$

It is easy to verify that $0 \leq q_{\omega_k} \leq 1$. Define $W_k$ as the sum of dependent random variables $q_{\omega_k}$

$$W_k = \sum_{k=1}^{N} q_{\omega_k} = \frac{\sqrt{B}|T_k|}{2c\rho_{\Psi}} \sum_{k=1}^{N} F_{\omega_k} \Psi_{jk} + \frac{|T_k|}{2}.$$  

(2)

Note that $\{F_{\omega_k}\}_{k=1}^{N}$ are zero-mean random variables because $F_i$ has zero average sum. Thus, $E(S_{ij}) = 0$ and $E(W_k) = \frac{|T_k|}{2}$. Then, applying the Sourav’s theorem of concentration inequality for a sum of dependent random variables, it results in:

$$P\left( \frac{\sqrt{B}|T_k|}{2c\rho_{\Psi}} |S_{ij}| \geq \epsilon \right) \leq 2 \exp\left(-\frac{\epsilon^2}{2|T_k| + 2\epsilon}\right).$$

Denote $t = \frac{2\epsilon}{\sqrt{B}|T_k|}$. The above inequality is equivalent to:

$$P\{ |S_{ij}| \geq t \} \leq 2 \exp\left(-\frac{t^2}{4|T_k| \log\left(\frac{2N^2}{\delta}\right)}\right).$$

By choosing $t = \frac{4c\rho_{\Psi}}{\sqrt{B}} \log\left(\frac{2N^2}{\delta}\right)$, we achieve:

$$P\{ |S_{ij}| \geq t \} \leq 2 \exp\left(-\frac{4|T_k| \log\left(\frac{2N^2}{\delta}\right)}{2|T_k| + 4\sqrt{|T_k| \log\left(\frac{2N^2}{\delta}\right)}}\right).$$

If $|T_k| \geq 4 \log\left(\frac{2N^2}{\delta}\right)$, the denominator inside the exponent is smaller than $4|T_k|$. Thus

$$P\{ |S_{ij}| \geq t \} \leq 2 \exp\left(-\frac{1}{B} \log\left(\frac{2N^2}{\delta}\right)\right) \leq 2 \exp\left(-\log\left(\frac{2N^2}{\delta}\right)\right) = \frac{\delta}{N^2}.$$  

Finally, after taking the union bound for the maximum absolute value of a random sequence and simplifying the inequality, we obtain the first claim of the Theorem:

$$P\left( \max_{1 \leq i,j \leq N} |S_{ij}| \leq O\left(\sqrt{\frac{\log(N/\delta)}{B}}\right) \right) \geq 1 - \delta.$$  

If $\Psi$ is known to be dense and uniform, i.e. $\max_{1 \leq i,j \leq N} |\Psi_{ij}| = \frac{c_1}{\sqrt{N}}$, where $c_1$ is some positive constant. We then define $\{q_{\omega_k}\}_{k=1}^{N}$ as the following:

$$q_{\omega_k} = \begin{cases} \frac{\sqrt{B|T_k|}}{2c_1} F_{ik} \Psi_{j\omega_k} + \frac{1}{2} & \text{if } F_{ik} \neq 0 \\ 0 & \text{if } F_{ik} = 0. \end{cases}$$

Note that $0 \leq q_{\omega_k} \leq 1$ and $E(q_{\omega_k}) = \frac{B}{2}$. Repeat the same arguments above, we have:

$$P\{ |S_{ij}| \geq t \} \leq 2 \exp\left(-\frac{NB}{4c_1^2 c^2} \frac{t^2}{2B + \frac{1}{c_1} \sqrt{NB}}\right).$$

Similarly, choose $t = 4c_1 \sqrt{\frac{1}{N} \log\left(\frac{2N^2}{\delta}\right)}$, we can derive:

$$P\{ |S_{ij}| \geq t \} \leq 2 \exp\left(-\frac{-AB \log\left(\frac{2N^2}{\delta}\right)}{2B + 4 \sqrt{B \log\left(\frac{2N^2}{\delta}\right)}}\right).$$
If $B \geq 4 \log(\frac{2N^2}{\delta})$, the denominator inside the exponent is smaller than $4B$. Thus,

$$P(|S_{ij}| \geq 2c_1 \sqrt{\frac{1}{N} \log\left(\frac{2N^2}{\delta}\right)}) \leq \delta N^2. $$

After taking the union bound of the maximum absolute value of a random sequence, we achieve the second claim of the Theorem.

Remark III.5. The first part of theorem implies that when $F$ is a dense and uniform matrix (e.g. DCT or normalized WHT) and $\Psi$ is a uniform matrix (not necessarily dense), the mutual coherence closely approaches the minimum bound $O\left(\sqrt{\frac{\log(N/A)}{N}}\right)$. Although in this theorem, the mutual coherence depends on the heterogeneity coefficient, one will see in the experimental Section V that this dependence is almost negligible in practice.

As a consequence of this theorem, when at least $A$ or $\Psi$ is dense and uniform, the mutual coherence of $A$ and $\Psi$ is roughly on the order of $O\left(\sqrt{\frac{\log(N)}{N}}\right)$, which is quite close to the minimal bound $\frac{1}{\sqrt{N}}$, except for the $\log N$ factor. Otherwise, the coherence linearly depends on the block size $B$ of $F$ and is on the order of $O\left(\sqrt{\frac{\log(N)}{B}}\right)$. As a matter of fact, this bound is almost optimal because when $\Psi$ is the identity matrix, the mutual coherence is actually equal to the maximum absolute magnitude of entries of $A$, which is on the order of $O\left(\frac{1}{\sqrt{N}}\right)$. Remark III.6. Although the theoretical results of the global randomizer seem to be always weaker than those of the local randomizer, there are a few practical motivations to study this global randomizer. Speech scrambling has been used for a long time for secure voice communication. Also, analog image/video scrambling have been implemented for commercial security related applications such as CCTV surveillance system. In addition, permutation does not change the dynamic range of the sensing signal, i.e. no bit expansion in implementation. The computation cost of random permutation is only $O(N)$, which is very easy to implement in software. From a security perspective the operation of random permutation offers a large key space than random sign flipping ($N!$ vs $2^N$). Also, as will be shown in the numerical experiment section, with random permutation, one can get highly sparse measurement matrix.

IV. COMPRESSION SAMPLING PERFORMANCE ANALYSIS

Section III demonstrates that under some mild conditions, the matrix $A$ and $\Psi$ are highly incoherent, implying that the matrix $A\Psi$ is almost dense. When $A\Psi$ is dense, energy of nonzero transform coefficients $\alpha_T$ is distributed over all measurements. Commonly speaking, this good for signal recovery from a small subset of measurements because if energy of some transform coefficients were concentrated in few measurements that happens to be bypassed in the sampling process, there is no hope for exact signal recovery even when employing the most sophisticated reconstruction method. This section shows that a random subset of rows of the matrix $A = FR$ yields almost optimal measurement matrix $\Phi$ for compressive sensing.

A. Assumptions for Performance Analysis

A signal $x$ is assumed to be sparse in some sparsifying basis $\Psi: x = \Psi \alpha$, where the vector of transform coefficients $\alpha$ has no more than $K$ nonzero entries. The sign sequence of nonzero transform coefficients $\alpha_T$ which is denoted as $z$, is assumed to be a random vector of i.i.d Bernoulli random variables (i.e. $P(z_i = \pm 1) = \frac{1}{2}$). Let $y = \Phi x$ be the measurement vector, where $\Phi = \sqrt{\frac{N}{B}}DF\Psi$ is a Structurally Random Matrix. Assumptions of the block-based local randomization and of the block-based global randomization models hold.

B. Theoretical Results

Theorem IV.1. With probability at least $1 - \delta$, the proposed sensing framework can recover $K$-sparse signals exactly if the number of measurements $M \geq O\left(\frac{N}{B}K \log^2\left(\frac{N}{\delta}\right)\right)$. If $F$ is a dense and uniform rather than block-diagonal (e.g. DCT or normalized WHT matrix), the number of measurements needed is on the order of $O\left(\frac{K \log^2(N)}{\delta}\right)$.

Proof. This is a simple corollary of the theorem of Candès et al. [14] Theorem 1.1 because (i) $A = FR$ is an orthonormal matrix, and (ii) our incoherence results between $A$ and $\Psi$ in the Theorem III.3 and Theorem III.5.

Remark IV.1. If $\Psi$ is dense and uniform, the number of measurements for exact recovery is always $O(K \log^2\left(\frac{N}{\delta}\right))$ regardless of the block size $B$. This implies that we can use the identity matrix for the transform $F$ ($B = 1$). For example, when the input signal is known to be spectrally sparse, compressively sampling it in the time domain is as efficient as in any other transform domain.

Compared with the framework that uses random projection, there is an upscale factor of $\log N$ for the number of measurements for exact recovery. In fact, by employing the bound of cumulative coherence, we can eliminate this upscale factor and thus, successfully showing optimal performance guarantee.

Theorem IV.2. Assume that the sparsity $K > 16 \log(\frac{N}{\delta})$. With probability at least $1 - \delta$, the proposed framework employing the local randomizer can reconstruct $K$-sparse signals exactly if the number of measurements $M \geq O\left(\frac{N}{B}K \log\left(\frac{N}{\delta}\right)\right)$.

Proof. The proof is based on the result of cumulative coherence in the Theorem III.4 and a modification of the proof framework of the compressed sensing [13].

Denote $U_T = \sqrt{\frac{N}{B}}DF \Psi$, $U_T = \sqrt{\frac{N}{B}}DF \Psi$, $U_\Omega = \sqrt{\frac{N}{B}}DF \Psi$, and $U_{\Omega T} = \sqrt{\frac{N}{B}}DF \Psi$, where the support $\Omega = \{k|D_{kk} = 1, k = 1, 2, \ldots, N\}$. Let $v_k$, $k \in \{1, 2, \ldots, N\}$, be columns of $U_T$. Denote $\mu_c = \max_{1 \leq k \leq N} \|v_k\|_2$, where $\mu_c = \mu_c(A, \Psi, T)$ is the cumulative coherence of $A = \sqrt{\frac{N}{B}}DF$ and $\Psi_T$. According to the above incoherence analysis, $\mu_c \leq O\left(\frac{\sqrt{N \log N}}{BM}\right)$. Also, denote $\mu$ as the mutual coherence of $A$ and $\Psi_T$, $\mu \leq O\left(\frac{\sqrt{N \log N}}{BM}\right)$. 

As indicated in [12], [14], to show $l_1$ minimization exact recovery, it is sufficient to verify the Exact Recovery Principle.

**Exact Recovery Principle.** With high probability, $|\pi_k| < 1$ for all $k \in T^c$, where $T^c$ is the complementary set of the set $T$ and $\pi = U_{1:T}U_{1:T}^\ast(U_{1:T}U_{1:T}^\ast)^{-1}z$, where $z$ is the sign vector of nonzero transform coefficients $a_T$.

Note that $\pi_k = \langle \nu_k(U_{1:T}U_{1:T}^\ast)^{-1}, z \rangle$, where $\nu_k$ is the $k^{th}$ row of $U_{1:T}U_{1:T}^\ast$, for some $k \in T^c$. To establish the Exact Recovery Principle, we will first derive following lemmas. The first lemma is to bound the norm of $\nu_k$.

**Lemma IV.1. (Bound the norm of $\nu_k$)** With high probability, $\|\nu_k\|$ is on the order of $O(\sqrt{\mu_c})$:

$$P (\|\nu_k\| \geq \mu_c + a\sigma) \leq 3 \exp(-\alpha^2),$$

where $\sigma$, $\gamma$ and $\alpha$ are some certain numbers.

**Proof.** Let $U_k$ be columns of $U$. For $k \in T^c$:

$$\nu_k = \frac{1}{M} \sum_{i=1}^{N} D_{i,k} U_i v_i = \frac{1}{M} \sum_{i=1}^{N} (D_{i,k} - \frac{\mu_c}{N}) U_i v_i$$

where the second equality holds because $\sum_{i=1}^{N} U_i v_i = U_k U_k^\ast = 0$ that results from the orthogonality of columns of $U$. Let $Z_i = (D_{i,k} - \frac{\mu_c}{N})$. Because $D_{i,k}$ are i.i.d binary random variables, $P (\{D_{i,k} = 1\}) = \frac{\mu_c}{M}$, $Z_i$ are zero mean i.i.d random variables and $E (Z_i^2) = \frac{\mu_c}{M} (1 - \frac{\mu_c}{N})$. Let $H$ be the matrix of columns $h_i = U_i v_i$, $i \in \{1, 2, \ldots, N\}$. Then, $\nu_k$ can be viewed as a random weighted sum of column vectors $h_i$:

$$\nu_k = \frac{1}{M} \sum_{i=1}^{N} Z_i h_i$$

and $\|\nu_k\|$ is a random variable. We have:

$$E (\|\nu_k\|^2) = \sum_{1 \leq i \neq j \leq N} E (Z_i Z_j) (W_i, h_j) = \sum_{1 \leq i \neq j \leq N} E (Z_i^2) \|W_i\|^2 \|h_j\|^2$$

where the last equality holds due to $E (Z_i Z_j) = 0$ if $i \neq j$. Thus,

$$E (\|\nu_k\|^2) = \frac{M}{N} (1 - \frac{\mu_c}{N}) \sum_{1 \leq i \leq N} U_i^2 \|v_i\|^2 \leq \frac{M}{N} \mu_c \sum_{1 \leq i \leq N} U_i^2 \leq \mu_c^2.$$ 

where the last inequality holds due to $\|U_k\|^2 = \frac{N}{M}$. This implies that $E (\|\nu_k\|) \leq \mu_c$. To show that $\|\nu_k\|$ is concentrated around its mean, we use the Talagrand’s theorem of concentration inequality [24].

In addition, it is obvious that $|Z_i| \leq 1$ and thus

$$B = \max_{1 \leq i \leq N} \|h_i\|_2 \leq \mu_c.$$ 

The Talagrand’s theorem [24] (see Appendix 2) shows that:

$$P (\|\nu_k\| - E (\|\nu_k\|) \geq t) \leq 3 \exp (-\alpha^2) \leq 3 \exp (-\alpha^2),$$

where $c$ is some positive constant. Replacing $E (\|\nu_k\|)$, $\alpha^2$ and $B$ by their upper bounds in the right-hand side, we obtain:

$$P (\|\nu_k\| - E (\|\nu_k\|) \geq t) \leq 3 \exp (-\alpha^2) \leq 3 \exp (-\alpha^2).$$

The next step is to simplify the right-hand side of the above inequality by replacing the denominator inside the log by two times the dominant term and note that $log(1+x) \geq \frac{x}{2}$ when $x \leq 1$. In particular, there are two cases:

- Case 1: $\mu_c^2 \geq \mu_c^2$ or equivalently, $\mu_c^2 \geq \mu_c$ denote $\sigma^2 = \mu_c^2$ and $t = a\sigma$. If $\mu_c \leq 2\mu_c^2$ or equivalently, $a \leq 2(1/\mu_c)^{\frac{1}{2}}$,

$$P (\|\nu_k\| - E (\|\nu_k\|) \geq t) \leq 3 \exp (-\alpha^2).$$

- Case 2: $\mu_c^2 \geq \mu_c^2$, denote $\sigma^2 = \mu_c^2$ and $t = a\sigma$. If $\mu_c \leq 2\mu_c^2$ or equivalently, $a \leq 2/\mu_c$,

$$P (\|\nu_k\| - E (\|\nu_k\|) \geq t) \leq 3 \exp (-\alpha^2).$$

where $\gamma$ is some positive constant.

In conclusion, let $\sigma = \sqrt {\max(\mu_c^2, \mu_c^2)}$. Then, for any $a \leq \min(2/\mu_c, 2/\sqrt {\mu_c})$:

$$P (\|\nu_k\| \geq \mu_c + a\sigma) \leq 3 \exp (-\alpha^2),$$

where $\gamma$ is some positive constant.

**Lemma IV.2. (Bound the spectral norm of $U_{1:T}^\ast U_{1:T}$)**

With high probability, $\|U_{1:T}^\ast U_{1:T}\| \geq \frac{1}{2}$

**Proof.** The Theorem 1.2 in [14] shows that with probability $1 - \delta$, $\|U_{1:T}^\ast U_{1:T}\| \geq \frac{1}{2}$ if $M \geq \mu_c^2 \max(c_1\log K, c_2\log(3/\delta))$, where $c_1$ and $c_2$ are some known positive constants.

And the third lemma is to bound the norm of $w_k = \nu_k (U_{1:T}^\ast U_{1:T})^{-1}$.

**Lemma IV.3. (Bound the norm of $w_k = \nu_k (U_{1:T}^\ast U_{1:T})^{-1}$)**

With high probability, $\|w_k\|$ is on the order of $O(\mu_c)$:

$$P (\sup_{k \in T^c} \|w_k\| \geq 2\mu_c + a\sigma) \leq 3N \exp (-\alpha^2) + P (\|U_{1:T}^\ast U_{1:T}\| \leq \frac{1}{2})$$

where $\alpha, \gamma$ and $\sigma$ are defined in the proof of the Lemma IV.1.

**Proof.** Let $A$ be the event that $\|U_{1:T}^\ast U_{1:T}\| \geq \frac{1}{2}$ or equivalently, $\|U_{1:T}^\ast U_{1:T}\| \leq \frac{1}{2}$. Let $B$ be the event that $\sup_{k \in T^c} \|w_k\| \leq \mu_c + a\sigma$. Note that

$$\sup_{k \in T^c} \|w_k\| = \|U_{1:T}^\ast U_{1:T}\|^{-1} \sup_{k \in T^c} \|\nu_k\|.$$
Thus,
\[ P\left( \sup_{k \in T^c} \|w_k\| \geq 2\mu_c + 2a\sigma \right) \leq P(A \cap B) \leq P(A) + P(B). \]
Note that \( P(B) \leq 3N \exp(-\gamma a^2) \) implies \( \ell \) holds.

To establish the Exact Recovery Principle, we will show that \( \sup_{k \in T^c} |\langle w_k, z \rangle| \leq 1 \) with high probability. Note that because \( z \) is assumed to be a vector of i.i.d Bernoulli random variables, \( |\langle w_k, z \rangle| \) is concentrated around its zero mean. In particular, according to the Hoeffding’s inequality:
\[ P(\{|\langle w_k, z \rangle| \geq 1\} \sup_{k \in T^c} \|w_k\| \leq \lambda) \leq 2N \exp(-\frac{1}{2\lambda^2}). \]
Note that with two arbitrary probabilistic events \( A \) and \( B \):
\[ P(A) = P(A|B)P(B) + P(A|\overline{B})P(\overline{B}) \leq P(A) + P(B). \]

Now, let \( A \) be the event \( \{\sup_{k \in T^c} \|w_k\| \leq \lambda\} \) and \( B \) be the event \( \{\sup_{k \in T^c} |\langle w_k, z \rangle| \leq 1\} \), we derive
\[ P(\{\sup_{k \in T^c} \|w_k\| \leq \lambda\} \sup_{k \in T^c} |\langle w_k, z \rangle| \geq 1) \leq 2N \exp(-\frac{1}{2\lambda^2}) + P(\{\sup_{k \in T^c} \|w_k\| \geq \lambda\}). \]
Choose \( \lambda = 2\mu_c + 2a\sigma \), according to \( \ell \) and \( \mu \), the probability of our interest \( P(\{\sup_{k \in T^c} |\langle w_k, z \rangle| \geq 1\}) \) is upper bounded by:
\[ 3N \exp(-\gamma a^2) + 2N \exp(-\frac{1}{2\lambda^2}) + \delta. \]
To prove the second term less than \( \delta \), it is required that
\[ \frac{1}{2\lambda^2} \geq \log\left(\frac{2N}{\delta}\right). \]

- Case 1: \( \mu_c^2 \geq \mu \). The condition that \( \ell \) holds is \( a \leq 2(1/\mu)^{\frac{1}{2}} \) that is equivalent to:
\[ 1 \geq \frac{1}{4}\gamma^{-2}\mu_c^2 \log^2(3N/\delta). \]
It is easy to see \( \mu_c \geq a\sigma \), where \( \sigma = (\mu\mu_c^2)^{1/2} \). In this case, \( \lambda \leq 4\mu_c \). Thus, \( \mu \) holds if
\[ 1 \geq 32\gamma^{-2}\mu_c^2 \log\left(\frac{2N}{\delta}\right). \]

- Case 2: \( \mu \geq \mu_c^2 \). The condition that \( \ell \) holds is \( a \leq 2/\mu_c \) or equivalently,
\[ 1 \geq \frac{1}{4}\gamma^{-2}\mu_c^2 \log^2(3N/\delta). \]
If \( \mu_c \geq a\sigma \), where \( \sigma = \mu \), \( \lambda \leq 4\mu_c \) and the condition is again \( \mu \). Otherwise, \( \lambda \leq 4a\sigma \). In this case, \( \mu \) holds if
\[ 1 \geq 32\gamma^{-1}\mu_c^2 \log\left(\frac{2N}{\delta}\right). \]

In conclusion, the Exact Recovery Principle is verified if \( 1 \geq \max(c_1\mu^2 \log^2(3N/\delta), c_2\mu^2 \log^2(3N/\delta)) \), where \( c_1 \) and \( c_2 \) are known positive constants.

Finally, note that \( \mu^2 \geq O\left(\frac{N}{BM}\right) \) and \( \mu_c^2 \leq O\left(\frac{NK}{BM}\right) \) and the assumption that \( K \geq 16 \log\left(\frac{2N}{\delta}\right) \), the sufficient condition for exact recovery is \( M \geq O\left(\frac{N}{K^2} \log^2\left(\frac{N}{\delta}\right)\right) \). When \( F \) is dense and uniform, the condition becomes \( M \geq O\left(K \log\left(\frac{N}{\delta}\right)\right) \).

V. NUMERICAL EXPERIMENTS

A. Simulation with Sparse Signals

In this section, we evaluate the sensing performance of several structurally random matrices and compare it with that of the completely random projection. We also explore the connection among sensing performance (probability of exact recovery), streaming capacity (block size of \( F \)) and structure of the sparsifying basis \( \Psi \) (e.g. sparsity and heterogeneity).

In the first simulation, the input signal \( z \) of length \( N = 256 \) is sparse in the DCT domain, i.e. \( z = \Psi \alpha \), where the sparsifying basis \( \Psi \) is the \( 256 \times 256 \) DCT matrix. Its transform coefficient vector \( \alpha \) has \( K \) nonzero entries whose magnitudes are Gaussian distributed and locations are at uniformly random, where \( K \in \{10, 20, 30, 40, 50, 60\} \). With the signal \( z \), we generate a measurement vector of length \( M = 128: y = \Phi z \), where \( \Phi \) is some structurally random matrix or a completely Gaussian random matrix. SRMs under consideration are summarized in Table

The software \( l_1 \)-magic is employed to recover the signal from its measurements \( y \). For each value of sparsity \( K \in \{10, 20, 30, 40, 50, 60\} \), we repeat the experiment 500 times and count the probability of exact recovery. The performance curve is plotted in Fig. 2(a). Numerical values on the \( x \)-axis denote signal sparsity \( K \) while those on the \( y \)-axis denote the probability of exact recovery. We then repeat similar experiments when an input signal is sparse in some sparse and non-uniform basis \( \Psi \). Fig. 2(b) and Fig. 2(c) illustrate the performance curves when \( \Psi \) is the Daubechies-8 wavelet basis and the identity matrix, respectively.

There are a few notable observations from these experimental results. First, performance of the SRM with the dense transform matrix \( F \) (all of its entries are non-zero) is in average comparable to that of the completely random matrix. Second, performance of the SRM with the sparse transform matrix \( F \), however, depends on the sparsifying basis \( \Psi \) of the signal. In particular, if \( \Psi \) is dense, the SRM with sparse \( F \) also has average performance comparable with the completely random matrix. If \( \Psi \) is sparse, the SRM with sparse \( F \) often has worse performance the SRM with dense \( F \), revealing a trade-off between sensing performance and streaming capacity. These numerical results are consistent with the theoretical analysis above. In addition, Fig. 2(b) shows that the SRM with the global randomizer seems to work much better than the SRM with the local randomizer when the sparsifying basis \( \Psi \) of the signal is sparse.

B. Simulation with Compressible Signals

In this simulation, signals of interest are natural images of size \( 512 \times 512 \) such as the \( 512 \times 512 \) Lena, Barbara and Boat
images. The sparsifying basis $\Psi$ used for these natural images is the well-known Daubechies $9/7$ wavelet transform. All images are implicitly regarded as 1-D signals of length $512^2$. The GPSR software in [3] is used for signal reconstruction.

For such a large scale simulation, it takes a huge amount of system resources to implement the sensing method of a completely random matrix. Thus, for the purpose of benchmark, we adopt a more practical scheme of partial FFT in the wavelet domain (WPFFT). The WPFFT is to sense wavelet coefficients in the wavelet domain using the method of partial FFT. Theoretically, WPFFT has optimal performance as the Fourier matrix is completely incoherent with the identity matrix. The WPFFT is a method of sensing a signal in the transform domain that also requires substantial amount of system resources. SRMs under consideration are summarized in Table I

| Notation | $\mathbf{R}$ | $\mathbf{F}$ |
|----------|-------------|-------------|
| WHT64-L  | Local randomizer | $64 \times 64$ block diagonal WHT |
| WHT64-G  | Global randomizer | $64 \times 64$ block diagonal WHT |
| WHT256-L | Local randomizer | $256 \times 256$ block diagonal WHT |
| WHT256-G | Global randomizer | $256 \times 256$ block diagonal WHT |

As clearly seen in Fig. 3, the PFFT is not an efficient sensing matrix for smooth signals like images because Fourier matrix and wavelet basis are highly coherent. On the other hand, the SRM method, which can roughly be viewed as the PFFT preceded by the pre-randomization process, is very efficient. In particular, with a dense SRM like SFFT, the performance difference between the SRM method and the benchmark one, WPFFT, is less than 1 dB. In addition, performance of DCT512-L and WHT512-L that are fully streaming capable SRM, degrades about 1.5 dB, which is a reasonable sacrifice as the buffer size required is less than 0.2 percent of the total length of the original signal. Less degradation is obtainable when the buffer size is increased. Also, in all cases, there is no observable difference of performance between DCT and normalized WHT transforms. It implies that orthonormal matrices whose entries have the same order of absolute magnitude generate comparable performance. In addition, highly sparse SRM using the global randomizer such as DCT32-G and WHT32-G has experimental performance comparable to that of the dense SRMs. Note that these SRM are highly sparse because their density are only $2^{-13}$. This observation again verifies that SRM with the global randomizer outperforms SRM with the local randomizer. This might indicate that our theoretical analysis for the global randomizer is inadequate. In practice, we believe that the global randomizer always works as well as and even better than the local randomizer. We leave the theoretical justification of this observation for our future research.

VI. DISCUSSION AND CONCLUSION

A. Complexity Discussion

We compare the computation and memory complexity between the proposed SRM and other random sensing matrices such as Gaussian or Bernoulli i.i.d. matrices. In implementation, the i.i.d Bernoulli matrix is obviously preferred than i.i.d Gaussian one as the former has integer entries \{1, −1\} and requires only 1 bit to represent each entry. A $M \times N$ i.i.d Bernoulli sensing matrix requires $MN$ bits for storing the matrix and $MN$ additions and multiplications for sensing operation. An $M \times N$ SRM only requires $2N + N \log N$ bits for storage and $N + N \log N$ additions and multiplications for sensing operation. With the SRM method, the computational complexity and memory space required is independent with the number of measurements $M$. Note that with the SRM method, we do not need to store matrices $\mathbf{D}$, $\mathbf{F}$, $\mathbf{R}$ explicitly. We only need to store the diagonals of $\mathbf{D}$ and of $\mathbf{R}$ and the fast transform $\mathbf{F}$, resulting in significant saving of both memory space and computational complexity.

Computational complexity and running time of $l_1$-minimization based reconstruction algorithms often depend critically on whether matrix-vector multiplications $\mathbf{A}\mathbf{u}$ and $\mathbf{A}^T\mathbf{u}$ can be computed quickly and efficiently (where $\mathbf{A} = \Phi\Psi$) [3]. For the sake of simplicity, assuming that $\Psi$ is identity matrix. $\mathbf{A}\mathbf{u} = \Phi\mathbf{u}$ requires $MN = O(KN \log N)$ additions and multiplications for a random sensing matrix $\Phi$ and $O(N \log N)$ additions and multiplications for the SRM method. This implies that at each iteration, SRM can speed up the reconstruction algorithm with at least $K$ folds. With compressible signals (e.g., images), the number of measurements acquired tends to be proportional with the signal dimension, for example, $M = N/4$. In this case, using SRM can achieve computational complexity reduction with the factor of $\frac{N}{4 \log N}$ times.

Table III summarizes computational complexity and practical advantages between SRM and a random sensing matrix.
TABLE II
SRMs employed in the experiment with compressible signals

| Notation | R                  | F                          |
|----------|--------------------|----------------------------|
| DCT32-G | Global randomizer  | 32 × 32 block diagonal DCT |
| WHT32-G | Global randomizer  | 32 × 32 block diagonal WHT  |
| DCT512-L| Local randomizer   | 512 × 512 block diagonal DCT|
| WHT512-L| Local randomizer   | 512 × 512 block diagonal WHT|

Fig. 4
Reconstructed 512 × 512 Boat images from M/N = 35% sampling rate. (a) The original Boat image; (b) using the WPFFT ensemble: 28.5dB; (c) using the WHT32-G ensemble: 28dB; (d) using the WHT512-L ensemble: 27.7dB

TABLE III
Practical feature comparison

| Features                              | SRMs          | Completely Random Matrices |
|---------------------------------------|---------------|----------------------------|
| No. of measurements for exact recovery| $O(K \log N)$ | $O(K \log N)$              |
| Sensing complexity                    | $N \log N$    | $O(K N \log N)$            |
| Reconstruction complexity at each iteration | $O(N \log N)$ | $O(K N \log N)$        |
| Fast computability                    | Yes           | No                         |
| Block-based processing                | Yes           | No                         |
B. Relationship with Other Related Works

When \( \mathcal{R} \) is the local randomizer, SRM is a little reminiscent to the so-called Fast Johnson-Lindenstrauss Transform (FJLT) \[27\]. However, SRM employs a simpler matrix \( D \). In FJLT, this matrix \( D \) is a completely random matrix with sparse distribution. It is unknown if there exists an efficient implementation of such a sparse random matrix. SRM is relevant for practical applications because of its high performance and fast computation.

In \[25\], \[26\], the Scrambled/Permuted FFT is experimentally proposed as a heuristic low-complexity sensing method that is efficient for sensing a large signal. To the best of our knowledge, however, there has not been any theoretical analysis for the Scrambled FFT. SRM is a generalized framework in which Scrambled FFT is just a specific case, and thus verifying the theoretical validity of the Scrambled FFT.

Random Convolution convolving the input signal with a random pulse followed by randomly subsampling measurements is proposed in \[19\] as a promising sensing method for practical applications. Although there are a few other methods that exploit the same idea of convolving a signal with a random pulse, for examples: Random Filter in \[17\] and Toeplitz structured sensing matrix in \[18\], only the Random Convolution method can be shown to approach optimal sensing performance. While sensing methods such as Random Filter and Toeplitz-based CS methods subsample measurements structurally, the Random Convolution method subsamples measurements in a random fashion, a technique that is also employed in SRM. In addition, the Random Convolution method introduces randomness into the Fourier domain by randomizing phases of Fourier coefficients. These two techniques decouple stochastic dependence among measurements and thus, giving the Random Convolution method a higher performance.

SRM is distinct from all aforementioned methods, including the Random Convolution one. A key difference is that SRM pre-randomizes a sensing signal directly in its original domain (via the global randomizer or the local randomizer) while the Random Convolution method pre-randomizes a sensing signal in the Fourier domain. SRM also extends the Random Convolution method by showing that not only Fourier transform but also other popular fast transforms, such as DCT or WHT, can be employed to achieve similar high performance.

In conclusion, among existing sensing methods, the SRM framework presents an alternative approach to design high performance, low-complexity sensing matrices with practical and flexible features.

APPENDIX I

Central Limit Theorem. Let \( Z_1, Z_2, \ldots, Z_N \) be mutually independent random variables. Assume \( E(Z_k) = 0 \) and denote \( \sigma^2 = \sum_{k=1}^{N} \text{Var}(Z_k) \). If for a given \( \epsilon \geq 0 \) and \( N \) sufficiently large, the following inequalities hold:

\[
\text{Var}(Z_k) < c \sigma^2 \quad k = 1, 2, \ldots, N
\]

then distribution of the normalized sum \( S = \sum_{k=1}^{N} Z_k \) converges to \( N(0, \sigma^2) \).

APPENDIX II

Combieral Central Limit Theorem. Given two sequences \( \{a_k\}_{k=1}^{N} \) and \( \{b_k\}_{k=1}^{N} \). Assume the \( a_k \) are not all equal and \( b_k \) are also not all equal. Let \( [\omega_1, \omega_2, \ldots, \omega_N] \) be a uniform random permutation of \( [1, 2, \ldots, N] \). Denote \( Z_k = a_{\omega_k} \) and

\[
S = \sum_{k=1}^{N} Z_k b_k;
\]

\( S \) is asymptotically normally distributed \( \mathcal{N}(E(S), \text{Var}(S)) \) if

\[
\lim_{N \to \infty} \frac{\max_{1 \leq k \leq N}(Z_k - \bar{Z})^2 \max_{1 \leq k \leq N}(b_k - \bar{b})^2}{\sum_{k=1}^{N}(Z_k - \bar{Z})^2 \sum_{k=1}^{N}(b_k - \bar{b})^2} = 0;
\]

where

\[
\bar{b} = \frac{1}{N} \sum_{k=1}^{N} b_k \quad \text{and} \quad \bar{Z} = \frac{1}{N} \sum_{k=1}^{N} Z_k.
\]

Hoeffding’s Concentration Inequality. Suppose \( X_1, X_2, \ldots, X_N \) are independent random variables and \( a_k \leq X_k \leq b_k \) (\( k = 1, 2, \ldots, N \)). Define a new random variable \( S = \sum_{k=1}^{N} X_k \). Then for any \( t > 0 \)

\[
P(|S - E(S)| \geq t) \leq 2e^{-\frac{2t^2}{\sum_{k=1}^{N}(a_k - b_k)^2}}.
\]

Ledoux’s Concentration Inequality. Let \( \{\eta_i\}_{1 \leq i \leq N} \) be a sequence of independent random variables such that \( |\eta_i| \leq 1 \) almost surely and \( v_1, v_2, \ldots, v_N \) be vectors in Banach space. Define a new random variable: \( S = \|\sum_{i=1}^{N} \eta_i v_i\| \). Then for any \( t > 0 \),

\[
P(S \geq E(S) + t) \leq 2 \exp(-\frac{t^2}{16\sigma^2})
\]

where \( \sigma^2 \) denote the variance of \( S \) and \( \sigma^2 = \max_{1 \leq i \leq N} \sum_{j=1}^{N} |(u_j, v_i)|^2 \).

Talagrand’s Concentration Inequality. Let \( Z_k \) be zero-mean i.i.d random variables and bounded \( |Z_k| \leq \lambda \) and \( u_k \) be column vectors of a matrix \( U \). Define a new random variable:

\[
S = \|\sum_{i=1}^{N} Z_i u_k\|.
\]

Then for any \( t > 0 \),

\[
P(S \geq E(S) + t) \leq 3 \exp(-\frac{t}{cB} \log(1 + \frac{Bt}{\sigma^2 + BE(S)}))
\]

where \( c \) is some constant, variance \( \sigma^2 = E(Z_k^2)\|U\|^2 \) and \( B = \lambda \max_{1 \leq k \leq N} \|u_k\| \).

Sourav’s Concentration Inequality. Let \( \{Z_{ij}\}_{1 \leq i, j \leq N} \) be a collection of numbers from \([0,1]\). Let \( [\omega_1, \omega_2, \ldots, \omega_N] \) be a uniformly random permutation of \([1,2,\ldots,N]\). Define a new random variable:

\[
S = \sum_{i=1}^{N} Z_{i\omega_i}.
\]

Then for any \( t > 0 \)

\[
P(|S - E(S)| \geq t) \leq 2 \exp(-\frac{t^2}{4E(S) + 2t}).
\]
