White Band Disease (type I) of Endangered Caribbean Acroporid Corals is Caused by Pathogenic Bacteria

David I. Kline1,2* & Steven V. Vollmer2,3

Diseases affecting coral reefs have increased exponentially over the last three decades and contributed to their decline, particularly in the Caribbean. In most cases, the responsible pathogens have not been isolated, often due to the difficulty in isolating and culturing marine bacteria. White Band Disease (WBD) has caused unprecedented declines in the Caribbean acroporid corals, resulting in their listings as threatened on the US Threatened and Endangered Species List and critically endangered on the IUCN Red List. Yet, despite the importance of WBD, the probable pathogen(s) have not yet been determined. Here we present in situ transmission data from a series of filtrate and antibiotic treatments of disease tissue that indicate that WBD is contagious and caused by bacterial pathogen(s). Additionally our data suggest that Ampicillin could be considered as a treatment for WBD (type I).

In the last three decades, there have been massive ecological changes in Caribbean coral reefs resulting from human impacts and culminating in phase shifts from coral to macroalgal dominance at many locations3–9 and an 80% decline in coral coverage across the region10. The emergence of new marine diseases has contributed to this decline3–8, with two disease epidemics in the late 1970’s and early 1980s causing the most damage. The most well known of these affected the long-spined sea urchin Diadema antillarum in 1983, and drastically reduced populations of this keystone herbivore across the Caribbean, with subsequent overgrowth of many reefs by seaweeds9,10. However, not all coral mortality can be unambiguously attributed to this event, as the Diadema die-off was slightly preceded by the emergence of White Band Disease (WBD) in the late 1970s, which caused massive population declines in the two dominant Caribbean shallow water coral species, Acropora palmata and A. cervicornis11–13. Loss of between 80–98% loss of individuals of these two species in parts of the Caribbean since the 1980’s, resulted in their addition to the Endangered Species list in 200614, critical habitat designation in 200815, and listing as critically endangered on the International Union for Conservation of Nature (IUCN) Red List in 200816. The mass die-off of the Caribbean Acropora corals was unprecedented in their 220,000 year geological record17,18; it not only altered the zonation patterns of Caribbean reefs but even resulted in geomorphological changes to the reefs15.

Despite the impact of WBD on the Caribbean Acropora corals, relatively little is known about its etiology and ecology. WBD is one of the few coral diseases exhibiting high host specificity, affecting only Acropora cervicornis and A. palmata19. WBD draws its name from its appearance as an advancing layer of diseased and necrotic tissue that spreads rapidly from the base of the coral colony at rates in excess of 1 cm per day20. It can be transmitted through direct contact with infected coral tissue20,21 and through animal vectors such as corallivorous snails20. The syndrome itself is complicated by the existence of two forms, WBD type I and type II, which can be distinguished by a band of bleached tissue that precedes the necrotic tissue in WBD type II.

WBD type II occurs predominantly in the Bahamas and a putative pathogen Vibrio characharii has been identified22. Additionally, Vibrio bacteria were isolated from infected A. cervicornis in Puerto Rico and were able to cause WBD type II symptoms in previously healthy corals, satisfying the first steps required to fulfil Henle-Koch’s postulates23,24. However, this work has not completely satisfied Henle-Koch’s postulates as the identity of the suspected pathogen was not determined in these experiments and the fourth Henle-Koch postulate requiring re-isolation of the inoculated microorganisms was not possible without identification of the suspected pathogen23,24.
WBD type I occurs throughout the Caribbean and an association with a marine *Rickettsia* bacteria has been suggested. However, recent histopathology studies of WBD type I using a FISH probe have not found the ovoid bodies containing rod shaped gram-negative bacteria found in some samples described in Peters et al (1983) and found no evidence of a bacterial pathogen. Thus, it remains unclear if the pathogen is bacterial, nor has a role of viruses been excluded in the pathogenicity of WBD. Almost four decades since WBD type I caused massive coral die-offs throughout the Caribbean a pathogen has not been identified.

Here we applied a series of filtered and antibiotic treated disease homogenates to healthy coral fragments and recorded *in situ* disease transmission in order to determine if the WBD pathogen(s) is bacterial, viral and/or eukaryotic.

### Results

The WBD symptoms in the transmission experiments included a clear line of necrotic tissue that rapidly progressed up the previously healthy coral branch at a rate of approximately 1 cm/day (Fig. 1). We rechecked all of the corals in these experiments one day and three days after starting the experiments to ensure that corals scored as having WBD transmission had a line of necrotic tissue that rapidly progressed up the coral branch. Tissue mortality near the point of gauze attachment that did not progress was not scored as WBD. WBD transmission differed significant across the six treatments (Table 1, Table 2, Fig. 2; Pearson chi-square = 71.318, df = 5, p < 0.0001). The untreated WBD homogenate had the highest rate of WBD transmission with 90% (18 out of 20) of the experimental coral fragments contracting WBD (Table 1). WBD transmission for the 0.45 μm filtrate was high (16 out of 20 fragments) and equivalent to the unfiltered WBD homogenate (Fisher’s exact p = 0.661 NS, Table 2). In contrast, the 0.22 μm filtrate of the WBD homogenate had a low rate of transmission (only 2 out of 20 fragments), which was equivalent to the healthy control values (Table 2; Fisher’s exact p = 1) and significantly different from the WBD homogenate (Fisher’s exact p = 0.0001). Likewise, both antibiotic treatments, Tetracycline and Ampicillin, had transmission rates that were significantly lower than either the WBD homogenate or 0.45 μm filtrate (Fisher’s exact p < 0.0001), and not significantly different from either the healthy control (Fisher’s exact p = 0.106 and 1, respectively) or 0.22 μm WBD filtrate (Fisher’s exact p = 0.661 and 0.487, respectively). The one WBD case in the “healthy” corals was likely a coral that appeared healthy in the field but that had contracted WBD and not shown symptoms until being used in the experiments.

### Discussion

Of the over 35 coral diseases reported globally only five bacterial and one fungal pathogen have been identified. Part of the problem is the difficulty in culturing the majority of marine bacteria, a step critical to the fulfillment of Henle-Koch’s postulates. Another major difficulty is that environmental conditions and host susceptibility often contribute to disease transmission. An additional complication is that within one coral polyp there is a complex community of organisms, including bacteria, viruses, archaea, fungus, dinoflagellates, and endolithic algae. Determining which components of the coral holobiont are involved in disease is a major challenge that has limited coral disease research. Furthermore it is likely that many coral diseases are likely caused by a consortium of disease organisms that precludes traditional Henle-Koch’s postulate testing. Finally, there is a gray zone between highly specialized pathogens and commensals that may become pathogenic when the hosts are stressed. Identification of coral disease pathogens has been so difficult and controversial that some suggest that many of the proposed disease may not even be infectious. Several

| Treatment (homogenate) | Transmission Absent | Transmission Present | Total | % Infection |

culture-independent techniques have been developed to study marine diseases\textsuperscript{33,47} but progress identifying potential pathogens has remained slow.

In the case of WBD type I, we have overcome some of these challenges to show that biological agents less than 0.45 μm (including bacteria and viruses) cause high rates of WBD transmission to experimental coral fragments, whereas the 0.22 μm filtrate, which lacks most of the bacteria and contains mostly viruses, does not cause significant WBD transmission. These data clearly implicate bacteria as the primary WBD pathogen(s) and suggest that viruses alone likely do not cause WBD. Coral-associated viruses are the least characterized members of the coral holobiont that are quickly being recognized as diverse and omnipresent members of the coral holobiont community\textsuperscript{43-45}. However, our results do not preclude the possibility that viruses in combination with bacteria cause WBD and additional experiments with anti-viral compounds would be necessary to test this hypothesis.

The antibiotic treatments verified that WBD (type I) is caused by one or more bacterial pathogen(s) as antibiotic treatment without filtration convincingly stopped WBD transmission. The comparison between Tetracycline and Ampicillin treatments suggests that WBD (type I) is likely caused by Gram positive bacteria and less likely by Gram negative bacteria. The data also suggest that Rickettsiales bacteria are likely not involved in causing WBD (type I); if Rickettsiales were involved in causing WBD as suggested previously\textsuperscript{39}, then we would have not expected Ampicillin which is not effective against obligate intracellular bacteria such as Rickettsia\textsuperscript{46} to completely suppress WBD transmission. Additionally, Tetracycline was not as efficient as Ampicillin in suppressing WBD (20% disease transmission compared to 0%), although this difference was not statistically significant (Fisher’s exact p = 0.106). If Rickettsiales had been the pathogen causing WBD, Ampicillin should have not been effective at stopping disease transmission.

Our experiments were conducted in August in Bocas del Toro, Panama which is one of the warmest months of the year with seawater temperatures often approaching or even exceeding 30 °C, low average rainfall, high solar radiation, and low wind speeds\textsuperscript{50}. Running the experiments in a warm month was essential as WBD could not be found in the cooler winter months and we needed to collect a large number of active disease fragments in order to run our experiments. The warm, calm, high solar irradiance conditions were likely critical environmental conditions necessary for WBD transmission and suggests that there is a strong environmental component to the disease. It is highly likely, that the stressful environmental conditions existing during August weaken the corals immune system and increase the likelihood that the pathogenic bacteria can transmit WBD. Most of the known coral diseases occur more frequently and progress more rapidly during the warm summer months\textsuperscript{52} and temperature has been found to be critical in diseases such as bacterial bleaching where higher temperatures are required for the expression of virulence genes\textsuperscript{25}. Similarly, it has been found in a study across the Great Barrier Reef that white syndrome disease outbreaks were highly correlated with warm temperature anomalies\textsuperscript{53}, and that disease outbreaks caused high levels of mortality following the 2005 mass bleaching event in the Caribbean\textsuperscript{54}. It would have been interesting to repeat our transmission experiment in the cooler winter months but because active WBD could not be found during this time this was not possible.

Our data provides evidence that WBD type I is an infectious disease caused by bacteria and likely not just an opportunistic infection as suggested by Lesser et al (2007).\textsuperscript{38} If WBD (type I) was an opportunistic rather than an infectious disease, we would have expected to have seen similar infection rates in the healthy homogenate (control) treatments as in the WBD homogenate treatment. That the WBD disease homogenate caused 90% disease transmission is strong evidence that it is an infectious disease and the filter results combined with the antibiotic data clearly show that the disease is caused by bacterial pathogens. This study provides a new culture-independent method for studying coral diseases that can not be evaluated using traditional Henle-Koch’s postulate testing either because the potential pathogens can’t be cultured or because the disease is caused by a consortium of organisms, such as in Black Band Disease\textsuperscript{55}. This study provides definitive proof that WBD is not an opportunistic pathogen but a contagious disease with a bacterial pathogen. Our results also suggest that Ampicillin treatment could be used for localized control of WBD (type I) transmission. Additional experiments will need to be performed to determine how Ampicillin can be applied to infected colonies in the field. Dissolving the antibiotic in a petroleum-based jelly that is then applied with a syringe to the disease interface could be a possibility.

**Methods**

An *in situ* transmission experiment was conducted in August 2007 at Casa Blanca reef (Bocas del Toro, Panama) in order to assess the transmissibility of WBD-infected coral tissue across a series of filtrates (no filtration, 0.45 μm filtration, and 0.22 μm filtration) and two antibiotic treatments (Tetracycline and Ampicillin) to assess which biological components of the disease, specifically eukaryote, bacteria or virus, are required for disease transmission. For the transmission experiment, 250 coral fragments (ca. 20cm in length) were collected from multiple genotypes of healthy (asymptomatic) *A. cervicornis* corals and placed on cinderblocks using PVC clips (three fragments per block) into a common garden plot located ten meters away from the Casa Blanca reef in Bocas del Toro, Panama in three meters of water (Fig 1A). These experimental coral fragments were then allowed to acclimate for one week prior to the transmission experiment and any unhealthy fragments were removed before the start of the experiment. Concurrently, approximately 200 WBD interfaces on WBD infected *A. cervicornis* colonies were marked with cable-ties, and then identified as active three days later if the disease progression was at least 1 cm per day. 125 active disease interfaces were
sampled with bone clippers for the transmission experiments and 125 fragments from healthy (asymptomatic) coral colonies were also sampled for the control treatment. Separate pairs of bone clippers were used to collect the healthy and diseased fragments. These cuttings of disease interfaces and healthy fragments were then transferred back to the Smithsonian Tropical Research Institute Bocas del Toro Station in separate buckets of seawater.

In the lab, the sampled diseased and healthy coral fragments were then made into two separate tissue homogenates (diseased vs. healthy) by airbrushing the tissues using 0.02 μm filtered seawater, prepared with a 0.02 μm syringe filter (Whatman, USA) and homogenizing the airbrushed tissue using a 15 ml Dounce tissue grinder (Wheaton, USA). A portion of the disease tissue homogenate was set aside as the diseased (i.e. unfiltered) treatment. This preparation hereafter referred to as disease homogenate, which included the coral tissue, mucus and any associated organisms including multicellular eukaryotes, protists, bacteria, and viruses. We then filtered a portion of the disease tissue homogenate with sterilized 0.45 μm filters (Whatman, USA) and reserved a portion of the 0.45 μm filtrate for the transmission experiment. The 0.45 μm filtrate presumably contained only bacteria and viruses, as corals’ isotropic cells and cellular debris are typically larger than 0.45 μm and should be retained on the filter. Bacteria are typically 0.5 – 2 μm in diameter, while viruses are typically 0.02 – 0.3 μm and the viruses and some of the bacteria should pass through the 0.45 μm filter. We then filtered the remaining 0.45 μm filtrate with sterilized 0.22 μm filters (Whatman, USA) and reserved the 0.22 μm filtrate for the transmission experiment. The bacteria should remain on the 0.22 μm filters while the viruses should pass through. Filtration of the disease coral tissue at these three levels, unfiltered, 0.45 μm filters and 0.22 μm filters, allows us to separate which components of WBD (eukaryote, bacteria or virus) are the most likely pathogens.

In addition to the homogenate filtrate, two broad-spectrum antibiotic treatments were applied to the unfiltered disease homogenate to determine if different bacterial groups could be implicated as the WBD pathogen(s). The broad-spectrum antibiotic Tetracycline was chosen since it is the most common treatment for marine rickettsia diseases such as withering syndrome in abalone23 and Rickettsia bacteria have been found in WBD type I tissue samples24. Tetracycline acts by disrupting the 30S ribosome translation and is effective against gram negative bacteria, gram positive bacteria, and obligately parasitic bacteria such as Chlamydia and Rickettsia25. The second antibiotic chosen was Ampicillin, which is a β-lactam antibiotic that inhibits cell wall synthesis and is effective against Gram-positive and some Gram-negative bacteria but not against obligately parasitic bacteria such as Rickettsiales26. For both antibiotic treatments, a portion of the WBD disease homogenate was treated with equal amounts (100 μg/ml) of either Tetracycline (Oxotetracycline, USP grade, with 20 μg/ml imidocarb dipropionate) or Ampicillin (Mecamip, Ampicillin Sodium B.P.) for two hours. The dosage (100 μg/ml) was based on dosages used in previous studies using antibiotics and corals27.

After the six treatment groups (disease tissue homogenate, 0.45 filtrate, 0.2 μm filtrate, control healthy tissue homogenate, Tetracycline treated disease tissue homogenate, and Ampicillin treated disease tissue homogenate) were prepared, the treatments (i.e. homogenates) were stored for more than three hours in sterile centrifuge tubes and transported to the field site for in situ transmission to the experimental coral fragment in the cinderblock common garden. Each fragment was achieved by soaking ten, 2 cm plugs of sterile cotton gauze in 50 ml of each treatment and then attaching the soaked gauze to the healthy experimental coral fragments using labelled, color-coded cable ties (Fig 1). For the controls the sterile gauze was soaked in 5 ml of healthy tissue homogenate and then attached to the healthy experimental coral fragment with a cable tie. Transmission was attempted on 20 replicate healthy coral fragments per treatment. Treatment groups were placed randomly into the cinderblock common garden. The transmission experiment was set up within 3 hours of making the tissue homogenates to ensure that the potential pathogens in the tissue homogenates remained viable. WBD transmission was then allowed to proceed for 2 days at which time the coral fragments were scored for the presence or absence of WBD. WBD transmission was readily apparent on the previously healthy coral branches, and was only scored as WBD if the tissue mortality progressed at a rate of at least 1 cm per day (Fig 1B). Controls in these experiments were sterile gauze soaked in healthy tissue homogenate (~5 ml/gauze) and cabled tied to the corals. Transmission data across the six treatment groups were compared using a Pearson’s chi-square goodness of fit test and then using pairwise Fisher-exact tests. Fisher-exact tests were used because some comparisons had less than five observations28. The significance values of Fisher-exact tests were corrected using sequential Bonferroni adjustments29.

Acknowledgements
We thank the staff of the STRI Bocas del Toro research station and the STRI research staff in Panama City for their assistance throughout our research project. We also wish to thank Nancy Knowlton and Paul Muir for critically reviewing and greatly improving this manuscript. This work was funded by a Smithsonian Marine Science Network postdoctoral fellowship to DIK & SVV. This is contribution #4 of the Caribbean Future Reef Project.

Author contributions
DIK and SVV designed the experiments, conducted the fieldwork, and analysed the data. SVV performed the statistical analysis and DIK wrote the manuscript. Both authors reviewed and edited the manuscript.
