In high fluence applications of lead halide perovskites for light-emitting diodes and lasers, multi-polaron interactions and associated Auger recombination limit the device performance. However, the relationship of the ultrafast and strongly lattice coupled carrier dynamics to nanoscale heterogeneities has remained elusive. Here, in ultrafast visible-pump infrared-probe nano-imaging of the photoinduced carrier dynamics in triple cation perovskite films, a ~20% variation in sub-ns relaxation dynamics with spatial disorder on tens to hundreds of nanometer is resolved. We attribute the non-uniform relaxation dynamics to the heterogeneous evolution of polaron delocalization and increasing scattering time. The initial high-density excitation results in faster relaxation due to strong many-body interactions, followed by extended carrier lifetimes at lower densities. These results point towards the missing link between the optoelectronic heterogeneity and associated carrier dynamics to guide synthesis and device engineering for improved perovskites device performance.

Lead halide perovskites are organic-inorganic hybrids of the established ABX$_3$ perovskite structure (Fig. 1a), with A-site cations (e.g., methylammonium MA$^+$, formamidinium FA$^+$ or Cs$^+$) occupying the lead halide octahedral network ($B = Pb^{2+}, X = I^-, Br^-, Cl^-$). They have recently gained significant attention for a variety of optoelectronic applications, including photovoltaics\cite{1,2}, photodetectors\cite{3}, light-emitting diodes (LEDs), and lasers\cite{4}. Their extraordinary photovoltaic performance, with power conversion efficiency of single-junction perovskite solar cells now exceeding 25%\cite{5}, has been attributed to the photo-generation of free carriers with a long lifetime, large diffusion length, and high defect tolerance\cite{6-8}.

Strong electron-lattice coupling and large polaron formation have been proposed\cite{9,10}, originating from a soft lattice exhibiting low-frequency polar fluctuations\cite{11,12}, leading to structural deformations across multiple unit cells that stabilize the photoinduced carriers (Fig. 1b). These large polarons screen the electron-hole Coulomb interaction to enhance the carrier lifetime with modest carrier mobility\cite{13,14}, and may account for the microscopic origin of the defect tolerance even in spin-coated polycrystalline films\cite{15}.

Understanding the nature of the dynamic lattice deformation of perovskites has been an outstanding goal of ultrafast spectroscopy. Optical Kerr effect (OKE) spectroscopy\cite{16,17} and 2D IR spectroscopy\cite{18-21} have revealed lattice structural fluctuation on ~ps time scale. Slow hot carrier cooling, exceeding 10 ps, has also been demonstrated and attributed to a hot phonon bottleneck\cite{22-24}. The dynamic evolution of polarons in perovskites has been tracked by ultrafast diffuse X-ray scattering, which resolved the lattice distortion that evolves over tens of ps\cite{25}. Mid- to far-infrared spectroscopy proved particularly advantageous for inferring the low-energy landscape of photoinduced polaron, vibrational lattice, and coupled phonon dynamics\cite{26,27}.

Notably, in visible-pump/infrared-probe nanosecond time-resolved spectroscopy, a transient response assigned to a polaron absorption has recently been identified, and attributed to a transition from a phonon-trapped to free-carrier state\textsuperscript{28-30}. However, with these spectroscopic signals representing ensemble averages, they cannot readily provide the full pictures of the complex spatio-temporal evolution of polarons in perovskites, given the extraordinary degree of spatial heterogeneity in the optoelectronic response that ranges across atomic, domain, grain, and device scales\textsuperscript{3,34}. To address this issue, a variety of microscopy experiments have helped resolving the spatial complexity of perovskites. Ground-state XRD microscopy has demonstrated heterogeneous lattice strain correlated with fluorescence lifetimes\textsuperscript{31}. In the excited state, ultrafast visible-probe microscopy has probed exciton dissociation and carrier diffusion dynamics\textsuperscript{34-36}, yet it lacks specificity to the evolving many-body interactions of carriers with phonons and neighboring carriers. Infrared vibrational scattering scanning near-field optical microscopy (IR s-SNOM) resolves nanometer spatial disorder in the cation-lattice interaction that is suggested to be associated with chemical heterogeneity\textsuperscript{37}. While these experiments imply that lattice disorder underlies the optoelectronic non-uniformity, the key excited-state heterogeneity in electron-phonon coupling and associated polaron dynamics has remained elusive.

Here, we apply ultrafast spatio-temporal infrared nano-imaging\textsuperscript{38-40} to a triple cation perovskite [(FA\textsubscript{0.83}MA\textsubscript{0.17})\textsubscript{0.95}Cs\textsubscript{0.05}]Pb\textsubscript{0.83}Br\textsubscript{0.17}I\textsubscript{3} (Fig. 1a) to resolve mid-infrared transient carrier absorption at the nanoscale (Fig. 1c). For injected carrier densities exceeding 10\textsuperscript{19} cm\textsuperscript{-3}, and as relevant to high-fluence applications of perovskites, we observe ultrafast nano-localized infrared absorption with 10\textsuperscript{5}–1000 ps relaxation dynamics, depending on carrier density and associated many-body interactions. The relaxation dynamics varies spatially by 10–20\% within the film both at intra- (~100 nm) and inter- (100–400 nm) grain scales. The lineshape evolution in the broadband far-field pump-probe spectra points to an increase in scattering time and associated increase in correlation length of the excited carriers. We analyze this behavior by applying both a phenomenological adiabatic polaron absorption model\textsuperscript{40} as well as the conventional Drude model\textsuperscript{41}. By projecting the non-uniform relaxation dynamics into a map of polaron fit parameters, the extracted polaron delocalization radii evolve from ~1 nm to ~2 nm with associated increase in an effective stabilization energy from ~150 cm\textsuperscript{-1} to ~250 cm\textsuperscript{-1} over a ~1 ns time scale. Equivalently, based on Drude modeling, correspondingly derived scattering times would evolve from ~2 fs to ~5 fs. We attribute the heterogeneity in the evolution of polaron delocalization to an underlying fundamental disorder in lattice dynamics and associated interaction with photoinduced carriers, which may be introduced inadvertently during synthesis or be photoinduced. These results suggest that optoelectronic properties of perovskite films may still be far from their fundamental limits and point to pathways for further improvements through the spatial and temporal control of electron-electron and electron-phonon interactions.

**Results**

AFM topography (Fig. 2a) and corresponding heterodyne-detected pump-probe IR s-SNOM image (Fig. 2b) of the triple cation perovskite acquired at a pump-probe delay of T = 2 ps show the nanoscale spatial variation of the photo-induced carrier absorption A\textsubscript{HPP}(T). A\textsubscript{HPP}(T) varies by ~30\% on both a grain-to-grain scale (~100 nm) as well as larger (100–400 nm) length scales. The amplitude of the s-SNOM signal in general is known to be highly susceptible to topographic features and may not directly be a measure of a material specific optical signature (topographic artifacts). While the variation of A\textsubscript{HPP}(T) is partly correlated with topography associated with the individual crystallites, a significant contribution from a topography-uncorrelated signal can be assigned to and correspondingly scales with the density of photoinduced carriers (Supplementary Fig. S3). We also show that the transient absorption nano-imaging exhibits a distinct feature from corresponding ground-state nano-imaging (Supplementary Fig. S4), which corroborates the non-trivial heterogeneity in the photoinduced carrier density (see Supporting Information for details).

The corresponding spatio-temporal evolution with varying pump-probe delays T (Fig. 2c) shows both a spatial and a temporal heterogeneity in the ultrafast carrier relaxation over few ps to 100s ps. The dynamics are characterized by two distinct time scales demonstrated via a biexponential fit to T\textsubscript{1} = 7 ± 11 ps and T\textsubscript{2} = 150–220 ps, as seen from the local A\textsubscript{HPP}(T) evolution extracted at two representative sample locations (Fig. 2d). This range of values is typical and similar for different samples, with an example shown in Fig. 2e for two representative local s-SNOM traces of A\textsubscript{HPP}(T).

To quantify the spatial disorder in the polaron relaxation rate, we calculate the average decay time constant τ\textsubscript{avg} Derived from fits of A\textsubscript{HPP}(T) to biexponentials of form a\textsubscript{1}e\textsuperscript{-T/τ\textsubscript{1}} + a\textsubscript{2}e\textsuperscript{-T/τ\textsubscript{2}} with τ\textsubscript{avg} = (a\textsubscript{1}T\textsubscript{1} + a\textsubscript{2}T\textsubscript{2})/(a\textsubscript{1} + a\textsubscript{2}) at each sample location, yielding a nanoscale map of τ\textsubscript{avg} (Fig. 2f). The variation in τ\textsubscript{avg} exhibits an anti-correlation with A\textsubscript{HPP}(T = 2ps) (Fig. 2g), suggesting that larger polaron densities
generally lead to faster relaxation (excitation induced relaxation). Correspondingly, a faster relaxation is observed with increasing pump fluence (see Supporting Information).

In order to relate the nanoscale spatial heterogeneity in photo-induced carrier absorption to the underlying microscopic mechanisms, we perform complementary visible-pump broadband-infrared-probe transient absorption spectroscopy. Figure 3a shows the observed sub-nm evolution of the spectrally-integrated transient absorption signal \( \Delta A(T) \) as a function of the injected carrier density \( n_0 \). This strong pump fluence dependence of the photo-induced carrier relaxation rate in perovskites, as established previously\(^{2,45}\), can be described by the following recombination model

\[
\frac{dn}{dT} = -k_2n^2 - k_3n^3
\]  

with time-dependent carrier density \( n \), bimolecular recombination rate \( k_2 \), and higher-order contribution \( k_3 \). A first-order term is negligible in the high-fluence regime that we study, thus leaving only second- and third-order terms in Eq. (1). We perform a corresponding global fit (dotted lines in Fig. 3a) of all time traces for the different injected carrier densities \( n_0 \), with \( k_2 \) and \( k_3 \) as fitting parameters. The rate constants obtained of \( k_2 = 4.7 \times 10^{-10} \text{cm}^3\text{s}^{-1} \) and \( k_3 = 1.2 \times 10^{-27} \text{cm}^6\text{s}^{-1} \) fall within the range of previously reported values for different types of perovskites and probe frequencies\(^{32,41}\). Using \( k_2 \) and \( k_3 \), Fig. 3b shows the derived dependence of \( dn/dT \) as a function of the injected carrier density \( n_0 \), demonstrating the transition from simple bimolecular recombination at low densities to higher-order for \( n_0 > 10^{19} \text{cm}^{-3} \) as discussed below.

We then spectrally resolve the transient absorption \( \Delta A(T, \nu) \) signal, acquired for a constant injected carrier density of \( n_0 = 1.7 \times 10^{19} \text{cm}^{-3} \), but for variable pump-probe delays with results shown in Fig. 3c. We note that the spectrally narrow feature at \(-1720 \text{cm}^{-1}\) arises from CN anti-symmetric vibration of the FA cation\(^{20,40,46}\). The narrowing of the transient absorption spectra (Fig. 3c, inset) clearly suggests that correlation lengths and scattering times associated with photoinduced carriers increase with increasing pump-probe delay. However, to the best of our knowledge, the theory of the optical response of photoinduced polarons has not yet been fully established, particularly in the high density regime aside from some studies in oxides\(^{30,44}\).

We thus first apply the simple phenomenological polaron absorption model proposed by Emin\(^{30}\). In this model, within the Franck–Condon approximation which assumes no relaxation of the lattice during the transition, the transition rate is calculated between a phonon-trapped hydrogen-like carrier wave function as a ground-state and a free-carrier state as an excited state. A larger polaron gives rise to a narrower linewidth in this model. This is because a correspondingly lower momentum would result in a momentum mismatch for the...
transition at higher frequencies. While the predicted absorption spectrum in this model has been suggested to deviate from that obtained by diagrammatic quantum Monte Carlo method based on Fröhlich model\(^{30}\) particularly in terms of the peak and onset energy of the absorption, the model by Emin still provides for an intuitive picture of how the polaronic delocalization of the carriers impact the linewidth of the transition. The same polaron absorption model has recently been used to interpret nanosecond time-resolved mid-infrared spectra of MAPbI\(_3\)\(^{33}\), where a resonance at \(-1200\text{ cm}^{-1}\) has been attributed to a polaron resonance.

The analytical form of the phenomenological polaron absorption model by Emin is given by\(^{30}\)

\[
\alpha(\omega) = \frac{128\pi e^2}{3mc^2} \frac{\beta R^3}{[1 + \beta R^3]} ,
\]

with

\[
\beta = \sqrt{2m(\hbar^2 - 3E_p)} / \hbar,
\]

with effective polaron radius \(R\) (corresponding to the \(1/e\) distance of the exponential electron delocalization length), polaron stabilization energy \(E_p\), and effective electron mass \(m = 0.2m_e\)\(^{26}\), and polaron density \(n_p\). In this model, the polaron absorption exhibits the onset of absorption at \(3E_p\) (Fig. 1c) with the peak position close to \(3E_p\) but with a blue-shift that depends on the polaron radius \(R\). However, this absorption onset of \(3E_p\) assumes the transition to a Franck–Condon state with no lattice relaxation\(^{30}\), which may not be applicable particularly for the relatively shallow phonon trapping under the high density of carriers explored in this work\(^{30}\). Therefore, \(E_p\) should only be viewed as an effective stabilization energy. The extracted values for \(E_p\) and \(R\), as plotted in Fig. 3d, increase on ps to sub-ns time scales as shown schematically in Fig. 3e. Over the course of 1 ns, \(E_p\) evolves from \(-200\text{ cm}^{-1}\) to \(-350\text{ cm}^{-1}\) while \(R\) increases from \(-1\) to \(-2.5\) nm. In comparison to the lattice constant of \(-1\) nm\(^{1}\), this demonstrates that multiple unit cells deform collectively to stabilize the carriers at later times, justifying the fitting with large polaron absorption model\(^{30}\). We also note that the model might underestimate the polaron radius for a given linewidth by neglecting a quantum nature of the polarization field\(^{31}\).

While the polaron absorption model by Emin would reproduce the subtle resonant-like feature centered at \(-1100\text{ cm}^{-1}\) (Fig. 3c), within the bandwidth of our mid-infrared laser source we cannot rule out a Drude response as an alternative mechanism. A Drude-like response was previously suggested in sub-microsecond time-resolved mid-infrared spectroscopy in MAPbI\(_3\) perovskite\(^{33}\). We thus also perform a Drude analysis with details in Supporting Information (Supplementary Fig. S10). In the case of a Drude response, the observed lineshape evolution would correspond to the Drude scattering time \(\tau_D\) increasing from \(-3\) fs to \(-7\) fs over the 1 ns time window, which would signify a decrease in carrier scattering and corresponding increase in carrier mobility\(^{31}\).

By comparing the evolution of \(R\) and \(E_p\) (polaron model) in Fig. 3d and \(\tau_D\) (Drude model) to the corresponding relaxation curve of \(\Delta A(T)\) in Fig. 3a (bold, magenta), we find that \(R\) and \(E_p\) and \(\tau_D\) are anti-correlated with respect to the instantaneous carrier relaxation rate \(k\). We determine the instantaneous relaxation rate \(k\), which is given by

\[
k = -\frac{1}{\Delta A(T)} \frac{d\Delta A(T)}{dT} = -\frac{1}{n(T)} \frac{dn(T)}{dT}.
\]

analytically from a phenomenological bi-exponential fit of \(\Delta A(T)\). The combined results as shown in Fig. 3e, f then demonstrate that, based on polaron absorption, smaller and less stable polaron should lead to rapid recombination, evolving towards fewer yet more stable larger polarons. Similarly, based on the Drude analysis, the increase in carrier...
The observed anti-correlation between the injected polaron density $n_0$ and relaxation time $\tau_{\text{avg}}$ (Fig. 2g) is characteristic of many-body interactions of carriers as expected from the high injection carrier density of $n_0 = 5.5 \times 10^{19} \text{cm}^{-3}$22–24. In contrast, hot carriers are unlikely to dominate the observed nano-localized mid-infrared transient absorption as follows from the observed fluorescence dependence where higher injected carrier densities result in faster relaxation. This behavior is not expected for the case of hot carrier dynamics, where a higher injection carrier densities would lead to slower relaxation due to the hot-photon bottleneck effect25–28. We also note that the heterogeneity we observe mainly occurs at the grain-to-grain scale, in contrast to a previously observed heterogeneity of exciton segregation at individual grain boundaries26.

Different mechanisms have been invoked to explain transient mid-infrared resonances in semiconductors in general29 and perovskites in particular. However, plasma oscillation via Coulomb interaction, as established in GaAs30,31, can be excluded as an origin of the mid-infrared resonances in perovskite57. In contrast, the observed anti-correlation between the injected polaron density $n_0$ and relaxation time $\tau_{\text{avg}}$ (Fig. 2g) is characteristic of many-body interactions of carriers as expected from the high injection carrier density of $n_0 = 5.5 \times 10^{19} \text{cm}^{-3}$22–24. In contrast, hot carriers are unlikely to dominate the observed nano-localized mid-infrared transient absorption as follows from the observed fluorescence dependence where higher injected carrier densities result in faster relaxation. to our higher excited carrier density of \(n_0 > 10^{39} \text{ cm}^{-3}\), where excitation-induced many-body interactions dominate. The competition for photon modes to couple initially blocks the formation of larger polarons (Fig. 3e) based on electron-electron interactions. The large third-order coefficient \(k_3 = 10^{-29} - 10^{-24} \text{ cm}^{6} \text{s}^{-1}\) in perovskites\(^{42-45,58}\) may thus be due to an effective two-body process where the binding energy is density dependent.

Our observed lineshapes are also well reproduced by the Drude model, which suggest an increase in carrier mobility due to reduced electron-electron interaction as the carrier density decays. The derived scattering times of ~7 fs at long pump-probe delays is in reasonable agreement with results from both carrier mobility\(^{39}\) and THz photoconductivity measurements\(^{39}\). Yet, given the pronounced Auger recombination in perovskites compared to conventional inorganic semiconductors, the evolving scattering time may not trivially be attributed to the simple electron-electron interactions, but includes many-body interactions also involving electron-lattice interactions with finite size effect as discussed above. With probable contributions from both models present in the multi-polaron system, it is the intricate interplay between electron-electron and electron-phonon interactions that controls the carrier relaxation dynamics in perovskites.

In the Supporting Information, we also provide the fluence-dependent transient absorption spectra that exhibit the behavior consistent with the time-dependent spectra in Fig. 3c, suggesting that the effect of hot-phonon bottleneck and other effects related to intraband relaxation in the observed signal appear to be minor (Supplementary Fig. S11). Also, based on the narrowband pump-probe measurement tracking the transient vibrational response in detail, a possible heating-induced contribution to the infrared response seems insignificant (Supplementary Fig. S12)\(^{46}\).

We attribute the spatio-temporal evolution of carrier dynamics (Fig. 4b) to the fundamental disorder in many-body interactions (Fig. 4d). The trap states with their typically lower density of \(n_{\text{trap}} = 10^{17} \text{ cm}^{-3}\)\(^{3,61,62}\) are unlikely to play a dominant role in inducing heterogeneity, given the much higher photo-injected carrier density of \(n_0 = 5.5 \times 10^{19} \text{ cm}^{-3}\)\(^{3,61}\).

In some domains, the photoinduced carriers can be more coupled to the perovskite lattice through enhanced electron-phonon coupling. This would allow for the rapid increase in polaron size \(R\) and effective stabilization energy \(E_p\) in the polaron model. Alternatively, screened electron-electron interactions give rise to enhanced scattering time \(\tau_D\) and enhanced mobility. In other domains, the electron-phonon coupling is less efficient, resulting in the slower growth of polarons that would compromise the stability of carriers. The spatial disorder in the perovskite lattice, previously identified by time-averaged measurements in the ground state and attributed to lattice strain\(^{3,61}\) and/or to chemical heterogeneity\(^{3,63}\) and associated intragrain defects\(^{3,64}\), likely gives rise to the observed spatial disorder in the dynamic electron-lattice interactions. We note that, due to the high-fluence excitation required to achieve sufficient contrast for nano-imaging, we cannot discern whether the heterogeneity is inherently introduced in synthesis or is photo-induced, both of which are critical for high-fluence application of perovskites.

For optoelectronic applications with high injected carrier densities (>\(10^5 \text{ cm}^{-3}\)), such as LEDs, lasers, nano-photonic, or solar-concentrated photovoltaics, suppressing the density dependent higher-order many-body relaxation by eliminating domains and grains could facilitate the rapid growth of polarons as a key factor for enhancing device performance. The optimization of the electron-phonon coupling through, e.g., chemical composition\(^{3,65,66}\), substrate and interface control\(^{3,63}\), and the combination with polaritonic systems\(^{3,67}\), could not only help further optimize photovoltaic performance but also expand the application space of perovskite-based devices.

For photovoltaic applications with typically lower injected carrier density (~\(10^4 - 10^5 \text{ cm}^{-2}\)), the disordered electron-phonon coupling then not only becomes the source of the observed photovoltaic heterogeneity\(^{34-36}\), but may also modulate the potential landscape of carriers, resulting in non-Langevin recombination with significantly enhanced carrier lifetime\(^{37-39}\). The nanoscale heterogeneity in carrier relaxation dynamics in such a regime has recently been successfully explored with nanosecond time-resolved microwave far-field optical microscopy\(^{40}\), which attributes the heterogeneous sub-carrier relaxation dynamics to non-uniform trap states. In contrast, in our study with the injected carrier density being much higher than the trap density, the observed heterogeneity is more sensitive to heterogeneous many-body electron-electron and electron-phonon interactions mediated by the perovskite lattice. Yet, we note that a future enhanced sensitivity and contrast of ultrafast infrared nano-imaging would also allow probing into the low-density carrier regime as, e.g., relevant for photovoltaic applications. Also, to distinguish polaron absorption and Drude response and to further elucidate the microscopic mechanism underlying the transient response, further spectroscopic extension towards the low frequency range would be necessary.

In summary, we performed ultrafast infrared nano-imaging of perovskite films, resolving a spatially heterogeneous transient infrared relaxation dynamics at ps to sub-ps time scales and nanometer sub-grain to inter-grain length scales. Far-field transient broadband infrared spectroscopy directly probes the relaxation dynamics onto the underlying spatio-temporal evolution of polaron size, stabilization energy, and Drude scattering time. The observed spatial heterogeneity and co-existence of domains with variable polaron evolution and associated carrier stabilization suggests that the device performance currently achieved based on spin-coated films is far from its fundamental limit. Equally, the current work motivates the further development of theory which can describe the photoinduced polaron absorption in the high carrier density regime with pronounced Auger recombination. The result suggests room for improvement in achieving efficient electron-phonon coupling and rapid polaron growth across a film, e.g., through further refinement in chemical composition, thin film processing, or interfacial control.

The approach of ultrafast infrared nano-imaging as demonstrated in this work is generally applicable to any type of perovskites to guide spatial engineering and nanostructuring of perovskites\(^{23}\) through nano-spectroscopy of polaron dynamics. This includes two-dimensional (2D) layered and quasi-2D perovskites where the control of the spatial heterogeneity in excitation dissociation and polaron formation is a key pathway to further improve their device performance\(^{3,41}\).

**Methods**

Triple cation perovskite films of ([FA\(_0.83\)MA\(_{0.17}\)Pb\(_{0.95}\)Cs\(_{0.05}\)I\(_{3}\)\(\times\)\([\text{Pb}(\text{I}\_0.83\text{Br}_{0.17})_3\] (Fig. 1a) are prepared by spin-coating a precursor solution onto a cleaned glass substrate\(^3\) for ultrafast infrared nano-imaging and onto a CaF\(_2\) substrate for far-field transient absorption spectroscopy. Atomic force microscopy (AFM) topography (Fig. 2a) shows grains of I00 \(-200 \text{ nm in size, characteristic of fresh samples without degradation}\(^{34,36}\).

We implement ultrafast heterodyne infrared (IR) nano-imaging as developed recently\(^{47}\) to probe the spatio-temporal evolution of the ultrafast carrier dynamics. As shown in Fig. 1c, S15 mm (2.4 eV) pump pulses (Pharos, Light Conversion; ~200 fs full width half maximum, ~80 μJ/cm\(^2\) fluence, modulated by an acousto-optic modulator at \(\Omega M = 50 \text{ kHz}\)) inject photoinduced carriers into the conduction band. Mid-infrared 8.3 μm pulses (Orpheus OPA/DFG, Light Conversion; ~120 fs full width half maximum, ~100 μJ/cm\(^2\) fluence) probe the resulting carrier absorption in transient IR s-SNOM. The transient mid-infrared response arises from optical absorption creating a high carrier density, which we analyze applying both the phenomenological adiabatic polaron absorption model\(^{35,3}\) and the Drude model\(^{41}\) to extract correlation lengths and times of the photoninduced carrier dynamics. The repetition rate of 1 MHz ensures complete relaxation of the photoinduced carriers between subsequent laser shots. In our home-built
ultrafast s-SNOM system, the collinear pump and probe pulses are directed to the apex of a metallic tip (Arrow-NCpT, NanoAndMore USA) in an atomic force microscope (AFM: Innova, Bruker) operating in tapping mode at the frequency $f_\text{tip} = 250$ kHz.\(^{40}\)

The tip-scattered near-field signal $E_{\text{NF}}$ is heterodyne amplified with a local oscillator pulse $E_{\text{LO}}$ and detected by a HgCdTe detector (KLD-0.1-H, Kolmar Technologies). The near-field pump-probe signal $\Delta E_{\text{NF}}$ is selectively detected by sideband lock-in detection at $2\omega_\text{pump} + \Omega_\text{M}.\,\text{Based on the two-phase measurement, the background-free near-field pump-probe amplitude} \Delta E_{\text{NF}}(T) \text{is isolated as a function of pump-probe delay}\, T,\text{ with spatial resolution of ~50 nm limited by the radius of the tip apex}^{40}.\,\text{Typically 1 mm \times 1 mm images are acquired at 64 \times 64 pixels with a scan rate of 0.2 Hz.}\)

We avoided measuring samples with already microscopically resolveable textures, which tended to result in rapid photo-induced degradation (Supplementary Fig. SSC, D). Despite the high fluorescence excitation, the near-field scattering intensity (Supplementary Fig. SSA) as well as the vibrational resonance arising from the formamidinium (FA) cation (Supplementary Fig. SSB) is temporally stable\(^{36}\), suggesting minor cation migration\(^2\). Careful inspection of AFM topography demonstrates that, while overall topographic features are well maintained even after 1 hour of constant illumination, some domains show signatures of roughening after 20 min of illumination that has been recently attributed to photoinduced nano-grain formation of PbI\(_2\) (Supplementary Fig. SSG).\(^{37}\) However, PbI\(_2\) itself is unlikely to contribute to the observed near-field pump-probe signal due to its much weaker absorption at 2.4 eV compared with the FAMACs perovskite. We further observe that the local formation of these nano-grains does not strongly correlate with the observed relaxation dynamics in bulk domains (Supplementary Figs. S6 and S7). The two domains we analyze in detail (domain 1 and 2 in Figs. 2 and 4) do not show the features of this nano-grain formation.

We complement infrared nano-imaging by far-field visible-pump/ infrared-probe transient absorption spectroscopy. To that end, a spectrally broad infrared pulse is generated by difference-frequency infrared-probe transient absorption spectroscopy. To that end, a NOPA\(^7\). The transmitted infrared probe pulse is subsequently selectively detected by sideband lock-in detection at $2\omega_\text{pump} \pm \Omega_\text{M}$. Based on the two-phase measurement, the background-free near-field pump-probe amplitude $\Delta E_{\text{NF}}(T)$ is isolated as a function of pump-probe delay $T$, with spatial resolution of ~50 nm limited by the radius of the tip apex\(^40\). Typically 1 mm $\times$ 1 mm images are acquired at 64 $\times$ 64 pixels with a scan rate of 0.2 Hz.

Acknowledgements
This work was supported by the NSF Science and Technology Center on Real-Time Functional Imaging (STROBE) under DMR-1548924 (J.N., P.T.S.C., D.M.W., S.C.J, and M.B.R.) and NSF DMR award No. 1906029 (S.E.S.). J.N. acknowledges the support from the Japan Society for Promotion of Science for a JSPS Overseas Research Fellowship. J.N. thanks Kuniyuki Miwa, Souichi Sakamoto, and Akihito Ishizaki (Institute for Molecular Science) for valuable discussions regarding different theories to describe the optical response of polarons.

Author contributions
J.N. and M.B.R. designed the research. J.Y.Y., P.S., and S.E.S prepared and contributed the samples. J.N., P.T.S.C. and D.M.W. performed the experiments. J.N. and P.T.S.C. analyzed the data. J.N., S.C.J., and M.B.R. wrote the manuscript with the feedback and contributions from the other authors.
