(Dated: May 2, 2014)

The proximity of antiferromagnetic order in high-temperature superconducting materials is considered a possible clue to the electronic excitations which form superconducting pairs. Here we study the transverse and longitudinal spin excitation spectrum in a one-band model in the pure spin density wave (SDW) state and in the coexistence state of SDW and the superconductivity. We start from a Stoner insulator and study the evolution of the spectrum with doping, including distinct situations with only hole pockets, with only electron pockets and with pockets of both types. In addition to the usual spin-wave modes, in the partially gapped cases we find significant weight of low-energy particle-hole excitations. We discuss the implications of our findings for neutron scattering experiments and for theories of Cooper-pairing in the metallic SDW state.

I. INTRODUCTION

Understanding the microscopic origin of interacting and competing phases with multiple order parameters (OP) is one of the central issues in condensed matter. This topic is particularly important for describing the complex phases of layered transition metal oxides such as the high-\(T_c\) superconductors in which superconductivity occurs upon hole or electron doping of an antiferromagnetic Mott insulator. As a consequence of the competition between the Mott insulator and superconductivity, a rich variety of ground states may emerge, such as charge, spin, or current density wave states, all of which have been proposed to play a role in the pseudogap region of the high-\(T_c\) phase diagram. For \(n\)-type cuprates, there is growing experimental evidence for the evolution of superconductivity in the background of the commensurate spin density wave (AF) state with ordering momentum \(\mathbf{Q} = (\pi, \pi)\).

One of the most interesting questions concerns the evolution of the spin excitations in a pure AF state upon introducing carriers by doping, and the possible coexistence of such a state with \(d_{x^2-y^2}\)-wave superconductivity. The former question was studied in detail within a strong-coupling models such as the \(t-J\) model Hamiltonian. It starts from a model of localized spins at zero doping which interact via the antiferromagnetic superexchange interaction and then introduces doped holes on the AF background. This approach is well justified in the hole-doped cuprates which are Mott insulators in the AF state. At the same time, experimental studies of the moderately electron-doped cuprate and parent iron-based superconductor show that both remain metallic in the AF state. In addition, a recent DMFT study of the undoped electron-doped cuprates with \(T'\) crystal structure suggests that their insulating behavior is more due to the presence of magnetic long-range order than to charge transfer gap physics. This implies that a conventional weak-coupling description of the spin excitations may be applied for the \(n\)-doped case. This approach was initially developed in the nineties and more recently shown to describe well the spin wave spectra of the parent cuprate superconductor \(\text{La}_2\text{CuO}_4\) and iron-based superconductors. At the same time, less is known about the spin excitation spectra in the doped situation when the AF state in the electron-doped cuprates is still metallic.

In this paper, we employ the RPA formalism within a single-band Hubbard framework to describe the evolution of the spin excitations from a Stoner insulator to the antiferromagnetic metal. In particular, we analyze the evolution of the transverse and longitudinal spin excitations when the system experiences a transition from (i) the Stoner insulator to the antiferromagnetic metal with electron Fermi surface pockets centered at \((\pm \pi, 0)\) and \((0, \pm \pi)\) points of the Brillouin Zone, and (ii) the Lifshitz transition between two types of the AF metal when in addition to the electron pockets the second small hole Fermi surface pockets appear at \((\pm \pi/2, \pm \pi/2)\) points of the Brillouin zone (BZ).

Furthermore, motivated by the observed coexistence of the AF and \(d_{x^2-y^2}\)-wave superconductivity in the electron-doped cuprates we compute the spin excitations in the coexistence regime. We find that the Goldstone mode in the transverse channel remains gapless in the coexistence regime and that the excitations in the transverse channel are dominated by the renormalized spectrum of the spin waves. At the same time, we find that the excitations in the longitudinal channel include a resonance mode at the commensurate momentum close to \((\pi, \pi)\). The simultaneous coexistence of the longitudinal resonance and the transverse spin waves opens up an interesting possibility to use inelastic neutron scattering (INS) to identify the microscopic coexistence of superconductivity and antiferromagnetism. We also stress the importance of well-defined particle-hole branches of the spin excitation spectrum which should also be observable in INS and should help to confirm our general picture.
FIG. 1: color online) Three possible types of Fermi surface topology in the commensurate SDW state in layered cuprates either for hole (a) or electron doping (b) and (c) analyzed in this paper. Due to the mean-field SDW order the original large Fermi surface (green curve) folds, yielding small hole pockets (blue curves) centered around \((±\pi/2,±\pi/2)\) and electron pockets (red curves) centered around \((±\pi,0)\) [[((±π, ±π))] points of the BZ. For larger doping and smaller sizes of the AF gap both types of the pockets can be present. As argued in the text, the commensurate SDW order becomes unstable once the hole pockets appear around \((±\pi/2,±\pi/2)\) points of the BZ. This occurs due to overall negative spin stiffness of the commensurate spin waves in this case, see Fig. 3(a).

Our starting point for investigating the coexistence of superconductivity and SDW order is the Hamiltonian

\[
\mathcal{H} = \sum_{\mathbf{k}\sigma} \varepsilon_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} + \sum_{\mathbf{k},\mathbf{k}',\sigma} U c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}+\mathbf{Q}\sigma} c_{\mathbf{k}'+\mathbf{Q}\bar{\sigma}} c_{\mathbf{k}'\bar{\sigma}} \\
+ \sum_{\mathbf{k},\mathbf{p},\mathbf{q},\sigma} V_{\mathbf{q}} c_{\mathbf{k}+\mathbf{q}\sigma}^\dagger c_{\mathbf{p}-\mathbf{q}\bar{\sigma}} c_{\mathbf{p}\bar{\sigma}} c_{\mathbf{k}\sigma}
\]

(1)

where \(c_{\mathbf{k}\sigma}^\dagger\) (\(c_{\mathbf{k}\sigma}\)) creates (annihilates) an electron with spin \(\sigma\) and momentum \(\mathbf{k}\). We consider a two-dimensional system with normal state tight-binding energy dispersion \(\varepsilon_{\mathbf{k}} = -2t (\cos k_x + \cos k_y) + 4t' \cos k_x \cos k_y - \mu\) and hopping matrix elements between nearest \((t)\) and next-nearest \((t')\) neighbors. The chemical potential \(\mu\) controls the doping, \(x\) which is determined by \(n = 1 + x\). The second and third terms in Eq. (1) lead in the appropriate Hartree-Fock factorization to the emergence of commensurate SDW order and superconductivity, respectively. While it is generally assumed that both phases emerge from the same underlying interaction, its renormalization due to vertex corrections gives rise to a different effective interaction in each channel, thus justifying the Hamiltonian of Eq. (1).

We first focus on the pure SDW ordered state, and consider the case \(V_{\mathbf{q}} = 0\) in Eq. (1). After decoupling the second term via a mean-field (MF) approximation and diagonalizing the resulting MF Hamiltonian via a conventional SDW Bogoliubov transformation, we obtain two electronic bands (labeled \(\alpha\) and \(\beta\)) in the reduced Brillouin zone (RBZ) with dispersions \(E_{\mathbf{k}}^{\alpha,\beta} = \varepsilon_{\mathbf{k}}^\pm + \sqrt{(\varepsilon_{\mathbf{k}})^2 + W^2}\) where \(W = U/2 \sum_{\mathbf{k}',\sigma} (c_{\mathbf{k}'+\mathbf{Q}\sigma}^\dagger c_{\mathbf{k}'-\mathbf{Q}\bar{\sigma}}) \sgn \sigma\) is the SDW order parameter which is determined self-consistently for a given \(U\), and \(\varepsilon_{\mathbf{k}}^\pm = (\varepsilon_{\mathbf{k}} \pm \varepsilon_{\mathbf{k}+\mathbf{Q}})/2\). For completeness, one also has to include the self-consistent determination of the chemical potential. Depending on the strength of the SDW gap and the doping level, the system can be either a (i) Stoner insulator for the half-filled case and large value of \(W\); or (ii) SDW metal with small size electron and hole Fermi surface pockets for intermediate values of \(W\) and non-zero electron or hole doping, respectively. Typical Fermi surfaces in the SDW metal are shown in Fig. 3.

The dynamical spin susceptibility for the longitudinal, \(zz\), and the transverse, \(+-\), components is defined as

\[
\chi^{lm}(\mathbf{q}, \mathbf{q}', \Omega) = \int dt \left[ \frac{i}{2N} (TS_{\mathbf{q}}(t)S_{-\mathbf{q}}^m(0)) \right] e^{i\Omega t}
\]

(2)

where \(lm = zz, +-\). As mentioned above, the antiferromagnetic ordering at \(\mathbf{Q} = (\pi, \pi)\) doubles the unit cell and requires accounting for the breaking of translational symmetry. As a result, the total susceptibility in the transverse channel is a \(2 \times 2\) matrix

\[
\hat{\chi}^{+-} = \begin{pmatrix}
\chi^{+-}(\mathbf{q}, \mathbf{q}, \Omega) & \chi^{+-}(\mathbf{q}, \mathbf{q}+\mathbf{Q}, \Omega) \\
\chi^{+-}(\mathbf{q}+\mathbf{Q}, \mathbf{q}, \Omega) & \chi^{+-}(\mathbf{q}+\mathbf{Q}, \mathbf{q}+\mathbf{Q}, \Omega)
\end{pmatrix}
\]

(3)
Then, within RPA the susceptibility is obtained via solving a Dyson equation and the result can be expressed as
\[
\chi_{RPA}^{\pm} = \left( \hat{1} - \hat{U} \chi_0^{\pm} \right)^{-1} \chi_0^{\pm},
\] (4)
and the bare components are given by
\[
\chi_0^{\pm}(q, q, \Omega) = -\frac{1}{2} \sum_{k, \gamma} \left( 1 + \frac{\varepsilon_k \varepsilon_{k+q} - W^2}{\sqrt{(\varepsilon_k)^2 + W^2}(\varepsilon_{k+q})^2 + W^2} \right) \frac{f(E_{k+q}^\gamma) - f(E_k^\gamma)}{\Omega + i0^+ - E_{k+q}^\gamma + E_k^\gamma} f(E_{k+q}^\gamma) - f(E_k^\gamma)
\]
\[-\frac{1}{2} \sum_{k, \gamma \neq \gamma'} \left( 1 - \frac{\varepsilon_k \varepsilon_{k+q} - W^2}{\sqrt{(\varepsilon_k)^2 + W^2}(\varepsilon_{k+q})^2 + W^2} \right) \frac{f(E_{k+q}^{\gamma'}) - f(E_k^{\gamma'})}{\Omega + i0^+ - E_{k+q}^{\gamma'} + E_k^{\gamma'}} f(E_{k+q}^{\gamma'}) - f(E_k^{\gamma'})
\] (5)
with \( \gamma = \alpha, \beta \) and for the Umklapp term
\[
\chi_0^{\pm}(q, q + Q, \Omega) = \frac{W}{2} \sum_{k} \left( \frac{1}{\varepsilon_{k+q}} + \frac{1}{\varepsilon_k} \right) \left( \frac{f(E_{k+q}^\alpha) - f(E_k^\alpha)}{\Omega + i0^+ - E_{k+q}^\alpha + E_k^\alpha} - \frac{f(E_{k+q}^\beta) - f(E_k^\beta)}{\Omega + i0^+ - E_{k+q}^\beta + E_k^\beta} \right) f(E_{k+q}^\gamma) - f(E_k^\gamma)
\]
\[- \left( \frac{1}{\varepsilon_{k+q}} + \frac{1}{\varepsilon_k} \right) \left( \frac{f(E_{k+q}^{\gamma'}) - f(E_k^{\gamma'})}{\Omega + i0^+ - E_{k+q}^{\gamma'} + E_k^{\gamma'}} - \frac{f(E_{k+q}^\alpha) - f(E_k^\alpha)}{\Omega + i0^+ - E_{k+q}^\alpha + E_k^\alpha} \right) f(E_{k+q}^\gamma) - f(E_k^\gamma)
\] (6)
where \( f(\epsilon) \) is the Fermi function and the prime refers to the sum over the magnetic (reduced) Brillouine Zone (MBZ). Observe that we have \( \chi_0^{\pm}(q, q + Q) = \chi_0^{\pm}(q + Q, q) \) and the expression for \( \chi_0^{\pm}(q + Q, q + Q, \Omega) \) can be obtained from Eq. 6.

The Umklapp component is absent for the longitudinal susceptibility and the RPA expression is given by
\[
\chi_{RPA}^{\pm}(q, q, \Omega) = \frac{\chi_0^{\pm}(q, q, \Omega)}{1 - U \chi_0^{\pm}(q, q, \Omega)}
\] (7)
with the bare longitudinal susceptibility in the form
\[
\chi_0^{\pm}(q, q, \Omega) = -\frac{1}{2} \sum_{k, \gamma} \left( 1 + \frac{\varepsilon_k \varepsilon_{k+q} + W^2}{\sqrt{(\varepsilon_k)^2 + W^2}(\varepsilon_{k+q})^2 + W^2} \right) \frac{f(E_{k+q}^\gamma) - f(E_k^\gamma)}{\Omega + i0^+ - E_{k+q}^\gamma + E_k^\gamma} f(E_{k+q}^\gamma) - f(E_k^\gamma)
\]
\[-\frac{1}{2} \sum_{k, \gamma \neq \gamma'} \left( 1 - \frac{\varepsilon_k \varepsilon_{k+q} + W^2}{\sqrt{(\varepsilon_k)^2 + W^2}(\varepsilon_{k+q})^2 + W^2} \right) \frac{f(E_{k+q}^{\gamma'}) - f(E_k^{\gamma'})}{\Omega + i0^+ - E_{k+q}^{\gamma'} + E_k^{\gamma'}} f(E_{k+q}^{\gamma'}) - f(E_k^{\gamma'})
\] (8)
Here, we note the opposite sign of the \( W^2 \) term in the coherence factors of the longitudinal and transverse susceptibilities. Although the general structure of the spin susceptibility in the SDW state at \( Q \) is known, it is useful to mention its main features. In particular, below \( T_N \) spin-rotational invariance is broken and \( \chi^\pm \neq 2\chi^{zz} \). The imaginary part of the transverse component is gapless and displays the Goldstone mode at \( Q = (\pi, \pi) \) and \( \Omega \to 0 \) for any temperature in the range \( 0 < T < T_N \). The latter is guaranteed by the fact that the condition of the pole formation in the RPA part of the transverse spin susceptibility coincides with the mean-field equation for \( W \) and, as clearly seen, is valid for any doping level as soon as the SDW order exists. At the same time, the longitudinal component of the spin susceptibility at \( Q \) is gapped by twice the SDW gap magnitude, \( W \).
At half-filling (x=0) and zero temperature, the Fermi surface is gapped for any value of W and t' [1]. Due to full gapping of the Fermi surface, the particle-hole Stoner excitations and the spin waves are separated in energy and may interact only around Ω_{p-h}(q), whose magnitude is controlled by the values of the SDW gap magnitude W and t'/t ratio. For t' = 0 the onset of the particle-hole continuum is gapped at least up to Ω_{p-h}(Q) = 2W. This is because the top of the lower β-band and the bottom of the upper α-band are located at the magnetic BZ boundary, i.e. cosk_x + cosk_y = 0, at energies -W and +W, respectively. Therefore, there exists a degenerate manifold of q wave vectors for which Ω_{p-h}(q) = 2W. As a result, the spin waves do not interact with the particle-hole continuum for sufficiently large values of W and look identical to those obtained within a Heisenberg model of localized spins which interact via an AF exchange between nearest neighbors, J_1 ∼ t^2, see Fig. 2(a).

The situation changes for non-zero values of t'/t. Its existence (i) introduces non-degenerate positions of the top of the β-band and bottom of the α-band, (ii) reduces the overall magnitude of the gap in the particle-hole continuum and shifts it to lower energies at the (π/2, π/2) point of the BZ as clearly seen from Fig. 2(b)-(c). To understand its origin, observe that for any non-zero t'/t the bottom of the upper α-band is located at (±π, 0) and (0, ±π) points of the BZ at energy -4t' + W - μ > 0, while the top of the lower β-band is located at (±π/2, ±π/2) points of the BZ at energy -W - μ < 0. As a result, the smallest gap between both bands which determines also the lowest position of the particle-hole continuum occurs at Ω_{p-h}(q_1) = 2W - 4t' for q_1 = (±π/2, ±π/2). For increasing t'/t ratio and constant value of W, the spin waves are bounded from above at momentum q_1 = (±π/2, ±π/2) and form a local minimum there at energies below 2W - 4t' > 0. In particular, in Fig. 2(b) it occurs below 0.7t with W = 0.75t and t' = 0.2t and is shifted to much lower energies for t' = 0.35t for a fixed W = 0.75t as shown in Fig. 2(c). Notice also that for zero doping we always find either an insulating SDW state (which guarantees the finite gap at momentum q_1) or a paramagnetic metallic state for U < U_c.

The observation of the local minimum for a finite t' at q_1 is due to an interaction of spin waves with the particle-hole continuum. This is certainly a signature of weak-coupling as it requires 2W to be of the same order as 4t'. This effect would not occur for the localized J_1 ∼ J_2 model, where J_2 refers to the antiferromagnetic exchange between the next-nearest neighbors. The inclusion of J_2 usually only lowers the position of the maximum of the spin wave dispersion at the Y point of the BZ, an effect clearly reproduced in the weak-coupling calculations as well [compare Fig. 2(a) and (c)]. At the same time, within the localized model the particle-hole excitations always remain gapped by the large value of U [W]. Correspondingly the local minimum in the spin susceptibility at q_1 never forms in this case.

To finish the discussion of the spin waves for the undoped case, we further notice that the spin wave dispersion obtained is symmetric with respect to the (0, 0) and (π, π) points, which reflects the fact that both are equivalent symmetry points of the magnetic BZ. At the same time, the absolute intensity of the spin waves is different and is determined by the SDW matrix elements which are suppressed around the Γ-point. Indeed, from Eq. 1 one finds that at low Ω the non-vanishing contribution to the intensity comes from the interband (α → β and visa versa) transitions which are proportional to the SDW coherence factor c_{k,q}^{inter} = \left( 1 - \frac{\epsilon_k \epsilon_{k+q} - W^2}{\sqrt{(\epsilon_k)^2 + W^2}(\epsilon_{k+q})^2 + W^2} \right). For q ∼ Q one finds the largest contribution to the spin wave intensity.
The intensity in states/t is shown on a log scale. The white arrows in (a) denote the incommensurate momentum associated with $2k_F$ scattering due to hole FS pockets shown in Fig. 3(a). Observe also the difference in the intensity maps between upper and lower panels.

$\epsilon_{k+Q}^\pm \approx -\epsilon_k$ and $\epsilon_{k+\text{inter}Q}^\pm \sim 2$, whereas it is $\epsilon_{k+Q}^\text{inter} \propto (1 - (\epsilon_k^2 - W^2)/(\epsilon_k^2 + W^2))$ for $Q \sim 0$.

Let us continue by looking at the spin excitations of the commensurate AF order upon electron or hole doping. As we are interested in the metallic ground state, we will only study the situation of the AF metal for finite $t'/t$ ratio and remain at very low temperatures. We remind the reader that in this case the Fermi surface topology for the electron- and hole-doped AF metal is different. In the hole-doped case the chemical potential crosses first the top of the upper $\alpha$-band and the spin stiffness, $\rho$, acquires a finite correction in the doped SDW metal as $\rho_s = \rho_s^0(1 - z)$ where $z = 2U \mu^*/\pi m^*$ is proportional to the Pauli susceptibility of the $\beta$-band, and $\rho_s^0$ is the bare spin stiffness in the undoped case. As one clearly sees, $z > 1$ for large $U$ which indicates that the commensurate SDW order is unstable upon hole doping. On the contrary, for the opposite case $U < t$ the expansion yields $E_k^\text{SDW} = -\mu - W - p_{||}^2/(2m_{||}) - p_{\perp}^2/(2m_{\perp})$, where here $m_{||} = m_{\perp} = (8t')^{-1}$ and $v_{||} \sim t$. This indicates that for $t' < t$ the dispersion along $p_{\perp}$ is essentially linear. As a result the static susceptibility of the $\beta$-band will have singular behavior at $2k_F$. Therefore, even if the Pauli susceptibility of $\beta$ electrons yields $z < 1$, there is an additional source of instability associated with $2k_F$ scattering on the hole pockets.
susceptibility and found that for the case of Fig.3(a) we have \( z > 1 \). Therefore, the instability of the commensurate SDW order for \( U \sim t \) and hole doping occurs due to negative corrections to the spin stiffness.

For electron doping the situation is different. In this case the chemical potential moves towards the \( \alpha \)-band which has a minimum at \((\pm \pi, 0)\) and \((0, \pm \pi)\) points of the BZ. Expanding now the dispersion of the \( \alpha \)-band around them yields \( E_0^\alpha = 4t' - \mu + W + \frac{k_x^2}{2m} + \frac{k_y^2}{2m} \) where \( m = (4t')^{-1} \). Observe that this expansion holds for any ratio of \( U/t \). As in the case of the hole pockets, there is a contribution of the \( \alpha - \alpha \) scattering to the spin stiffness. However, it is easy to see that for the intermediate values of \( U \sim t \) and \( t' = 0.35t \) one has \( z < 1 \). In addition, there are additional \( k^4 \) corrections in the dispersions (proportional to \( t^2/W \)) which further reduce the value of \( z \). We verified it numerically by varying values of \( U \) and still finding commensurate SDW order to be a stable solution for electron doping.

Thus, one of the main results of our paper is that for non-zero \( t'/t \) ratio there is a strong anisotropy in the evolution of the commensurate SDW order in the hole- and electron-doped cases [Note that the situation is just opposite for the negative sign of \( t' \)]. While for hole doping the commensurate SDW order is unstable due to an additional response associated with the hole pockets at \((\pm \pi/2, \pm \pi/2)\) which introduce negative spin stiffness to the spin waves, the influence of the electron pockets appearing at \((\pm \pi, 0)\) or \((0, \pm \pi)\) is less dramatic and the commensurate SDW persists to a much larger doping. Observe, for example, that for \( x = 0.1 \) (Fig.3(b)) the spin waves disperse all over the BZ despite the damping introduced by the \( \alpha - \alpha \) scattering which is clearly seen in Fig.3(c). It is tempting to connect our findings to the experimental observations which show that the commensurate AF order persists up to larger doping concentrations in the electron-doped compounds as compared to the hole-doped ones.\(^6\) Despite the fact that our calculations are done in the weak coupling limit, we believe that the main result still holds in the strong coupling case as well. In particular, the appearance of the Fermi surface pockets upon doping introduces a negative correction \( z \) to the spin stiffness. Its exact magnitude can be different in the strong coupling case; however, the asymmetry between the energy dispersions near the bottom of the conduction near \((\pm \pi, 0)\) \([0, \pm \pi]\) points of the BZ and the top of the valence band near \((\pm \pi/2, \pm \pi/2)\) points of the BZ will be similar. Therefore, independent of the details we expect that the trend found in the weak-coupling, i.e. the relative stability of the commensurate AF order in the electron-doped cuprates as compared to the hole-doped ones, will remain.

A natural question arises: when does the commensurate SDW order becomes unstable for the electron-doped case? Upon increase of the electron doping the pockets at \((\pi, 0)\) and \((0, \pi)\) grow in size. However, the Pauli susceptibility in two dimensions is doping independent and consequently the doping does not immediately influence the commensurability of the SDW order. At the same time, it is natural that for increasing \( x \) the SDW gap will decrease. This will reduce the gap between the \( \alpha \) and the \( \beta \) band in principle, at certain doping level one would expect that both hole and electron pockets may appear at the Fermi level, as shown in Fig.1(b). Although this situation seems to be supported by ARPES experiments in the electron-doped cuprates, the commensurate SDW order will become unstable in this case. For the same reason as in the hole-doped case, the presence of the hole pockets at \((\pi/2, \pi/2)\) immediately introduces critical scattering for the commensurate spin waves. An example of this behavior is shown for the spin excitations in Fig.3(c),(f) where the commensurate SDW order produces two types of the pockets, see Fig.1(c). One immediately finds that spin stiffness is again negative and there are incommensurate peaks forming around \( Q \). Therefore, the system will either develop incommensurate spiral SDW order or it will readjust the chemical potential such that the hole pockets will disappear with a corresponding change of the electron pocket’s size. There is, however, another interesting possibility which we would like to discuss in the next section.

II. SPIN EXCITATIONS IN THE COEXISTENCE AF+DSC PHASE

As shown above, the presence of electron pockets at \((\pm \pi, 0)\) \([0, \pm \pi]\) points of the BZ do not make the commensurate AF order at \((\pi, \pi)\) unstable. This in principle opens an interesting possibility to have a nodeless \( d_{x^2-y^2} \)-wave superconducting gap in the electron-doped cuprates which would coexist with AF order. Its features have been discussed previously in a number of mean-field studies\(^{16,17}\). Nevertheless, our results indicate that in many cases commensurate AF order becomes unstable with doping due to a negative spin stiffness introduced by the dopants carriers. Therefore, to see whether commensurate AF order can coexist with dSC requires a simultaneous analysis of the spin excitations. In addition, the study of the spin excitations itself in the unconventional superconducting state is interesting on its own due to formation of the spin resonance mode at the wave vector \( Q = (\pi, \pi) \) and \( \Omega = \Omega_{\text{res}} \). Such a feedback effect is quite interesting because its presence allows to confirm the phase structure of the superconducting order parameter even in the situation when thermodynamics reveals an isotropic \( s \)-wave behavior as in some of the iron-based superconductors.\(^6\) In the coexistence phase of AF+dSC, the situation is trickier due to the presence of the Goldstone mode at \( Q \) and the anisotropy of the spin fluctuations in the transverse and the longitudinal channel.

To study the spin dynamics in the coexistence phase we follow Ref.\(^{18}\) and apply the SDW Bogoliubov transformation to the pairing interaction [third term in Eq.\(^{11}\)] and subsequently perform a mean-field decoupling in the particle-
particle channel, keeping anomalous expectation values of the form \( \langle \alpha_{k,\downarrow}^{\dagger} \alpha_{k,\uparrow} \rangle \) and \( \langle \beta_{k,\uparrow} \beta_{k,\downarrow}^{\dagger} \rangle \), and their complex conjugates. As in Ref. 13, we further neglect terms of the form \( \langle \alpha_{k,\uparrow} \beta_{k,\downarrow} \rangle \) due to the FS mismatch between the \( \alpha \) and \( \beta \) bands. As we show below these terms can be safely ignored once the Umklapp Cooper-pairing terms are absent in the coexistence phase. The resulting mean-field Hamiltonian can be diagonalized by two independent Bogolyubov transformations, yielding \( \Omega_k = \sqrt{E_k^0 + \Delta_k^0} \) \((\gamma = \alpha, \beta)\) as the energy dispersion of the two bands. The SC gaps \( \Delta_k^{\alpha,\beta} \) are determined self-consistently from two coupled gap equations, derived previously,\(^{13}\)

\[
\Delta_k^{\alpha} = - \sum_{p \in RBZ} \left[ \frac{L_{k,p} \Delta_p^{\alpha}}{2E_p^{\alpha}} + \frac{M_{k,p} \Delta_p^{\beta}}{2E_p^{\beta}} \right] \\
\Delta_k^{\beta} = - \sum_{p \in RBZ} \left[ \frac{M_{k,p} \Delta_p^{\alpha}}{2E_p^{\alpha}} + \frac{L_{k,p} \Delta_p^{\beta}}{2E_p^{\beta}} \right] 
\]

where \( L_{k,p} = \left( V_{k-p} F_{u,v} - V_{k-p+Q} F_{u,v} \right) \), \( M_{k,p} = \left( V_{k-p} N_{u,v} - V_{k-p+Q} N_{u,v} \right) \) with \( N_{u,v}^{\alpha,\beta} = u_k^2 x_p^2 \pm 2u_v k u_p v_p x_p + v_k^2 y_p^2, x,y = u,v, u_k^2 v_k^2 = \frac{1}{2} \left[ 1 \pm \frac{\epsilon_k}{2\sqrt{(\epsilon_k^2 + W^2)}} \right] \), and \( u_k v_k = \frac{W}{2\sqrt{(\epsilon_k^2 + W^2)}} \). For the \( d_{x^2-y^2}\)-wave pairing potential \( V_{k-p} = \tilde{V}_k \phi_k \phi_p \) case where \( \phi_k = \cos k_x - \cos k_y \), the SDW coherence factors can be factorized\(^{13}\) and one finds

\[
\Delta_k^\gamma = \varphi_k (\Delta_k^\beta + u_v k v_k \Delta_k^\alpha) \quad (10)
\]

with \( \Delta_k^\gamma = F_0^0 + F_0^\beta \), \( \Delta_k^\alpha = - \Delta_k^\beta = F_1^\beta - F_1^\alpha \). Here, \( F_0^0 = \frac{\tilde{V}_k}{4} \sum_p D_p \varphi_p \Delta_k^{\gamma} \tanh \left( \frac{\Omega_k^\alpha}{2T} \right) \) and \( F_1^0 = V_d \sum_p D_p \varphi_p \Delta_k^{\gamma} \tanh \left( \frac{\Omega_k^\beta}{2T} \right) \). Note, \( D_p^\gamma \) is unity if \( |E_k^\gamma| \leq h\omega_D \), and zero otherwise, with \( h\omega_D \) being the Debye frequency. The SC OP in the \( \alpha \) and \( \beta \)-bands are in phase without additional line nodes, in contrast to the \( s \)-wave case\(^{15,20}\). Nevertheless, the coexistence of commensurate AF and dSC phases can generate a higher harmonic, \( \Delta_1 \), in the \( d_{x^2-y^2} \)-wave gap which has an opposite sign on the electron and hole FS pockets. This harmonic is proportional to the magnitude of the SDW and dSC gaps and arises due to Umklapp Cooper-pairing in terms of original fermions, i.e. averages of the type \( \langle c_{k,\uparrow} c_{-k,\downarrow} \rangle \). These averages appear naturally in the coexistence phase as the wavevector \( Q \) becomes the new reciprocal wave vector of the lattice in the SDW state. At the same time, due to additional breaking of the spin rotational symmetry associated with the SDW transition the Umklapp Cooper-pairing terms formally belong now to the spin-triplet component of the Cooper-pair wave function with \( m_z = 0 \) as was discussed previously by several authors\(^{8,13,21}\). This indicates that the appearance of the \( \Delta_1 \) would be then associated with an additional phase transition in the dSC+SDW coexistence phase with a further change of the underlying symmetry of the mean-field Hamiltonian, i.e. from \( SU(2) \times U(1) \) to \( SO(5) \) symmetry.

For self-consistency the SC gap equations have to be complemented by the new equation which determines the SDW gap value in the dSC+SDW state

\[
W = - \frac{U}{2} \sum_k \frac{W}{\sqrt{(\epsilon_k^2 + W^2)}} \left[ \frac{E_k^\alpha}{\Omega_k^\alpha} \tanh \left( \frac{\Omega_k^\alpha}{2k_BT} \right) - \frac{E_k^\beta}{\Omega_k^\beta} \tanh \left( \frac{\Omega_k^\beta}{2k_BT} \right) \right] \quad (11)
\]

and that for the chemical potential, \( 1 + x = \sum_k \left[ 1 - \frac{E_k^\alpha}{2\Omega_k^\alpha} \tanh \left( \frac{\Omega_k^\alpha}{2T} \right) - \frac{E_k^\beta}{2\Omega_k^\beta} \tanh \left( \frac{\Omega_k^\beta}{2T} \right) \right] \). Note that the mean-field equations are complemented by the calculations of the total energy

\[
\langle \mathcal{H} \rangle = \sum_k E_k^\alpha - \Omega_k^\alpha + E_k^\beta - \Omega_k^\beta + \frac{(\Delta_k^\alpha)^2}{2\Omega_k^\alpha} \tanh \left( \frac{\Omega_k^\alpha}{2T} \right) + \frac{(\Delta_k^\beta)^2}{2\Omega_k^\beta} \tanh \left( \frac{\Omega_k^\beta}{2T} \right) \\
\quad + 2\Omega_k^\alpha f (\Omega_k^\alpha) + 2\Omega_k^\beta f (\Omega_k^\beta) + \frac{W^2}{U} \quad (12)
\]

to guarantee that their solution refers to its minimum.

We further mention that a comparison of our eigenenergies \( \Omega_k^\gamma \) with those found in Ref.\(^{22}\) by the diagonalization of the \( 4 \times 4 \) matrix allows us to make a connection between our approach of taking the sequential transformations and the exact diagonalization of the mean-field matrix. In particular, it is straightforward to see that the eigenenergies
are the same for $\Delta_1 = 0$. Thus, the use of sequential unitary transformations, performed by us, is exact as long as the triplet component of the Cooper-pair wave function is absent. For $\Delta_1 \neq 0$ the eigenenergies agree only up to terms of the order $\sim O(\Delta_1)$ but start to differ for the higher order terms. To recover the same energy spectrum as in Ref[22] for the coexistence phase one needs to take into account the Cooper-pair terms $\langle \alpha_{\mathbf{k}, \uparrow}^\dagger, \beta_{-\mathbf{k}, \downarrow}^\dagger \rangle$ in the AF state. They can be particularly important in the case when the magnetic gap becomes small when the interband Cooper-pairing may be non-negligible. Furthermore, the particular form of the pairing interaction in the momentum space can further modify the structure of the superconducting gap equations in the coexistence state.

The expression for the transverse spin susceptibility in the coexistent state within a RPA remains structurally the same as in the pure AF state, see Eq.(3), except that the bare susceptibilities contain Cooper-pair creation and annihilation processes in addition to the quasiparticle scattering within one band and between the bands. The full expression is given in the Appendix. The situation is more complicated for the $zz$ component as there is a mixing of the charge and longitudinal spin susceptibilities at $\mathbf{Q}$ for a finite doping $x$. Nevertheless, the pole in total RPA susceptibility is still determined by $1 - \chi_{zz}^0(\mathbf{q}, \mathbf{q}, \Omega)$ which allows us to use Eq.(7) also in the coexistence phase.

In Fig[4] we present the results for the mean-field phase diagram of the electron-doped cuprates for coexisting commensurate AF and $d$-wave superconducting order. Although this type of phase diagram was already obtained in the literature, there are several features which are important to mention. Observe, for example that within a pure SDW phase at finite doping there is a Lifshitz transition (blue dashed curve) separating phases with a different FS topology with either one or two types of FS pockets. At higher temperatures, both electron and hole type of pockets are present at the FS, while below the Lifshitz transition only the electron pockets are present. Another interesting feature concerns the character of the phase transition into the coexisting AF+dSC state at low temperatures. In particular, analyzing the free energy we find that the transition from AF to AF+dSC state is of first order as a function of doping, while it becomes second order as a function of temperature. Furthermore, we notice that our total energy analysis shows that the stationary solutions for coexistence of SDW and $d$-wave superconductivity in the electron-doped cuprates have always slightly lower free energy in the case $\Delta_1 = 0$, i.e. when the triplet component of the Cooper-pairing is absent. In other words in our approach the symmetry of the problem remains $SU(2) \times U(1)$ in the coexistence regime. We believe that it is connected to the fact that we ignored the contribution from the interband Cooper-pair averages $\langle \alpha_{\mathbf{k}, \uparrow}^\dagger, \beta_{-\mathbf{k}, \downarrow}^\dagger \rangle$ in the coexistence phase. Although small they could change the balance of the free energy towards the coexistence state with finite ‘triplet’ component of the Cooper-pairing. Furthermore, a modification of the momentum dependence of the Cooper-pairing interaction may also change the balance of the mean-field states. This, however, would require a separate analysis which is beyond the scope of the present paper.

Next we compute the transverse spin response in the coexistence region of the phase diagram for three characteristic electron doping levels, $n = 1.06$, $n = 1.09$, and $n = 1.12$ (we fixed $T = 0.02t$). First it is easy to check analytically that as soon as $\Delta_k^c = \Delta_k^d$ which is fulfilled for $\Delta_1 = 0$ the condition for the pole in transverse susceptibility,
coexistence region exhibit a kink structure due to the interaction with the p is shown in the left panel, Fig.5(a)-(c). The effect is particularly strong around 2\(\Delta_0\) the transverse spin excitations spectra of the coexistence SDW+dSc state with that of the pure SDW state which the Appendix. The influence of the superconducting gap on the spin wave spectra is also seen by comparison of the coefficients for gapless Goldstone mode also in the coexistence region. This is because the pure spin singlet d-wave superconductivity alone does not break the spin symmetry of the Hamiltonian. Here, our results do agree with those found very recently in a different formalism Ref[24] At the same time, in Ref[25] the spectrum of the transverse spin excitations computed numerically in the coexistence phase for hole doping seems to be gapped at the antiferromagnetic momentum, \(Q\), which would contradict our analytical and numerical results. We speculate that this discrepancy arises from the fact that at the hole doping studied in Ref[24] the commensurate AF order is not a stable solution. In particular, although the mean-field solution for the commensurate AF order exists, the resulting spin waves have negative spin stiffness[12] (see also our Fig.3). As a result the true magnetic order in this case is incommensurate.

Although the spin waves are gapless in the coexistence phase, their velocity is affected by the presence of d-wave superconductivity. In particular, in the Fig.5(d)-(f) we show the behavior of the transverse, \(\Im \chi_{RPA}(q,\Omega)\) spin excitations for three different electron dopings, \(n = 1.06\), \(n = 1.09\), and \(n = 1.12\) (from upper to lower panel) in the coexistence state. Observe that in all three cases the spin excitations are gapless but the spin wave velocity is influenced by the superconducting gap. For small energies this can be seen analytically by expanding the denominator of Eqs. (4) around \(q,\Omega = 0\) up to quadratic order. This procedure leads to the spin wave velocity, \(c\) of the form:

\[ c^2 = \frac{yt^2(1/U - W^2z)}{W^2x^2 + (v)(1/U - W^2z)} \]  

(13)

The coefficients for \(x, y, z\) contain in the lowest order terms proportional to \(\Delta_0^2\). Their exact form is given in the Appendix. The influence of the superconducting gap on the spin wave spectra is also seen by comparison of the transverse spin excitations spectra of the coexistence SDW+dSc state with that of the pure SDW state which is shown in the left panel, Fig.5(a)-(c). The effect is particularly strong around 2\(\Delta_0\) where the spin waves in the coexistence region exhibit a kink structure due to the interaction with the p – h continuum of the intraband \(\alpha - \alpha\) and \(\beta - \beta\) transitions. They are enhanced due to d-wave symmetry of the superconducting gap, i.e. due to the fact that one finds \(\Delta^*_k = -\Delta^*_k + q_i\) for incommensurate momenta \(q_i > (0.8,0.8)\pi\). This then leads to an enhancement of

---

**FIG. 5:** color online) Calculated transverse, \(\Im \chi_{RPA}(q,\Omega)\) spin excitation spectra \(\Omega\) vs. \(q\) in units of \(\pi/a\) for three different electron dopings, \(n = 1.06\), \(n = 1.09\), and \(n = 1.12\) (from upper to lower panel) in the coexistence SDW+dSc state and \(\Delta_0 = 0\) (right panel). For comparison the left panel shows the results for the pure SDW state. The blue lines denote \(1 = U\Re \chi_{0}^-(q,\Omega)\) condition. The intensity is shown on the log scale. The following parameters are used in the units of \(U = 0.5362, W = 0.5617, \mu = -0.4573, W = 0.4617\), for \(\mu = -0.3694, W = 0.3456\), for \(\mu = -0.5349, W = 0.5530, \Delta_0 = 0.0727\), for \(\mu = -0.4509, W = 0.4555, \Delta_0 = 0.0705\), and for \(\mu = -0.3624, W = 0.3458, \Delta_0 = 0.0618\).
the intraband particle-hole continuum of both bands for $\Omega \approx 2\Delta_0$. As the electron band around $(\pm \pi, 0)$ and $(0, \pm \pi)$ points of the BZ always crosses the Fermi level in the SDW state, the enhancement of the particle-hole continuum of this band around $2\Delta_0$ is responsible for the kink structure seen in the spin waves. In other words, the damping effects of the particle-hole continuum on the spin waves are present in both pure metallic SDW and coexisting SDW+dSC states. However, in the coexistence region there is also an effect of the strong renormalization of the spin wave due to the $2\Delta_0$ structure of the particle-hole continuum of the intraband susceptibility, which then yields the renormalization of the spin wave velocity around $2\Delta_0$. Another interesting feature is that $d$–wave superconductivity stabilizes the commensurate AF state by partial gapping the particle-hole continuum in the coexistence state. Observe, for example that the spin waves computed for $n = 1.12$ in the pure SDW state show a tendency towards incommensurability, while in the coexistence state the spin excitations are still commensurate.

In Fig. 6(d)-(f) we also show the behavior of the longitudinal response in the coexistence region. These are again compared to the pure SDW state Fig. 6(a)-(c). It is interesting that in this case the same structure of the particle-hole continuum at $2\Delta_0$ for the intraband transitions which generates the strong damping of the spin waves around $2\Delta_0$ in $\chi^{+ -}$ introduces the formation of the spin resonance at energies below $2\Delta_0$ in $\chi^{zz}$. In particular, the resonance occurs because of the discontinuous jump of the imaginary part of the intraband susceptibility at $2\Delta_0$. Correspondingly, there is a log singularity of the real part and below it $\Re \chi_0(Q, \Omega) \propto \omega^2$ for the intraband susceptibility. As a result, the total $\Re \chi(Q, \Omega)$ is enhanced at $2\Delta_0$ and the resonance condition $1/U = \Re \chi(Q, \Omega = \Omega_{res})$ is fulfilled for $\Omega_{res} < 2\Delta_0$. This is in contrast to the pure SDW state where the main contribution at $Q$ comes from the interband excitations which are gapped by the SDW gap magnitudes. At the same time, the intraband quasiparticle scattering in the SDW state is suppressed for the wavevector $Q$. In the coexistence state, in addition to the intraband quasiparticle scattering, there are also intraband Cooper-pairing annihilation processes, which start to contribute to the spin susceptibility at $2\Delta$. These processes are enhanced by the $d$–wave symmetry of the gap and are responsible for the formation of the spin resonance. This resonance, however, now occurs in a very narrow $q$ region, which is bounded by the dispersion of the particle-hole continuum. In particular, the spin resonance in the longitudinal component of the spin susceptibility is bounded from above at the wavevector $Q$ by the onset of the particle-hole continuum associated with breaking of the Cooper-pairs at approximately $2\Delta_0$ and from the left and right at finite $\delta q$ by the onset of the continuum associated with intraband quasiparticle scattering which is gapless due to the presence of nodes on the $\alpha$ Fermi surface in the $d$–wave gap. As a result the spin resonance shows a characteristic upward dispersion and then becomes overdamped. This is quite different from the typical downward dispersion of the spin...
Finally we also note that our expression for the spin susceptibility computed for the metastable state for \( \Delta_1 \neq 0 \) consistently signals its instability, that is we find \( 1 - U \text{Re} \chi^{\dagger \dagger}_{\mathbf{Q}}(\mathbf{q} = \mathbf{Q}, \Omega = 0) < 0 \) in this case. This indicates that the calculations of the spin response in presence of the triplet Cooper-pairing requires one to go beyond the sequential transformations, which we leave for the future studies.

III. CONCLUSION

In this work, we studied the behavior of the transverse and longitudinal spin excitation spectrum in a one-band model within a pure spin density wave (SDW) state and in the coexistence region of SDW and \( d \)-wave superconductivity. In particular, we analyze the evolution of the transverse and longitudinal spin excitations in doped AF metals. We have shown that for the sign of \( t' \) appropriate for the cuprates, commensurate spin excitations are stable within weak-coupling only on the electron-doped side of the phase diagram. Otherwise, the results we obtained in the SDW phase have been obtained in various forms by previous authors. However, in addition to the spin wave spectrum in this phase, we have focused on the evolution of particle hole excitations. These may play an important role in any instability of such an AF phase to superconductivity, since the pairing vertex due to exchange of the magnons themselves is suppressed due to the Adler principle. Calculations along these lines are in progress.

Furthermore, motivated by the observed coexistence of the AF and \( d_{x^2 - y^2} \)-wave superconductivity in the electron-doped cuprates we computed the spin excitations in the coexistence region. We find that the Goldstone mode in the transverse channel remains gapless in the coexistence regime and that the excitations in the transverse channel are dominated by the renormalized spectrum of the spin waves. This happens, however, only if the Umklapp Cooper-pairing term, \( \langle c_{\mathbf{k}} c_{-\mathbf{k} - \mathbf{Q}} \rangle \), which actually belongs to the spin-triplet component of the Cooper-wave function is absent. We show also that within our approach this triplet component never appears as the free energy is always higher for the solution with non-zero Umklapp terms. This is a subtle point which requires a careful, fully self-consistent treatment of competing order parameters in the problem. At the same time, we find that the excitations in the longitudinal channel include a resonance mode at the commensurate momentum close to \( (\pi, \pi) \). The simultaneous coexistence of the longitudinal resonance and the transverse spin waves opens up an interesting possibility to use inelastic neutron scattering (INS) to identify the microscopic coexistence of the superconductivity and antiferromagnetism. We also stress the importance of well-defined particle-hole branches of the spin excitation spectrum which should also be observable in INS and should help to confirm our general picture.

IV. ACKNOWLEDGEMENTS

We acknowledge helpful discussions with G. Blumberg, A.V. Chubukov, R. Fernandes, J.-P. Ismer, R. Moessner, D.K. Morr, and J. Schmalian. W. Rowe and P.J.H. were supported by NSF-DMR-1005625. W. Rowe is thankful for hospitality of the Ruhr-University Bochum where the final stage of this work was done. Appendix A: Spin susceptibility in the coexistent AF+dSC state

Here, we present the expression for the spin susceptibility in the coexistent AF+dSC region. In particular the transverse component has the form

\[
\chi^{\perp} - (q, q, \Omega) = \sum_{k, \gamma} \gamma' \left( \frac{1}{4} \left( 1 + \frac{\varepsilon_k \varepsilon_{k+q} - W^2}{\sqrt{\varepsilon_k^2 + W^2} \sqrt{\varepsilon_{k+q}^2 + W^2}} \right) \left[ 1 + \frac{E_k^\gamma E_{k+q}^\gamma + \Delta_k^\gamma \Delta_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right] f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma) \right)
\]

\[
+ \frac{1}{2} \left[ 1 - \frac{\varepsilon_k \varepsilon_{k+q} - W^2}{\sqrt{\varepsilon_k^2 + W^2} \sqrt{\varepsilon_{k+q}^2 + W^2}} \right] \left[ 1 + \frac{E_k^\gamma E_{k+q}^\gamma + \Delta_k^\gamma \Delta_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right] f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)
\]

and

\[
\chi^{\perp +} (q, q + Q, \Omega) = \sum_{k, \gamma} \gamma' \left( \frac{1}{4} \left( 1 + \frac{1}{\sqrt{\varepsilon_{k+q}^2 + W^2}} - \frac{1}{\sqrt{\varepsilon_k^2 + W^2}} \right) \left[ \pm \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \left( f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma) \right) \right]
\]

\[
\pm \left( \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right) \left( 1 - \frac{f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ - \Omega_{k+q}^\gamma - \Omega_k^\gamma} \right)
\]

\[
+ \frac{W}{4} \sum_{k, \gamma' \neq \gamma} \gamma' \left( \frac{1}{\sqrt{\varepsilon_{k+q}^2 + W^2}} + \frac{1}{\sqrt{\varepsilon_k^2 + W^2}} \right) \left[ \pm \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \left( f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma) \right) \right]
\]

\[
\pm \left( \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right) \left( 1 - \frac{f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ - \Omega_{k+q}^\gamma - \Omega_k^\gamma} \right)
\]

\[
\pm \left( \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right) \left( 1 - \frac{f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ - \Omega_{k+q}^\gamma - \Omega_k^\gamma} \right)
\]

\[
\pm \left( \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right) \left( 1 - \frac{f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ - \Omega_{k+q}^\gamma - \Omega_k^\gamma} \right)
\]

\[
\pm \left( \frac{E_k^\gamma E_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right) \left( 1 - \frac{f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ - \Omega_{k+q}^\gamma - \Omega_k^\gamma} \right).
\]

(A1)
Here, + or − refers to the $\gamma = \alpha$ and $\gamma = \beta$, respectively. Correspondingly, the longitudinal component has the form

$$
\chi^z_0(q, q, \Omega) =
$$

$$
\sum_{k, \gamma} \left\{ \frac{\varepsilon_k^\gamma \varepsilon_{k+q} + W^2}{\sqrt{\varepsilon_k^\gamma + 1}} \right\} \left\{ \left[ 1 + \frac{E_k^\gamma E_{k+q}^\gamma + \Delta_k^\gamma \Delta_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right] \frac{f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ - \Omega_{k+q}^\gamma + \Omega_k^\gamma} 
+ \frac{1}{2} \left[ 1 - \frac{E_k^\gamma E_{k+q}^\gamma + \Delta_k^\gamma \Delta_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right] \left( f(\Omega_{k+q}^\gamma) + f(\Omega_k^\gamma) - 1 \right) \frac{1 - f(\Omega_{k+q}^\gamma) - f(\Omega_k^\gamma)}{\Omega + i0^+ + \Omega_{k+q}^\gamma + \Omega_k^\gamma} \right\} 
+ \sum_{k, \gamma \neq \gamma'} \left\{ \frac{1}{4} \left( 1 - \frac{\varepsilon_k^\gamma \varepsilon_{k+q}^\gamma + W^2}{\sqrt{\varepsilon_k^\gamma + 1}} \right) \right\} \left\{ \left[ 1 + \frac{E_k^\gamma E_{k+q}^\gamma + \Delta_k^\gamma \Delta_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right] \frac{f(\Omega_{k+q}^\gamma') - f(\Omega_k^\gamma')}{\Omega + i0^+ - \Omega_{k+q}^\gamma + \Omega_k^\gamma'} 
+ \frac{1}{2} \left[ 1 - \frac{E_k^\gamma E_{k+q}^\gamma + \Delta_k^\gamma \Delta_{k+q}^\gamma}{\Omega_k^\gamma \Omega_{k+q}^\gamma} \right] \left( f(\Omega_{k+q}^\gamma') + f(\Omega_k^\gamma) - 1 \right) \frac{1 - f(\Omega_{k+q}^\gamma') - f(\Omega_k^\gamma)}{\Omega + i0^+ + \Omega_{k+q}^\gamma + \Omega_k^\gamma} \right\} \right\} \right\} \right\} (A3)

To evaluate the spin wave velocity, we expand the denominator of Eqs. (4) around $q, \Omega = 0$ up to quadratic order. This procedure leads to the spin wave velocity, $c$ of the form

$$
c^2 = \frac{yt^2(1/U - W^2 z)}{W^2 x^2 + (v)(1/U - W^2)} 
$$

(A4)

where

$$
x = \sum_k 1 \left( \frac{\varepsilon_k^\alpha + \Omega_k^\alpha \Omega_k^\beta}{\Omega_k^\alpha + \Omega_k^\beta} \right) \left( \frac{E_k^\alpha}{\Omega_k^\alpha} - \frac{E_k^\beta}{\Omega_k^\beta} \right) \right) 
$$

(A5)

$$
v = \sum_k \frac{1}{\Omega_k^\alpha + \Omega_k^\beta} \left( 1 - \frac{E_k^\alpha E_k^\beta - \Delta_k^2}{\Omega_k^\alpha \Omega_k^\beta} \right) \right) 
$$

(A6)

$$
z = \sum_k \frac{1}{\Omega_k^\alpha + \Omega_k^\beta} \left( \frac{1}{W^2} \right) \left( \frac{E_k^\alpha E_k^\beta + \Delta_k^2}{\Omega_k^\alpha \Omega_k^\beta} \right) \right) \right) 
$$

(A7)

The coefficient $y$ is comprised of two terms. The first one arises from the intraband contribution

$$
y_1 = \sum_{k, \gamma = \alpha, \beta} \frac{\Delta_k^2}{2(\Omega_k^\gamma)^2} \left\{ \frac{W^2 \sin^2 k_x}{(\varepsilon_k^\gamma)^2 + W^2} \right\} \left( \frac{(\cos k_x + \cos k_y)^2}{(\varepsilon_k^\gamma)^2 + W^2} \right) 
- \frac{3\varepsilon_k^\gamma \Delta_k^2 E_k^\gamma}{(\varepsilon_k^\gamma)^2 + W^2} \frac{2 \sin^2 k_x \cos k_y \pm \varepsilon_k^\gamma \sin^2 k_x}{\sqrt{(\varepsilon_k^\gamma)^2 + W^2}} \right) \right\} 
$$

(A8)
and the other one from the interband contributions

\[ y_2 = \frac{1}{4} \sum_{k, \gamma \neq \gamma'} \frac{2W^2 \sin^2 k_x}{(\epsilon_k^\gamma)^2 + W^2} \left( \frac{\Omega_k^\gamma + \Omega_k^\gamma'}{\Omega_k^\gamma + \Omega_k^\gamma'} \right) \left( 1 - \frac{E_k^\gamma E_k^{\gamma'} - \Delta_k^2}{\Omega_k^\gamma + \Omega_k^\gamma'} \right) \]

\[ - \frac{2}{\Omega_k^\gamma + \Omega_k^\gamma'} \left[ \left( \frac{t' \cos(k_x + k_y)}{\Omega_k^\gamma + \Omega_k^\gamma'} \right) \left( \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \Omega_k^\gamma \Omega_k^\gamma' \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \right) \right] \]

\[ - \frac{1}{(\Omega_k^\gamma)^2 \Omega_k^\gamma'} \left( \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \Omega_k^\gamma \Omega_k^\gamma' \right) \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \left( 1 - \frac{E_k^\gamma E_k^{\gamma'} - \Delta_k^2}{\Omega_k^\gamma + \Omega_k^\gamma'} \right) \left( \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \right) \]

\[ - \frac{1}{(\Omega_k^\gamma)^2 \Omega_k^\gamma'} \left( \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \Omega_k^\gamma \Omega_k^\gamma' \right) \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \left( 1 - \frac{E_k^\gamma E_k^{\gamma'} - \Delta_k^2}{\Omega_k^\gamma + \Omega_k^\gamma'} \right) \left( \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \right) \]

\[ \times \left[ \frac{\Delta_k^2 (E_k^\gamma)^2 + (E_k^{\gamma'})^2 \Delta_0^2 \sin^2 k_x / t^2}{(\Omega_k^\gamma)^2 \Omega_k^\gamma'} \right] \left( \frac{t' \cos(k_x + k_y)}{\Omega_k^\gamma + \Omega_k^\gamma'} \right) \left( \left( \Omega_k^\gamma + \Omega_k^\gamma' \right) \right) \]

(A9)

Here \( (E_k^{\alpha \beta})^2 = 8 \left[ 2 \sin^2 (k_x + k_y) \right] \) and we further use \( \Delta_k = \Delta_0^\alpha = \Delta_0^\beta \).
