I have discussed in my talk several remaining issues in the standard three-flavor mixing scheme of neutrinos, in particular, the sign of $\Delta m_{13}^2$ and the leptonic CP violating phase. In this report I focus on two topics: (1) supernova method for determining the former sign, and (2) illuminating how one can detect the signatures for both of them in long-baseline ($\gtrsim 10$ km) neutrino oscillation experiments. I do this by formulating perturbative frameworks appropriate for the two typical options of such experiments, the high energy and the low energy options with beam energies of $\sim 10$ GeV and $\sim 100$ MeV, respectively.

1. INTRODUCTION

Despite the current trend that many people jumped into the four neutrino scheme (see [1] for comprehensive references), the three-flavor mixing scheme of leptons, together with the three-flavor mixing scheme of quarks, still constitutes the most promising standard model for the structure of the (known to date) most fundamental matter in nature. It is worth to note that the two of the evidences for the neutrino oscillation, one compelling [2] and the other strongly indicative [3], can be nicely fit into the three-flavor mixing scheme of neutrinos. I want to call the scheme the standard 3ν mixing scheme in my talk.

I would like to address in this talk some aspects of the three-flavor mixing scheme of neutrinos which remain to be explored until now. While I have started with a brief remark on robustness of the standard 3ν mixing scheme, I do not repeat it here because I have described it elsewhere [4]. In this manuscript I discuss mainly two key issues, (1) the sign of $\Delta m_{13}^2$, and (2) how to measure leptonic CP violation. I will use, throughout this manuscript, the MNS matrix [5] in the convention by Particle Data Group.

Let me start by raising the following question: "Suppose that the standard 3ν mixing scheme is what nature exploits and the atmospheric and the solar neutrino anomalies are the hints kindly provided by her to lead us to the scheme. Then, what is left toward our understanding of its full structure?"

It is conceivable that the future atmospheric and solar neutrino observations as well as currently planned long baseline experiments will determine four parameters, $\Delta m_{23}^2$, $\Delta m_{12}^2$, $\theta_{23}$, and $\theta_{12}$, to certain accuracies. I then cite four things as in below which will probably be unexplored in the near future:

(i) $\theta_{13}$
(ii) the sign of $\Delta m_{13}^2 = m_3^2 - m_1^2$, the normal versus inverted mass hierarchies
(iii) the CP violating leptonic Kobayashi-Maskawa phase $\delta$
(iv) the absolute masses of neutrinos

I make brief comments on (i) and (iv) one by one before focusing on (ii) and (iii):

Measuring $\theta_{13}$ is one of the goals of the currently planned long baseline experiments [6,7], and therefore I do not discuss it further. Among them the expected sensitivity in JHF, the recently approved experiment in Japan, is one of the best examined case [8].

Measuring absolute masses of neutrinos is cer-
tainly the ultimate challenge for neutrino experiments, but it is not clear at this moment how one can do it. Presumably, neutrinoless double $\beta$ decay experiments are the most promising. We, however, do not discuss it further, but just recommend the interested readers to look into a report at this conference \[10\].

2. SIGN OF $\Delta m_{13}^2$

Nunokawa and I recently discussed \[11\] that the features of neutrino flavor transformation in supernova (SN) is sensitive to the sign of $\Delta m_{13}^2 \equiv m_3^2 - m_1^2$, making contrast between the normal ($\Delta m_{13}^2 > 0$) vs. inverted ($\Delta m_{13}^2 < 0$) mass hierarchies. Therefore, one can obtain insight on the sign of $\Delta m_{13}^2$ by analyzing neutrino events from supernova. With use of the unique data at hand from SN1987A \[12\], we have obtained a strong indication that the normal mass hierarchy, $m_3 \gg m_1 \sim m_2$, is favored over the inverted one, $m_1 \sim m_2 \gg m_3$.

The point is that there are always two MSW resonance points in SN for neutrinos with cosmologically interesting mass range, $m_\nu \lesssim 100$ eV. The higher density point, which I denote the H resonance, plays a deterministic role. If the H resonance is adiabatic the feature of $\nu$ flavor transformation in SN is best characterized as $\nu_e = \nu_{\text{heavy}}$ exchange, as first pointed out in Ref. \[13\]. Here, $\nu_{\text{heavy}}$ collectively denotes $\nu_\mu$ and $\nu_\tau$, which are physically indistinguishable in SN. See also Ref. \[14\] for a recent comprehensive treatment of 3 $\nu$ flavor conversion in SN.

Now the question is: how does the sign of $\Delta m_{13}^2$ make difference? The answer is: if $\Delta m_{13}^2$ is positive (negative) the neutrino (antineutrino) undergoes the resonance. Then, if the inverted mass hierarchy is the case and assuming the adiabaticity of H resonance, the $\bar{\nu}_e$ which to be observed in terrestrial detectors comes from original $\bar{\nu}_{\text{heavy}}$ in neutrinosphere. It is widely recognized that, due to their weaker interactions with surrounding matter, $\nu_{\text{heavy}}$ and $\bar{\nu}_{\text{heavy}}$ are more energetic than $\nu_e$ and $\bar{\nu}_e$. Since the $\bar{\nu}_e$ induced CC reaction is the dominant reaction channel in water Cherenkov detectors, the effect of such flavor transformation would be sensitively probed by them.

We draw in Fig. 1 equal likelihood contours as a function of the heavy to light $\nu$ temperature ratio $\tau \equiv T_{\bar{\nu}_e}/T_{\nu_e} = T_{\bar{\nu}_e}/T_{\nu_e}$ on the space spanned by $\bar{\nu}_e$ temperature and total neutrino luminosity by giving the neutrino events from SN1987A. The data comes from Kamiokande and IMB experiments \[15\]. In addition to it we introduce an extra parameter $\eta$ defined by $L_{\nu_e} = L_{\bar{\nu}_e} = \eta L_{\nu_e}$ which describes the departure from equipartition of energies to three neutrino species and examine the sensitivity of our conclusion against the change in $\eta$.

![Likelihood Contours for Inverted Mass Hierarchy](image)

Fig.1: Contours of constant likelihood which correspond to 95.4% confidence regions for the inverted mass hierarchy under the assumption of adiabatic H resonance. From left to right, $\tau \equiv T_{\bar{\nu}_e}/T_{\nu_e} = T_{\bar{\nu}_e}/T_{\nu_e} = 2, 1.8, 1.6, 1.4, 1.2$ and 1.0 where $x = \mu, \tau$. Best-fit points for $T_{\bar{\nu}_e}$ and $E_\beta$ are also shown by the open circles. The parameter $\eta$ parametrizes the departure from the equipartition of energy, $L_{\nu_x} = L_{\bar{\nu}_x} = \eta L_{\nu_e} = \eta L_{\bar{\nu}_e}$ ($x = \mu, \tau$), and the dotted lines (with best fit indicated by open squares) and the dashed lines (with best fit indicated by stars) are for the cases $\eta = 0.7$ and 1.3, respectively. Theoretical predictions from supernova models are indicated by the shadowed box.
At $\tau = 1$, that is at equal $\bar{\nu}_e$ and $\nu_e$ temperatures, the 95 % likelihood contour marginally overlaps with the theoretical expectation represented by the shadowed box in Fig. 1. When the temperature ratio $\tau$ is varied from unity to 2 the likelihood contour moves to the left, indicating less and less consistency between the standard theoretical expectation and the observed feature of the neutrino events. This is simply because the observed energy spectrum of $\bar{\nu}_e$ must be interpreted as that of the original one of $\nu_{\text{heavy}}$ in the presence of the MSW effect in $\bar{\nu}$ channel. It implies that the original $\bar{\nu}_e$ temperature must be lower by a factor of $\tau$ than the observed one, leading to stronger inconsistency at larger $\tau$.

The solid lines in Fig. 1 are for the case of equipartition of energy into three flavors, $\eta = 1$, whereas the dotted and the dashed lines are for $\eta = 0.7$ and 1.3, respectively. We observe that our result is very insensitive against the change in $\eta$.

We conclude that if the temperature ratio $\tau$ is in the range 1.4-2.0 as the SN simulations indicate, the inverted hierarchy of neutrino masses is disfavored by the neutrino data of SN1987A unless the H resonance is nonadiabatic, i.e., unless $s_{13} \lesssim 10^{-4}$.

3. HOW TO MEASURE SIGN OF $\Delta m_{13}^2$ AND CP VIOLATION IN NEUTRINO OSCILLATION EXPERIMENTS?

The possibility that SN can tell about the sign of $\Delta m_{13}^2$ is, I think, interesting and in fact it is the unique available hint on the question at this moment. We, the authors of Ref. [14], feel that our argument and the analysis done with the SN1987A data is reasonably robust. But, of course, it would be much nicer if we can have independent confirmation by terrestrial experiments. With regard to the CP violating effect mentioned in (iii) it appears, to my understanding, that the best place for its measurement is long (\gtrsim 10 km) baseline neutrino oscillation experiments.

We develop an analytic method by which we can explore various regions of experimentally variable parameters to illuminate at where CP violating effects are large and how one can avoid serious matter effect contamination. Actually we formulate below a perturbative framework to have a bird-eye view of at where the sign of $\Delta m_{13}^2$ is clearly displayed and the CP violating phase manifests itself. Some of the earlier attempts to formulate perturbative treatment to explore the various regions may be found in [14].

We rewrite the Schrödinger equation by using the basis $\nu$ defined by (A is a CP phase matrix) $\nu_\alpha = [e^{-i\lambda_3 \theta_{13}/2} e^{i\lambda_2 \theta_{23}/2}]_{\alpha \beta} \nu_\beta$, into the form

$$i\frac{d}{dx} \nu_\alpha = (H)_{\alpha \beta} \nu_\beta$$

(1)

where Hamiltonian $H$ contains the following three terms:

$$H = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & \Delta_{12} \\ \Delta_{12} & 0 & 0 \end{bmatrix} + a(x) \begin{bmatrix} c_{13}^2 & 0 & c_{13} s_{13} \\ 0 & 0 & 0 \\ c_{13} s_{13} & 0 & s_{13}^2 \end{bmatrix}$$

(2)

We first note the order of magnitude of a relevant quantity to observe the hierarchies of various terms in the Hamiltonian:

$$\frac{\Delta m^2}{E} = 10^{-13} \left( \frac{\Delta m^2}{10^{-3} \text{eV}^2} \right) \left( \frac{E}{10 \text{GeV}} \right)^{-1} \text{eV}. \quad (3)$$

It may be compared with the matter potential $a(x) = \sqrt{G F} N_e(x)$ where $N_e$ denotes electron number density in the earth;

$$a(x) = 1.04 \times 10^{-13} \left( \frac{\rho}{2.7 \text{g/cm}^3} \right) \left( \frac{Y_e}{0.5} \right) \text{eV}, \quad (4)$$

where $Y_e \equiv N_p/(N_p + N_n)$ is the electron fraction.

In view of these results one can identify two typical cases, the high and low energy options with $\nu$ beam energies $\sim 10 \text{ GeV}$ and $\sim 100 \text{ MeV}$, respectively, each with a hierarchy of energy scales:

(1) High energy option

$$\frac{\Delta m^2}{E} \sim a(x) \gg \frac{\Delta m^2_{13}}{E} \quad (5)$$

(2) Low energy option

$$\frac{\Delta m^2}{E} \gg a(x) \sim \frac{\Delta m^2_{12}}{E} \quad (6)$$

Now let us discuss the high and low energy options one by one. The focus will be on the sign of $\Delta m_{13}^2$ in the former and the CP violation in the latter.

3.1. High energy option: matter enhanced $\theta_{13}$ mechanism

In the high energy option one can formulate perturbation theory by regarding the 1st and the 2nd terms in the Hamiltonian in (3) as unperturbed part and the 3rd term as perturbation; solar $\Delta m^2$ perturbation theory. The unperturbed system is essentially the two-flavor MSW system and it is well known that
it leads to the matter enhanced $\theta_{13}$ mechanism in neutrino (if $\Delta m_{12}^2 > 0$) or antineutrino (if $\Delta m_{12}^2 < 0$) channels. Therefore, the high energy option is advantageous if $\theta_{13}$ is extremely small.

In leading order one can easily compute the oscillation probability in matter under the adiabatic approximation. It reads

$$P(\nu_\mu \rightarrow \nu_e) = s^2_{13} \sin^2 2\theta_{13} \sin^2 \left( \xi_{HE} \frac{\Delta m_{12}^2 L}{4E} \right) \tag{7}$$

$$\sin 2\theta_{13}^M = \frac{\sin 2\theta_{13}}{\xi_{HE}}, \tag{8}$$

where

$$\xi_{HE} = \sqrt{\left( \cos 2\theta_{13} \pm \frac{2Ea}{\Delta m_{12}^2} \right)^2 + \sin^2 2\theta_{13}} \tag{9}$$

where $\pm$ refers to antineutrino and neutrino channels, respectively.

Let us expand the oscillation probability by the parameter $\frac{\Delta m_{12}^2 L}{4E}$. In fact, it is a small parameter in most of the practical cases;

$$\frac{\Delta m_{12}^2 L}{4E} = 0.127$$

$$\times \left( \frac{\Delta m_{12}^2}{10^{-3} \text{eV}^2} \right) \left( \frac{L}{1000 \text{ km}} \right) \left( \frac{E}{100 \text{ GeV}} \right)^{-1}. \tag{10}$$

Then, the oscillation probability reads to next to leading order as

$$P(\nu_\mu \rightarrow \nu_e) = s^2_{13} \sin^2 2\theta_{13} \left( \frac{\Delta m_{12}^2 L}{4E} \right)^2 \times \left[ 1 - \frac{1}{3} \xi_{HE} \left( \frac{\Delta m_{12}^2 L}{4E} \right)^2 \right]. \tag{11}$$

The first term in (11) is identical with the vacuum oscillation probability $P_{\text{vac}}$ under the small $\frac{\Delta m_{12}^2 L}{4E}$ approximation. It is the simplest version of the vacuum mimicking mechanism discussed in Ref. [8] where a much more extensive version including the CP (or T) violating piece is uncovered.\footnote{In passing I have a few comments on the vacuum mimicking mechanism. It might be curious that it works at the MSW resonance point because the mixing angle is certainly enhanced. But it works in such a way that there is a prolongation of oscillation length which exactly cancels the exahncement of the mixing angle. But the phenomenon of vacuum mimicking is more general which occurs not only off resonance but also in nonresonant channel as far as neutrino path length is shorter than the vacuum oscillation length. This mechanism has triggered some interests quite recently [15][17][18].}

If the measurement is done in both neutrino and antineutrino channel, one may obtain the difference

$$\Delta P = P(\nu_\mu \rightarrow \nu_e) - P(\bar{\nu}_e \rightarrow \bar{\nu}_e) \approx \frac{8}{3} \left( \frac{Ea}{\Delta m_{12}^2 L} \right) \left( \frac{\Delta m_{13}^2 L}{4E} \right)^2 P_{\text{vac}}. \tag{12}$$

If I use $\Delta m_{13}^2 = 3 \times 10^{-3} \text{ eV}^2$, $\Delta P \sim 0.1 P_{\text{vac}}$ for baseline $\sim 1000 \text{ km}$ and energy $\sim 10 \text{ GeV}$ since the first parenthesis is of order unity in the high energy option. Thus, the sign of $\Delta m_{13}^2$ is determined as the sign of $\Delta P$ \cite{20}.

My next and the last message about the high energy option is that the CP violating effect is small. It is obvious in leading order that no CP violating effect is induced; it is a two-flavor problem and hence there is no room for CP violation even in matter. Therefore, we have to go beyond the leading order to have CP violation. Then, the CP and T violating effect is always accompanied by the suppression factor $\frac{\Delta m_{12}^2}{\Delta m_{13}^2} \approx 0.1 - 0.01$ which comes from the energy denominator. Therefore, CP-odd effect is small in the high energy option.\footnote{It appears that this statement made some of the neutrino factory workers unhappy; probably they felt it difficult to reconcile this statement with the reported enormous sensitivities that extends toward a very small value of $\sin^2 \theta_{13}$ which will be achieved by neutrino factory. However, it appears that they are actually consistent because the sensitivity is in fact achieved by the CP conserving $\cos \theta$ term not by the CP violating term in the oscillation probability at least for $L \lesssim 1000 \text{ km}$.}

### 3.2. Low energy option: matter enhanced $\theta_{12}$ mechanism

The high energy option is certainly advantageous for the determination of the sign of $\Delta m_{13}^2$ thanks to larger matter effects by available longer baseline due to better focusing of the $\nu$ beam. On the other hand, I will show that the low energy option is the natural place to look for genuine CP violation.

Because of the hierarchy in the energy scale \cite{17}, the first term in the Hamiltonian in \cite{18} is the unperturbed term and the matter and the $\Delta m_{12}^2$ terms are small perturbations. It is important to recognize that it is a degenerate perturbation theory because of the degeneracy in the unperturbed Hamiltonian. Then, one must first diagonalize the degenerate subspace to obtain \textit{zeroth order} wave function and the first order correction to the energy eigenvalues. Then, the zeroth order wave function contains the CP violating phase effect. This is the reason why the low energy option
allows large CP violation unsuppressed by the hierarchical mass ratio $\Delta m_{12}^2/\Delta m_{13}^2$, which is to my knowledge the unique case.

In this setting one can derive the oscillation probability $P(\nu_\mu \to \nu_e)$ as follows:

$$P(\nu_\mu \to \nu_e) = 4s_{23}c_{13}s_{13}^2 \sin^2 \left( \frac{\Delta m_{13}^2 L}{4E} \right) + c_{13}^2 \sin 2\theta_{12}^M \left( c_{23}^2 - s_{23}^2 s_{13}^2 \right) \sin 2\theta_{12}^M + 2c_{23}s_{23}s_{13} \cos \delta \cos 2\theta_{12}^M \sin^2 \left( \xi_{LE} \frac{\Delta m_{12}^2 L}{2E} \right) - 2J_M(\theta_{12}^M, \delta) \sin \left( \xi_{LE} \frac{\Delta m_{12}^2 L}{2E} \right) \tag{13}$$

where $\xi_{LE} = \xi_{HE}(\theta_{13} \to \theta_{12}, \Delta m_{13}^2 \to \Delta m_{12}^2)$, and $J_M$ is the matter enhanced Jarlskog factor. The probability $P(13)$ represents, apart from the $\cos \delta$ term which is small due to the factor $s_{13}$, the vacuum mimicking mechanism in its most extensive form including the CP violating Jarlskog term. To check how well the system mimics vacuum oscillations see Ref [17].

The number of appearance events in water Cherenkov detector for a beam energy $E = 100$ MeV is estimated by assuming 10 times stronger $\nu_\mu$ flux at $L = 250$ km than the K2K design flux (despite lower energy!) and 100% conversion of $\nu_\mu$ to $\nu_e$ as

$$N \simeq 6300 \left( \frac{L}{100 \ \text{km}} \right)^{-2} \left( \frac{V}{1 \ \text{Mton}} \right) \left( \frac{F_{250}}{10 F_{K2K}} \right). \tag{14}$$

where $F_{250}$ and $F_{K2K}$ are the assumed flux at a detector at $L = 250$ km and the design neutrino flux at SK in K2K experiment, respectively. The latter is approximately, $3 \times 10^6 \left( \frac{\text{POT}}{10^{20}} \right)$ cm$^{-2}$ where POT stands for proton on target.

To estimate the optimal distance we compute the expected number of events in neutrino and antineutrino channels as well as their ratios as a function of distance by taking into account of neutrino beam energy spread. For definiteness, we assume that the average energy of neutrino beam $\langle E \rangle = 100$ MeV and beam energy spread of Gaussian type with width $\sigma_E = 10$ MeV. We present our results in Fig. 2.

![Fig. 2: Expected number of events for (a) neutrinos, $N(\nu_\mu \to \nu_e)$, (b) anti-neutrinos, $N(\bar{\nu}_\mu \to \bar{\nu}_e)$, and (c) their ratio $R \equiv N(\nu_\mu \to \nu_e)/N(\bar{\nu}_\mu \to \bar{\nu}_e)$ with a Gaussian type neutrino energy beam with $\langle E \rangle = 100$ MeV with $\sigma = 10$ MeV are plotted as a function of distance from the source. Neutrino fluxes are assumed to vary as $\sim 1/L^2$ in all the distance range we consider. $\sin^2 2\theta_{13}$ is taken as 0.1, a "maximal value" allowed by the CHOOZ limit. The remaining mixing parameters used are of the LMA MSW solution; see Ref [17]. The error bars are only statistical.](image-url)

While this particular proposal may have several experimental problems it is sufficiently illuminative of the fact that the low energy option is in principle more appropriate for experimental search for CP violating effect. There is a large CP violation and the matter effect is small or controllable. The remain-
ing question is of course how to develop a feasible experimental proposal. A possibility which employs medium energy ($\sim 1 - 2$ GeV) conventional $\nu$ beam is raised by an eminent experimentalist and triggered much interests \[23\].

There were many debates between supporters of high and low energy options in the workshop. I have concluded with my personal best three flavor scenario; we measure CP violation by low energy superbeam in Japan, and you measure $\delta$ by neutrino factory in Europe, and then let us compare the results!

ACKNOWLEDGMENTS

I express deep gratitude to G. L. Fogli for cordial invitation to such a focused and the well-organized workshop, in which I was able to enjoy the stimulating atmosphere of the European neutrino physics community. I thank Hiroshi Nunokawa for collaboration and his kind help in dealing with the Elsevier latex format. This work was supported by the Grant-in-Aid for Scientific Research in Priority Areas No. 11127213, Japan Ministry of Education, Culture, Sports, Science and Technology.
