Transforming Growth Factor β Blocks Tec Kinase Phosphorylation, Ca\textsuperscript{2+} Influx, and NFATc Translocation Causing Inhibition of T Cell Differentiation

Chang-Hung Chen, Carole Seguin-Devaux, Nancy A. Burke, Timothy B. Oriss, Simon C. Watkins, Neil Clipstone, and Anuradha Ray

Abstract

Transforming growth factor (TGF)-β inhibits T cell proliferation and differentiation. TGF-β has been shown to inhibit the expression of transcription factors such as GATA-3 and T-bet that play important roles in T cell differentiation. Here we show that TGF-β inhibits T cell differentiation at a more proximal step. An early event during T cell activation is increased intracellular calcium levels. Calcium influx in activated T cells and the subsequent activation of transcription factors such as NFATc, events essential for T cell differentiation, are modulated by the Tec kinases that are downstream of the T cell receptor and CD28. We show that in stimulated CD4\textsuperscript{+} T cells, TGF-β inhibits phosphorylation and activation of the Tec kinase Itk, increase in intracellular Ca\textsuperscript{2+} levels, NFATc translocation, and activation of the mitogen-activated protein kinase ERK that together regulate T cell differentiation. Our studies suggest that by inhibiting Itk, and consequently Ca\textsuperscript{2+} influx, TGF-β limits T cell differentiation along both the Th1 and Th2 lineages.

Key words: TGF-β • T cell • NFAT • Itk • calcium

Introduction

TGF-β inhibits the function of macrophages, T cells, B cells, and NK cells (1). Mice deficient in TGF-β have been shown to develop multi-organ inflammatory immune infiltrate at the age of 2–3 wk (2). Also, it has been shown that TGF-β signaling is critical for controlling T cell homeostasis as well as T cell differentiation by using transgenic mice which express a dominant-negative TGF-β receptor type 2 under a T cell–specific promoter (3). The major effect of TGF-β on mature T cells was thought to be at the level of inhibition of T cell proliferation and IL-2 production (4). But it has been reported that TGF-β can interfere with T cell polarization even under conditions in which T cell proliferation is normal (5).

Because of its potent immunoinhibitory effects, some studies have focused on the role of TGF-β on allergic airway inflammation (6, 7). Transfer of antigen-specific CD4\textsuperscript{+} T cells expressing latent TGF-β into mice resulted in profound inhibition of Th2-induced airway inflammation and airway hyperreactivity (7). Conversely, in another study, overexpression of Smad7, an intracellular antagonist of TGF-β signaling, resulted in enhanced airway reactivity and inflammation (8). These studies strongly suggest a potential regulatory role of TGF-β in asthma. Asthma has been characterized as a Th2-mediated airway inflammation (9). Several molecules are now known to be essential for Th2 differentiation including STAT6, c-Maf, NFATc, and GATA-3 (9–11). Recently, we demonstrated that by regulating GATA-3 expression, nuclear factor (NF)\textsuperscript{κB also

Abbreviations used in this paper: EMSA, electrophoretic mobility shift assay; ERK, extracellular signal–regulated kinase; IP\textsubscript{3}, inositol 1,4,5-triphosphate; LMB, leptomycin B; MAP, mitogen-activated protein; NF, nuclear factor; PMA, phorbol myristate acetate.
plays a critical role in Th2 differentiation (12). The activation of these factors appears to be regulated by signaling through TCR, costimulatory molecules, and the IL-4 receptor (10, 13, 14), indicating the requirement for multiple signaling events for efficient Th2 differentiation. T cell differentiation along the Th1 lineage is similarly regulated by specific transcription factors, among which T-bet, expressed in a lineage-specific fashion, plays an essential role in IFN-γ production (15, 16). Although it is well recognized that TGF-β suppresses T cell-mediated immune responses, whether TGF-β targets upstream pathways that prime for T cell differentiation along either lineage, has not been investigated. Here, we show that TGF-β can interfere with critical upstream signaling events such as Tec kinase phosphorylation and Ca2+ mobilization that are critical for T cell differentiation.

Materials and Methods

Antibodies and Reagents. Anti-CD28 (37,51), anti-CD3ε (145-2C11) were purchased from BD Biosciences. Anti-STAT6, anti-GATA-3, anti-NFATc1, anti Txk (Rlk), anti-Oct-1, and anti-STAT5, were purchased from BD Biosciences. Anti-phospho–extracellular signal–regulated kinase (ERK), anti-Erk, anti-phospho-JNK, anti-JNK, and anti-phospho-GSK-3 were purchased from Cell Signaling. The rabbit anti-murine Rlk antiserum used to immunoprecipitate Rlk was provided by Dr. Pamela Schwarzberg (National Institutes of Health, Bethesda, MD) and its specificity described previously (17). Rabbit anti-mouse antibody was obtained from Sigma-Aldrich and goat anti-mouse from Jackson ImmunoResearch Laboratories. Anti–T-bet antibody was provided by Dr. Laurie Glimcher (Harvard School of Public Health, Boston, MA).

Cytokine Assays. Cytokine concentrations were measured by ELISA using commercially available kits: IL-2, and IL-5 (Endogen), IL-13, IL-4, and IFN-γ (R&D Systems). For intracellular cytokine staining, purified spleen CD4+ T cells were stimulated with plate-bound anti-CD3 and anti-CD28 for 72 h. After blocking of Fc receptors with excess mouse Fc Block™ (2.4G2), and anti-phosphotyrosine (4G10) were purchased from Upstate Biotechnology. Anti-phospho-ZAP-70, anti-ZAP-70, anti-phospho-Lck, anti-Lck, anti-phospho-extracellular signal-regulated kinase (ERK), anti-Erk, anti-phospho-JNK, anti-JNK, and anti-phospho-GSK-3 were purchased from Cell Signaling. The rabbit anti-murine Rlk antiserum used to immunoprecipitate Rlk was obtained from Sigma-Aldrich and goat anti-mouse from Jackson ImmunoResearch Laboratories. Anti–T-bet antibody was provided by Dr. Laurie Glimcher (Harvard School of Public Health, Boston, MA).

Cytokine Assays. Cytokine concentrations were measured by ELISA using commercially available kits: IL-2, and IL-5 (Endogen), IL-13, IL-4, and IFN-γ (R&D Systems). For intracellular cytokine staining, purified spleen CD4+ T cells were stimulated with plate-bound anti-CD3 and anti-CD28 for 72 h. After blocking of Fc receptors with excess mouse Fc Block™ (2.4G2), 106 CD4+ T cells were cell surface stained with Peridinin-Chlorophyll-a Protein–anti–mouse CD4 (RM4–5). Fixation and permeabilization was done using reagents from the Cytofix–Cytoperm Plus kit with the Golgi-plug protocol. Allophycocyanin–anti–mouse IL-4 (11B11) and Phycocerythrin–anti–mouse IL-5 (TRFK-5) were added to permeabilized cells (30 min on ice) for the staining of cytoplasmic IL-4 and IL-5, respectively. Samples were analyzed by flow cytometry using FACScalibur™ and CELLQuest™ software (BD Biosciences) and the frequency of cytokine–positive cells was obtained by subtracting the value obtained with the respective isotype controls. All antibodies and reagents were purchased from BD Biosciences.

Preparation of Nuclear Extracts, Immunoblot Analysis, and Electrophoretic Mobility Shift Assay. CD4+ T cells were stimulated with immobilized anti-CD3 (1 μg/ml) and anti-CD28 (1 μg/ml) and IL-2 (50 U/ml) in the presence of IL-4 (200 U/ml; Becton Dickinson) and anti–IFN-γ (XM1G1.2) for Th2 differentiation or IL-12 (5 ng/ml; R&D Systems) and anti–IL-4 (4 μg/ml; Becton Dickinson) for Th1 differentiation with or without of TGF-β (50 μM). Nuclear extracts were prepared at the indicated time points and used for electrophoretic mobility shift assay (EMSA) or Western blot analysis essentially as described previously (12, 18–20).

Retroviral Infections of Primary Murine CD4+ T Cells. The retroviral plasmid construct pMSCV-caNFATC1-H-2Kb (caNFATC1), and methods for retrovirus production and infection have been described previously (21). CD4+ T cells were stimulated under neutral conditions with anti-CD3 and anti-CD28 and infected at 24 and 48 h after activation by centrifugation at 2,000 rpm for 1.5 h at room temperature with 1.5 ml viral supernatants (containing 6 μg/ml polybrene [Sigma-Aldrich] and 10 μg/ml ml−2). The viral supernatant was removed after the spin infection and replaced with medium containing 10 μg/ml murine IL-2. The expression of green fluorescent protein (GFP) in infected CD4+ T cells was determined by FACS® analysis and over 40% of the cells were found to be infected. The infected CD4+ T cells were then restimulated under Th2 conditions in the presence or absence of TGF-β. Nuclear extracts were prepared after 5 d of culture as described previously and culture supernatants were used for cytokine estimation (12, 18, 19).

In Vitro Kinase Assays. The Itk kinase assay was performed as described previously (22, 23) with minor modifications. Itk immunocomplexes were washed twice in kinase buffer (Cell Signaling) and then incubated in 45 μl of kinase buffer containing 10 μCi of [γ-32P] ATP (NEN Life Science Products), 10 μM ATP and 5 μg of a peptide (Arg-Arg-Leu-Ile-Glu-Asp-Ala-Glu-Tyr-Ala-Ala-Arg-Gly; Sigma-Aldrich) derived from the sequence surrounding the SRC tyrosine kinase autophosphorylation site. This mixture was incubated for 15 min at room temperature and the reaction was stopped by adding 30% glacial acetic acid. The mixture was then blotted onto phosphocellulose paper and washed 6 times with 1% phosphoric acid. The amount of 32P incorporated into the peptide was determined by scintillation counting. To immunoprecipitate Itk, equivalent amounts of whole cell protein were incubated with the rabbit anti-Itk serum for 2 to 4 h at 4°C. The complexes were recovered by Western blotting with the goat anti-Itk antibody (Santa Cruz Biotechnology, Inc.). Itk kinase assay was performed as described previously using 20 μCi of [γ-32P] ATP (NEN Life Science Products) and 10 μM ATP and incubating for 15 min at room temperature (17).

Measurement of Intracellular Calcium Concentration by Microscopy. Chambered glass coverslips were washed and first coated with poly-l-lysine and next with anti-CD3 and anti-CD28 (1 μg/ml). The coverslips were extensively washed, covered with a thin layer of PBS and stored at 4°C for up to 1 wk before use. Purified CD4+ T cells were loaded with 2 μM Fura2-AM (Molecular Probes) for 30 min at 37°C in serum free medium. The cells were then washed and suspended in HEPES buffered media for imaging. Coverslips coated with antibodies were mounted in a Harvard Systems culture chamber and heated to 37°C. Using a 40× dry High NA objective (0.95), and an Olympus automated microscope, driven by Simple PCI, the upper surface of the coverslip was focused and focused. Cells were added to the chamber, and images collected every 10 s using motorized excitation filters at 340 and 380 nm, emission at 510 nm and an Orca 100 camera. The total imaging period for each experiment was 10 min. Using Simple PCI, ratios were calculated for the 340/380 spectra and corrected for background fluorescence.
Results

Impaired Th2 Polarization in the Presence of TGF-β. We first investigated whether we could set up conditions in which the effect of TGF-β on cell proliferation could be dissociated from its effects on T cell differentiation. Toward this end, we stimulated CD4⁺ T cells from OVA TCR transgenic mice with antigen (Ag; pOVA323–339) in the presence of various doses of TGF-β. Cell proliferation was measured by [³H]thymidine incorporation and IL-2 production was examined. Fig. 1 A shows dose-dependent inhibition of cell proliferation by TGF-β. TGF-β affected IL-2 production even at the lowest dose of 10 pM (Fig. 1 A, top panel). However, when IL-2 (50 U/ml) was provided in culture, T cell proliferation was sustained even at a dose of 100 pM of TGF-β (Fig. 1 A, bottom panel). As a dose of 50 pM TGF-β did not interfere with cell proliferation in the presence of exogenously added IL-2, we used this dose in subsequent experiments to investigate its effects on T cell differentiation.

We next investigated the effects of TGF-β on Th2 differentiation to identify proximal targets during T cell differentiation. CD4⁺ T cells were primed under Th2 conditions with Ag and APCs in the presence or absence of TGF-β for 5 d. Cells were then harvested and restimulated for 48 h and Th2 cytokine production was measured. A significant decrease in Th2 cytokine production was observed in the presence of TGF-β (Fig. 1 B). These results indicate that TGF-β not only exerts antiproliferative effects on T cells, but even when conditions are conducive to proliferation in the presence of IL-2 in the microenvironment, TGF-β is able to inhibit T cell differentiation. When CD4⁺ T cells are stimulated to differentiate, several transcription factors important for Th2 differentiation are activated through phosphorylation or dephosphorylation events which ultimately result in the presence of transcriptionally competent factors inside the nucleus (11, 25, 26).

We next examined whether TGF-β affected the nuclear presence of these factors. Consistent with the finding of other groups (27, 28), TGF-β did not affect nuclear translocation of STAT6 even after incubation with TGF-β for 5 d. However, the transcription factors NFATc and GATA-3 could be barely detected in the nuclear fraction prepared from TGF-β-treated cells (Fig. 1 C). These results suggested that TGF-β spares IL-4 receptor-mediated signaling and probably targets TCR/CD28-signaling.
TGF-β Does Not Inhibit NF-κB Activation but Impairs NFATc Translocation and GATA-3 Expression. The series of experiments described next were performed to determine the effects of TGF-β during primary stimulation of CD4+ T cells under Th2-differentiating conditions. As shown in Fig. 2 A, TGF-β inhibited Th2-type cytokine production during primary stimulation of cells using a combination of anti-CD3/anti-CD28. Recently, we have shown that TCR-induced NF-κB activation is essential for GATA-3 expression and in turn Th2 differentiation (12). Because our data suggested that TGF-β may interfere with TCR signaling, we asked whether TGF-β interfered with the activation of NF-κB. As shown in Fig. 2 B, there was essentially no effect of TGF-β on NF-κB activation as measured by EMSA.

NFATc is known to be an important regulator of IL-4 production and thus of Th2 differentiation (29, 30). In resting cells, NFATc resides in the cytoplasm as a phosphorylated protein. Upon stimulation, NFATc undergoes dephosphorylation by the calcium-dependent phosphatase calcineurin, which allows it to translocate to the nucleus to induce gene transcription (31, 32). The dephosphorylation of NFATc by calcineurin is inhibited by cyclosporin A (CsA). As shown in Fig. 2 C, treating cells with CsA not only inhibited the nuclear translocation of NFATc, but the up-regulation of GATA-3 expression in stimulated cells was also compromised despite the presence of exogenously added IL-4. It is to be noted that the basal low level of GATA-3 expression that is typically observed in CD4+ T cells was not affected by either CsA or TGF-β but only the induced expression was inhibited by both reagents. A direct effect of calcineurin on GATA-3 is unlikely as, unlike NFATc, GATA-3 resides in the nucleus in nuclear bodies in unstimulated cells (33) and undergoes phosphorylation and not dephosphorylation upon stimulation of cells, as we recently demonstrated (34). These results suggest a potential role for NFATc in the expression of GATA-3 which may be direct or indirect through regulation of other NFATc-dependent transcription factors. The early induction of NFATc during Th2 differentiation and its essential role in IL-4 gene expression together with the inhibition of GATA-3 expression by CsA prompted us to explore effects of TGF-β on TCR/CD28-induced proximal pathways that are linked to NFATc activation.

The effects of TGF-β on NFATc could be either on suppression of NFATc expression or on inhibition of NFATc translocation. As shown in Fig. 3 A, CD4+ T cells stimulated by a combination of anti-CD3 and anti-CD28 under Th2-differentiating conditions displayed a net increase in NFATc levels which was not inhibited by either TGF-β or CsA as determined by immunoblotting of whole cell lysates. There are three splice variants of NFATc and the slightly slower migration pattern of the bands in TGF-β– and CsA-treated cultures reflects inhibition of dephosphorylation of NFATc that is normally effected by calcineurin. These observations showed that although TGF-β, like CsA, inhibits processing of NFATc, it does not interfere with net NFATc accumulation in the
The Journal of Experimental Medicine

condition with or without TGF-β inhibited by TGF-β/H9252 were stimulated with PMA and ionomycin under Th2 differentiating conditions. NFATc is detected at 5 d after stimulation with a combination of (caNFATc1) in CD4

cell. In a recent study, Feske et al. showed that the duration of nuclear presence of NFAT influences the pattern of expression of several cytokines in human T cells (35). This observation led us to suspect that TGF-β may interfere with the nuclear residence of NFATc either by inhibiting its import (by suppressing dephosphorylation) or by expediting its export (by enhancing rephosphorylation). To investigate this, we used the drug leptomycin B (LMB), which inhibits Crm-1–mediated export of NFATc causing accumulation of NFATc in the nucleus (36). Thus, if TGF-β interfered with NFATc import, LMB would be unable to cause nuclear accumulation of NFATc. On the other hand, if TGF-β did not interfere with import of NFATc but only expedited its export, similar levels of NFATc should be observed in control and TGF-β–treated cells in the presence of LMB. As shown in Fig. 3 B, cells stimulated under Th2-differentiating conditions in the presence of both TGF-β and LMB showed very little evidence of nuclear trapping by LMB compared with control stimulated cells that were treated with LMB suggesting that TGF-β interfered with a signaling event that controls NFATc import (dephosphorylation).

One key check point in the initiation and maintenance of nuclear presence of NFATc is calcium (Ca²⁺) influx in cells (37, 38). We reasoned that if Ca²⁺ influx into cells was affected by the presence of TGF-β, then we should be able to bypass the effects of TGF-β by addition of a calcium ionophore such as ionomycin to the cells. CD4+ T cells were stimulated with phorbol myristate acetate (PMA) and ionomycin under Th2-stimulatory conditions in the presence or absence of TGF-β and the expression of NFATc and GATA-3 was analyzed. As illustrated in Fig. 3 C, TGF-β did not inhibit the nuclear presence of NFATc or of GATA-3 when cells were treated with PMA and ionomycin indicating that TGF-β targeted pathways that regulated [Ca²⁺], levels.

To assess the importance of inhibited NFATc1 on T cell differentiation by TGF-β, a constitutively active mutant form of NFATc1 or control virus was introduced into CD4+ T cells by retroviral-mediated gene transfer techniques (21). As shown in Fig. 3 D, infection of cells with virus expressing the mutant but not with the control virus restored GATA-3 expression in the cells. It is interesting that this mutant was found to increase IFN-γ expression and actually decrease IL-4 expression in recent studies (21). Similarly, we have also found significant restoration of IL-5 levels (unpublished data). It should be noted that since TGF-β was added to the cultures after infection with retrovirus to allow efficient infection with the virus, the inhibition of IL-13 production by TGF-β was not as drastic as shown in Figs. 1 and 2 where TGF-β was present since the beginning. Given its ability to restore GATA-3 expression and maintain IL-5 and IL-13 expression, the effect of caNFATc1 on IL-4 could be specific and suggests that while NFATc1 is undoubtedly important for IL-4 expression as previous studies have shown (29, 30), unregulated expression of NFATc1 may ultimately inhibit IL-4 expression by conflicting with the expression of or antagonizing other transcription factors such

Figure 3. TGF-β interferes with signals essential for NFATc translocation but not gene expression. In all experiments (A) whole cell lysates were prepared from CD4+ T cells stimulated under Th2 differentiating conditions in the presence or absence of TGF-β or CsA. The expression of NFATc was assessed by immunoblotting. (B) CD4+ T cells were incubated with or without leptomycin B (20 ng/ml) for 30 min and then stimulated with anti-CD3 and anti-CD28 under Th2 differentiating conditions ± TGF-β (50 pM). Nuclear extracts were prepared after 4 h of stimulation and analyzed for the presence of NFATc. (C) CD4+ T cells were stimulated with PMA and ionomycin under Th2differentiating conditions with or without the addition of TGF-β (50 pM). Nuclear extracts were prepared and analyzed for the presence of NFATc and GATA-3. It is to be noted that while stimulation by Ag + APC or anti-CD3 + anti-CD28 maintains nuclear presence of NFATc up to 5 d, very little active NFATc is detected at 5 d after stimulation with a combination of PMA and ionomycin. (D) Expression of constitutively active NFATc (caNFATc1) in CD4+ T cells restores the expression of GATA-3 and IL-13 inhibited by TGF-β. Activated CD4+ T cells were infected with recombinant retrovirus expressing caNFATc1 and or control virus. Infected CD4+ T cells were subsequently incubated under Th2differentiating condition with or without TGF-β (50 pM). Nuclear extracts were prepared at 5 d of culture and analyzed by immunoblotting for the presence of GATA-3. The same blot was then stripped and reprobed with anti-Oct-1 antibody. Culture supernatants were analyzed for the presence of IL-13.
as c-maf that are important for IL-4 gene transcription but not for IL-5 or IL-13 expression (39).

**TGF-β Does Not Prevent Th2 Responses in Committed Th2 Cells.** To investigate whether TGF-β was also able to influence Th2 responses in already committed Th2 cells which have high levels of GATA-3 expression, we allowed CD4⁺ T cells to differentiate along the Th2 lineage without TGF-β and added it only during restimulation. As shown in Fig. 4, addition of TGF-β during secondary stimulation did not impair either GATA-3 or NFATc expression or Th2 cytokine production. This shows that TGF-β can prevent the development of Th2 cells but does not affect activation of already committed Th2 cells. Our results are not unexpected since it has been previously shown that T cells developing along the Th2 lineage undergo loss of calcium signaling pathways (40) and thus these cells can be expected to be less susceptible to inhibition by TGF-β.

**TGF-β Affects Th1 Development by Inhibiting Both T-bet and NFATc Expression.** Although TGF-β has been shown to affect Th1 development (41, 42), given the IFN-γ–stimulating effect of the constitutively active NFATc and the demonstrated role of NFATc in IFN-γ gene transcription (43, 44), we were interested to determine whether TGF-β was able to inhibit NFATc activation in Th1-developing cells. As shown in Fig. 5 A, while TGF-β did inhibit T-bet expression as shown previously, the effect on NFATc was more pronounced. These inhibitory effects were reflected in inhibition of IFN-γ production by the cells (Fig. 5 B).

**TGF-β Interferes with Activation of the Tec Kinase Itk.** Stimulation of the TCR/CD28 signaling pathways results in a complex series of sequential phosphorylation/dephosphorylation events that control cell proliferation and differentiation. The Tec family of nonreceptor tyrosine kinases has an important role in integrating multiple signals from TCR/CD28 and transmitting them to molecules downstream in the signaling cascade. In T cells, three Tec-family members have been well studied: Itk, Rlk, and Tec (45). Both TCR signaling and costimulatory signals contribute to tyrosine phosphorylation of these kinases resulting in their activation (45). Tec kinases such as Itk and Tec have been demonstrated to play a role in TCR signaling for IL-2 production, Ca²⁺ mobilization and in turn NFATc translocation (46–48). To determine if TGF-β could interfere with Itk activity, Itk was immunoprecipitated with anti-Itk antibody after stimulation of CD4⁺ T cells in the presence or absence of TGF-β and Itk phosphorylation was analyzed by immunoblotting with anti-phosphotyrosine antibody. As shown in Fig. 6 A, Itk phosphorylation was rapidly induced when cells were stimulated by cross-linking of cell surface-bound anti-CD3 and anti-CD28. The phosphorylation peaked at 2 min and was detected until 20 min after stimulation (unpublished data). When cells were stimulated with plate-bound antibodies, the increased phosphorylation was sustained until 60 min after TCR/CD28 stimulation in the absence of TGF-β. Itk phosphorylation, however, did

**Figure 4.** TGF-β does not inhibit Th2 cytokine production when added during secondary stimulation of already committed Th2 cells. (A) CD4⁺ T cells were stimulated with anti-CD3 and anti-CD28 under Th2 differentiating conditions. After 5 d of culture, cells were harvested and restimulated with anti-CD3 and anti-CD28 (IL-2, 50 U/ml) in the presence or absence of TGF-β (50 pM). Nuclear extracts were prepared 2 d after restimulation and analyzed by immunoblotting with antibodies to GATA-3 and NFATc. (B) Supernatants were harvested after 48 h and assayed for the production of IL-4, IL-5, and IL-13 by ELISA.

**Figure 5.** Inhibition of Th1 differentiation by TGF-β. (A) CD4⁺ T cells were stimulated with anti-CD3 and anti-CD28 under Th1 differentiating conditions ± TGF-β (50 pM). Nuclear extracts were prepared at 3 d and 5 d of culture and analyzed for the presence of T-bet. The same blot was then stripped and sequentially reprobed with anti-NFATc antibody and anti-CREB-1 antibody. (B) IFN-γ concentrations in the culture supernatants collected at days 2 and 5 after stimulation were determined by ELISA.
not increase in the presence of TGF-β using either method of cell stimulation. We also examined Itk kinase activity in Th2-differentiating cells in the presence or absence of TGF-β and found an inhibition of Itk kinase activity in the presence of TGF-β (Fig. 6 B). Recently, unlike Itk-/- mice which are defective in Th2 responses in vivo, Itk-/- mice were found to maintain Th2 responses (49).

To investigate Rlk phosphorylation in Th2 developing cells, Rlk was immunoprecipitated and an immunocomplex kinase assay was performed to detect autophosphorylation of Rlk as described previously (17). As shown in Fig. 6 C, we detected basal levels of phosphorylation of Rlk which did not change upon stimulation of cells. In other experiments, this protein band was not detected using control rabbit serum confirming the specificity of the antisera (unpublished data). Because Itk has been shown to regulate Ca²⁺ mobilization, which is critical for NFATc translocation, we next examined the Ca²⁺ response in the presence of TGF-β.

To determine the effects of TGF-β on Ca²⁺ flux in activated CD4⁺ T cells, we used both flow cytometry and real-time imaging techniques using the Ca²⁺-binding ratiometric dye Fura-2M. In the flow cytometry method, cells were loaded with fluo-3 AM and incubated with anti-CD3 and anti-CD28. Cells were activated by cross-linking the bound antibodies and the intracellular Ca²⁺ level was monitored by flow cytometry. As shown in Fig. 7 A, in the absence of TGF-β, the typical biphasic response was noted with an initial rapid increase in [Ca²⁺]ᵢ that was followed by a sustained low level of [Ca²⁺]ᵢ. Addition of TGF-β caused the initial increase in [Ca²⁺]ᵢ which dropped to basal levels by 4 min. We have also monitored [Ca²⁺]ᵢ in the cells using a ratiometric technique that is being increasingly used to track T cell dynamics at several levels in vitro (50). In this technique, Fura-2M-loaded CD4⁺ T cells were added to anti-CD3 and anti-CD28-coated chambered glass coverslips mounted in a Harvard Systems culture chamber maintained at 37°C and containing medium with or without TGF-β. Images were collected every 10 s using motorized excitation filters at 340 and 380 nm and emission at 515 nm. Images at two time points are shown in Fig. 7 B. As shown in Fig. 7 C, there was an initial small change in the ratio in both control and TGF-β-treated cells which returned to baseline by ~150 s. However, the subsequent steady, dramatic increase in the ratio observed in the control cells due to increased calcium levels in the cells was not observed in the presence of TGF-β.

**Fig. 6.** Impaired Itk phosphorylation in the presence of TGF-β. (A) CD4⁺ T cells were stimulated either by cross-linking of cell surface-bound anti-CD3 and anti-CD28 with rabbit anti-mouse antibody or with plate-bound anti-CD3 and anti-CD28 antibodies ± TGF-β (50 pM). Cells were harvested and lysed at the indicated time points. Cell lysates were immunoprecipitated with anti-Itk antibody. The immunoprecipitates were analyzed by immunoblotting using anti-phosphotyrosine antibody (4G10) to detect the level of phosphorylation. The same blot was then stripped and reprobed with anti-Itk antibody. (B) TGF-β decreases Itk kinase activity in stimulated CD4⁺ T cells. CD4⁺ T cells were stimulated by anti-CD3 and anti-CD28 under Th2 differentiating conditions ± TGF-β (50 pM). Equal amounts of cell lysate proteins were immunoprecipitated with anti-Itk antibody. The kinase reaction was performed during 15 min with [γ-³₂P] ATP, cold ATP, and the SRC peptide. The reaction was stopped, blotted onto phosphocellulose paper, and incorporation was measured. (C) Effect of TGF-β on Rlk autophosphorylation. CD4⁺ T cells were stimulated by anti-CD3 and anti-CD28 under Th2 differentiating conditions with or without TGF-β (50 pM). Equal amounts of cell lysate proteins were immunoprecipitated with anti-Rlk antisera. The kinase reaction was performed with [γ-³₂P] ATP and cold ATP for 15 min. The reaction was stopped by adding SDS-sample buffer and the samples were subjected to SDS-PAGE. Protein phosphorylation was assessed by autoradiography.
The Journal of Experimental Medicine

1696 TGF-β Blocks Ca²⁺ influx in Activated CD4⁺ T Cells

phorylation (at ~60 min; unpublished data) as has been previously observed in other studies (53). The JNK MAP kinase pathway has been shown to inhibit Th2 responses through phosphorylation of NFATc (54, 55). We therefore examined whether TGF-β treatment led to increase in JNK phosphorylation. However, no increase in JNK phosphorylation was observed in the presence of TGF-β. Yet another mechanism that regulates shuttling of NFATc between the cytoplasm and the nucleus is glycogen synthase kinase-3 (GSK-3). By phosphorylating serine residues within serine-rich regions and serine-proline repeats in NFATc, GSK-3 enhances export of NFATc from the nucleus. Thus while a kinase-inactive mutant of GSK-3 has been shown to slow down nuclear export of NFATc, overexpression of GSK-3 expedites nuclear export of this factor (56). As TCR engagement leads to phosphorylation of GSK-3, which inhibits its activity thereby allowing nuclear localization of NFATc, we investigated whether TGF-β interfered with GSK-3 phosphorylation which would prevent normal activation of NFATc. Our results show that TGF-β does not interfere with the phosphorylation status of GSK-3 in stimulated cells (Fig. 8 B).

Discussion

The immunosuppressive functions of TGF-β are well recognized. TGF-β has been found to inhibit primary responses in CD4⁺ T cells during both Th1 and Th2 differentiation and memory Th2 cells were found to resist TGF-β-mediated suppression (57). In Th1 cells, the inhibitory effect of TGF-β was initially associated with the attenuation of IL-12Rβ2 expression and, more recently, with inhibition of T-bet expression (41, 42). Consistent with the reports of two other groups (27, 28), we show inhibition of

Figure 7. TGF-β blocks Ca²⁺ influx in activated CD4⁺ T cells. (A) Fluo-3 AM loaded CD4⁺ T cells were incubated with anti-CD3 and anti-CD28 for 15 min on ice. After measuring the basal mean fluorescence intensity (mean F0) for 80 s, cells were stimulated by cross-linking with rabbit anti–mouse antibody in a Hepes-buffered saline solution containing IL-2 (50 U/ml) with or without TGF-β. Ca²⁺ flux was monitored by measuring mean fluorescence intensity (F) for the next 10 min. (B) CD4⁺ T cells were added to the warmed chambered anti-CD3- and anti-CD28-coated cover-slip containing culture medium and images were collected every 10 s. The cells are colored to show the relative intensities of the 340 nm (green) and 380 nm (red) signal. At early time points (for example in the 1 min and 40 s time point shown here), most cells appear red/orange reflecting the higher 380 nm component to the signal. However, at later time points (in this example the 8 min 30 s images are shown), while there is little change in the ratio in cells treated with TGF-β, the control cells show a clear change in the ratio, and most of the cells have a significant increase in the 340 component (bar = 50 microns). (C) Graphical representation of the results. The measured values represent the ratio for 15 cells in each experimental condition.
GATA-3 expression in Th2 cells in the presence of TGF-β and absence of any effects on STAT6 activation. In developing Th1 cells, TGF-β caused inhibition of IFN-γ production and T-bet expression as shown previously (42). Addition of TGF-β during differentiation to either lineage inhibited NFATc activation. A critical requirement for NFATc activation is sustained levels of elevated \([\text{Ca}^{2+}]_i\). We show that TGF-β prevents \(\text{Ca}^{2+}\) influx in CD4+ T cells that is important for both Th1 and Th2 differentiation. The phosphorylation of the Tec kinase, Itk, which regulates \(\text{Ca}^{2+}\) mobilization and NFATc translocation (45, 47, 52, 58) was impaired in the presence of TGF-β.

We and others have demonstrated an essential role for GATA-3 in Th2 differentiation (18, 59). Inhibition of GATA-3 function in mice limits Th2 responses in a model of allergic airway inflammation (19). We have also shown that the p50 subunit of NF-κB plays a nonredundant role in GATA-3 gene expression in developing Th2 cells (12), most likely involving the classic NF-κB complex, the p50:p65 heterodimer, that is activated by TCR signaling. NF-κB, however, does not appear to be a target of TGF-β. Instead our data suggest that the inhibition of GATA-3 expression by TGF-β may be secondary to inhibition of NFATc activation by TGF-β since CsA inhibited not only NFATc translocation but also GATA-3 expression and inhibition of a constitutively active mutant of NFATc restored GATA-3 expression and also Th2 cytokine production. The precise mechanism by which NFATc controls GATA-3 expression remains to be determined. It is to be noted that multiple NFAT-binding sequences can be identified in the 5′-flanking region of the GATA-3 gene.

Activation of transcription factors such as NF-κB and NFATc, that play crucial roles in orchestrating multiple responses in T cells including proliferation, differentiation, and apoptosis, is dependent on \(\text{Ca}^{2+}\) mobilization. There are two stages of \(\text{Ca}^{2+}\) mobilization in T and B cells which are coupled to differential transcription factor activation through various signaling intermediates. TCR stimulation leads to an initial rapid but transient peak of \(\text{Ca}^{2+}\) influx. This is triggered by TCR-induced activation of PLC-γ which cleaves phosphatidylinositol 4,5 bisphosphate (PIP2) to inositol 1,4,5-triphosphate (IP3) and diacylglycerol (DAG). IP3 then binds to IP3 receptors on the endoplasmic reticulum which triggers release of intracellular stores of \(\text{Ca}^{2+}\) into the cytoplasm. This initial rise in \([\text{Ca}^{2+}]_i\), then signals influx of \(\text{Ca}^{2+}\) across the plasma membrane which is mediated by specialized depletion-activated channels called calcium-release-activated \(\text{Ca}^{2+}\) channels (CRAC; reference 60). The initial \([\text{Ca}^{2+}]_i\) spike is sufficient to activate NF-κB (38). However, other transcription factors such as NFAT require more sustained \([\text{Ca}^{2+}]_i\) levels (37, 38). Our results show that while TGF-β does not affect the initial rapid increase in \([\text{Ca}^{2+}]_i\), it compromises the duration of the \(\text{Ca}^{2+}\) signal which is consistent with our observation that the activation of NFAT, but not of NF-κB, is affected by TGF-β.

After TCR ligation or engagement of IgM on B cells, nonreceptor tyrosine kinases including members of the Src and Syk family are activated by phosphorylation, which in turn activate another family of kinases, the Tec kinases, which include Itk/Tsk/Emt, TxK/Rlk, and Tec in T cells and Btk in B cells which play an important role in transmitting signals that ultimately result in \(\text{Ca}^{2+}\) mobilization and appropriate responses in T cells and B cells (17, 47, 52, 61). It is believed that the Tec kinases are involved in sustained \(\text{Ca}^{2+}\) influx through capacitative calcium entry which requires prolonged activation of PLC-γ in stimulated lymphocytes (46). Gene targeting studies showed that Btk- or Itk- or Itk/Rlk-deficiency affects PLC-γ activation as well as \(\text{Ca}^{2+}\) mobilization and MAPK activation after TCR ligation despite preservation of normal patterns of tyrosine phosphorylation and maintenance of the initial rise in \([\text{Ca}^{2+}]_i\) due to release from intracellular stores (46, 52, 58). The phosphorylation of Itk has been shown to depend on the activation of both Lck and ZAP70 although Itk does not appear to be a direct substrate of ZAP-70. As our studies did not reveal any inhibition of Lck or ZAP70 phosphorylation by TGF-β, lack of Itk phosphorylation in the presence of TGF-β may be due to blockade by TGF-β of Itk recruitment to the membrane complex that is necessary for Itk phosphorylation and activation. It is also possible that the kinase that phosphorylates Itk is a more proximal target of TGF-β.

Itk has been shown to be essential for Th2 responses in vivo (62). However, stimulated CD4+ T cells from Itk-deficient mice are unable to mount \(\text{Ca}^{2+}\) flux across the plasma membrane that is essential for NFATc activation (58). As an increase in \([\text{Ca}^{2+}]_i\) is important for both Th1 and Th2 differentiation and the subsequent translocation of NFATc also appears to be important for both Th1 and Th2 responses, it stands to reason that Itk is important for both Th1 and Th2 differentiation. By establishing Itk as a target of TGF-β-mediated immunosuppression, our studies strengthen the importance of Tec kinases in controlling critical downstream events in T cell differentiation such as the induction of sustained \([\text{Ca}^{2+}]_i\) levels and the nuclear localization of NFAT. It will be interesting to determine the precise relationship between proximal signaling events such as Tec kinase phosphorylation, \(\text{Ca}^{2+}\) influx and NFATc and the expression of the transcription factors T-bet in Th1 cells and GATA-3 in Th2 cells.

We thank P. Ray for helpful discussions, L. Glimcher and P. Schwartzberg for anti-T-bet and anti-Rlk antisera, respectively, and M. Yoshida for leptomycin B and A. Gambotto for retrovirus production.

Supported by grants AI 48927, HL 60995, and P50-HL56389 from the National Institutes of Health (to A. Ray).
