Almost 70 years ago A. Turing showed how species diffusion can lead to the emergence of coherent patterns in otherwise stable reactive systems. In this letter, we introduce a novel mechanism to generate spontaneous patterns even in absence of diffusion. We consider a class of purely reactive systems, where immobile species associated to distinct patches, the nodes of a network, interact both locally and at a long-range, as specified by couplings encoded in an (interaction) adjacency matrix. Non local reactions are treated in a mean-field setting which enables the system to reach a homogeneous consensus state, either constant or time dependent. We provide analytical evidence that such homogenous solution can turn unstable under externally imposed disturbances, following a symmetry breaking mechanism that is reminiscent of the Turing instability for reaction-diffusion systems, and which anticipates the subsequent outbreak of the patterns. The onset of the instability can be traced back, via a linear stability analysis, to a dispersion relation that is shaped by the spectrum of an unconventional reactive Laplacian. Examples of systems displaying a fixed point or a limit cycle, in their uncoupled versions, are discussed. Taken together, our results pave the way for alternative mechanisms of pattern formation, opening new possibilities for modeling ecological, chemical and physical interacting systems.

Reaction-diffusion systems are universally invoked as a reference modeling tool, owing to their inherent ability to sustain the spontaneous generation of – spatially extended – patterned motifs. The theory of pattern formation was laid down by A. Turing in a seminal paper appeared in the early 1950’s [1] and later on fertilized in a cross-disciplinary perspective to eventually become a pillar to explain self-organization in nature [2,3]. In the original Turing setting, two chemicals, here termed species, can relocate in space following Fickean diffusion. The species are then assumed to mutually interact via an activator-inhibitor cycle. Small inhomogeneous perturbations, superposed to an underlying homogeneous equilibrium, can trigger the system unstable, via a symmetry breaking instability that is customarily referred to as the Turing instability. This latter sets the onset of diffusion driven patterns, which materialize at later times and indirectly reflect the specificity of the imposed non-linear reaction scheme. The theory of Turing instability has been recently extended to account for an ensemble made of species bound to diffuse on a complex and compartmentalized spatial domain. Local niches are identified as the nodes of a network. Routes linking adjacent sites form a web of intertwined paths, crawled by diffusing individuals, and define the skeleton of the network’s architecture [5,7].

Both in the continuous and discrete (lattice or network based) versions, diffusion is a key ingredient for the Turing paradigm to apply. Assume in fact that a stable fixed point (or, alternatively a time dependent equilibrium, e.g. a limit cycle) exists for the scrutinized reaction scheme in its a-spatial local version. Then, the spatial counterpart of the inspected model admits a homogeneous equilibrium. This follows trivially by recalling that by definition the Laplacian, the operator that implements the diffusive transport, returns zero when applied to a constant density background. Tiny erratic disturbances, that happen to perturb the uniform solution, may therefore activate the diffusion term, and consequently feed on the reaction part, in this way promoting a self-sustained instability which sits at the core of the Turing mechanism.

Natural systems display however an innate drive towards self-organization, which certainly transcends the realms of validity of Turing’s ideas. In many cases of interest, the quantities to be monitored are anchored to the nodes of a virtual graph. The information to be processed on site is carried across the edges of the graph. Nevertheless, the spreading of information springing from nearby nodes is not necessarily bound to obey linear diffusion, as in the spirit of the original Turing formulation. At variance, it can in principle comply with a large plethora of distinct dynamical modalities. In ecological applications, the number of nodes reflects the biodiversity of the sample. Inter-species interactions are usually epitomized by a quadratic response function, which accounts for a wide range of possible interactions, from competitive predator-prey to symbiotic dependences [8,9]. In genetic networks, the pattern of activation reflects the fact that inputs between neighboring genes are shaped by a sigmoidal function, a non linear step function profile often invoked to mimic threshold activation processes [10]. The colored motifs on the skin of zebrafish can be reproduced by postulating an experimentally justified long-ranged regulatory mechanism, in absence of cell motility [11]. At a radically different scale, the dynamics of opinions in sizable social systems are customarily traced back to pairwise exchanges, which can echo physical encounters or be filtered by device-assisted long-ranged interactions [12]. Similarly, global pandemic events mirror complex migra-
tion patterns, which cannot be explained as resorting to the simplistic archetype of diffusion \cite{13}.

Motivated by these observations, here we extend the theory of pattern formation to systems which implement purely reactive schemes, mediated by local (on site) and non local (distant, possibly long-ranged) interactions. To this end, we will assume that non local interactions, as specified by a binary or weighted adjacency matrix, can be scaled by the node degree, following a mean-field working ansatz. The elemental units of the system being inspected (species) are permanently linked to the nodes they are bound to, and therefore classified as immobile. As an application of the proposed framework, we will consider a model of interacting Volterra equations and a family of linearly coupled Stuart-Landau oscillators.

The scheme of interaction. Consider a reactive system made of two, mutually interacting species and label with $x$ and $y$ their respective concentrations. Assume that the dynamics of the inspected system is governed by the following set of coupled differential equations:

$$\begin{cases}
\dot{x} = f(x, y) \\
\dot{y} = g(x, y).
\end{cases}$$

(1)

where $f(\cdot, \cdot)$ and $g(\cdot, \cdot)$ are generic non linear functions. Suppose that the above system admits an equilibrium solution, hereafter $(x^*, y^*)$, which can be either a fixed point or a limit cycle. Linearizing equations \cite{1} around $w^* = (x^*, y^*)$ returns a (linear) first order system for the evolution of the imposed perturbation $\delta w = (\delta x, \delta y)^T$, where $T$ stands for the transpose operation. In formulae, one gets $\delta \dot{w} = J(w^*) \delta w$, where

$$J(w^*) = \begin{pmatrix}
\frac{\partial f}{\partial x} & \frac{\partial f}{\partial y} \\
\frac{\partial g}{\partial x} & \frac{\partial g}{\partial y}
\end{pmatrix}$$

is the Jacobian matrix of the system evaluated at equilibrium. When the equilibrium is a fixed point, the stability of $w^*$ is set by the spectrum of $J$: if the largest real part of the eigenvalues of $J$ is negative the imposed perturbation fades away exponentially and the fixed point is deemed stable. This amounts to requiring $\text{Tr}(J) < 0$ and $\det(J) > 0$, a pre-requisite condition for our analysis to apply. Otherwise, the spectrum of $J$ displays a positive real part and $w^*$ eventually proves unstable. When the equilibrium solution is a limit cycle, the Jacobian exhibits a periodic dependence on time. To assess the stability of the scrutinized solution, one needs to evaluate the so called Floquet exponents, the analogue of the Jacobian spectrum for a periodic orbit \cite{14-16}. In the following, we develop our reasoning by assuming a constant Jacobian, which implies dealing with a fixed point equilibrium. Our analysis and conclusions, however, readily extend to a limit cycle setting, provided one replaces $J$ with the time-independent matrix $B$, with $\det B = \exp(\int_0^T \text{Tr}(J) dt)$, from which the Floquet exponents are computed. It is also worth emphasising that the analysis carried out in the following is in principle not limited to a setting where just two species are made to interact, as assumed for practical reasons in \cite{1}.

Starting from a local formulation of the reactive model, we move forward and account for non local interactions. To this end, we begin by replicating the examined system on $N$ different patches, defining lumps of embedding space or specific criteria to effectively group the variables involved. The collection of $N$ isolated spots where the local reaction scheme is replicated are the nodes of a network, identified by the discrete index $i = 1, \ldots, N$. The edges of the network provide a descriptive representation of the non-local reaction scheme, where $A_{ij} = 1$ if nodes $i$ and $j$ are sharing a reactive link (the formalism extends readily to account for weighted interactions). For the sake of simplicity we limit the analysis to undirected networks, $A_{ij} = A_{ji}$. We note that, by definition, we have $A_{ii} = 1$. The connectivity of node $i$ is hence $k_i = \sum_j A_{ij}$. Rewrite the non linear function $f$ as $f(x, y) = f_0(x, y) + f_1(x, y)$, where $f_0$ speaks for the interaction terms that are genuinely local, i.e. those not modulated by distant couplings. Conversely, $f_1(x, y)$ will be replaced by a generalized reaction function, which encodes for the remote interaction. More precisely, in the spirit of a nearest neighbors mean-field approximation, we shall substitute $f_1(x, y)$ with its averaged counterpart in the heterogeneous space of the interaction network.

Similarly, $g$ will be split as $g(x, y) = g_0(x, y) + g_1(x, y)$. Then we set:

$$\begin{cases}
\dot{x}_i = f_0(x_i, y_i) + \frac{1}{k_i^2} \sum_j A_{ij} \delta_{ij} \dot{f}_1(x_i, x_j, y_i, y_j) \\
\dot{y}_i = g_0(x_i, y_i) + \frac{1}{k_i^2} \sum_j A_{ij} \delta_{ij} \dot{g}_1(x_i, x_j, y_i, y_j).
\end{cases}$$

(2)

where $\dot{f}_1$ (resp. $\dot{g}_1$) reduces to $f_1$ (resp. $g_1$) when the system is in a homogeneous state. Mathematically, we require $\dot{\delta}_{ij} = \delta_{ij}$ and $\dot{g}_1(x_i, x_j, y_i, y_j) = g_1(x_i, y_i)$. As an illustrative example, consider a local quadratic interaction of the type $f_1(x_i) = x_i^2$. This latter can be turned into $f_1(x_i, x_j) = x_i x_j$, a choice that matches the above constraints. This would yield $(x_i/k_i^4) \sum_j A_{ij} x_j = x_i(x_i)$ in the first of equations \cite{2}, where the average $\langle \cdot \rangle$ runs over the nodes adjacent to $i$. In practical terms, as anticipated above, we replace the local reaction term $f_1(x_i, y_i)$ to include interactions at distance, where the average runs over the $k_i^4$ terms defining the neighborhood of $i$. The remote interaction is assumed to depend only on the species that populate the selected pair of nodes.

By adding and subtracting $f_1(x_i, y_i)$ (resp. $g_1(x_i, y_i)$) in the first (resp. second) of equations \cite{2} and making use of the definition of $f(\cdot, \cdot)$ and $g(\cdot, \cdot)$ yields:

$$\begin{cases}
\dot{x}_i = f(x_i, y_i) + \sum_j L_{ij}^R \dot{f}_1(x_i, x_j, y_i, y_j) \\
\dot{y}_i = g(x_i, y_i) + \sum_j L_{ij}^R \dot{g}_1(x_i, x_j, y_i, y_j)
\end{cases}$$

(3)
where $\mathcal{L}^R_{ij} = \frac{A_{ij}}{k^2} - \delta_{ij}$. As a first remark, we observe that the above equations are formally identical to system (1) when $A \equiv 1_N$, where $1_N$ stands for the $N \times N$ identity matrix. In this case, in fact, the $N$ nodes are formally decoupled and system (1) reduces to (4) for each node of the ensemble. Secondly, system (3) admits an obvious homogeneous solution. This latter is found by assigning $(x_i, y_i) = (x^+, y^+) \forall i$. A natural question thus arises: can one make the homogeneous equilibrium unstable to tiny external non homogeneous perturbations by acting on the network of interactions, as encoded in the operator $\mathcal{L}^R$? Answering this question amounts to extending Turing’s theory for pattern formation to purely reactive models, i.e. in absence of species diffusion. To expand along this line one needs to characterize the operator $\mathcal{L}^R$. As shown in the SI, it is easy to prove that $\mathcal{L}^R$ displays a non-negative spectrum and that has an eigenvector $(1, \ldots, 1)^T$ associated to the $0$ eigenvalue. This justifies referring to $\mathcal{L}^R$ as to a reactive Laplacian. In the literature it is also known as the consensus Laplacian [17–20]..

**Linear stability analysis.** The stability of the homogeneous equilibrium $(x_i, y_i) = (x^+, y^+) \forall i$ can be analytically probed by performing a linear stability analysis. Introduce a small inhomogeneous perturbation, $x_i = x^+ + u_i$, $y_i = y^+ + v_i$, and expand the governing equations up to the leading (linear) order to yield:

$$
\begin{pmatrix}
\dot{u} \\
\dot{v}
\end{pmatrix} = J \otimes 1 \begin{pmatrix}
u \\
\mathcal{L}^R \begin{pmatrix} u \\
v \end{pmatrix}
\end{pmatrix}
$$

(4)

where $u = (u_1, u_2, \ldots, u_N)$, $v = (v_1, v_2, \ldots, v_N)$, $J_R = (\partial_2 \tilde{f}_1, \partial_4 \tilde{g}_1)$. The symbols $\partial_2$ and $\partial_4$ indicate that the derivatives are computed with respect to the second and fourth arguments of the function to which they are applied.

To solve the above linear system, we introduce the eigenvectors ($\phi^{(\alpha)}_j$) and eigenvalues ($\Lambda^{(\alpha)}$) of the reactive Laplacian $\mathcal{L}^R$; i.e. $\sum_j \mathcal{L}^R_{ij} \phi^{(\alpha)}_j = \Lambda^{(\alpha)} \phi^{(\alpha)}_i$ with $\alpha = 1, \ldots, N$. Expanding the perturbations on the basis defined by the set of eigenvectors $\phi^{(\alpha)}_j$, $\alpha = 1, \ldots, N$, and following a straightforward calculation (see SI), we obtain the $2 \times 2$ modified Jacobian $J^\alpha = J + \Lambda^{(\alpha)} J_R$, which determines the stability of the system. For each choice of $\Lambda^{(\alpha)}$, one needs to compute $\lambda^{(\alpha)}$, the largest real part of the eigenvalues of $J^\alpha$. The discrete collection of $\lambda^{(\alpha)}$ vs. $-\Lambda^{(\alpha)}$ defines the so called dispersion relation. The homogeneous equilibrium is stable if $\lambda^{(\alpha)} < 0$, $\forall \alpha$. Conversely, the perturbation grows if at least one $\Lambda^{(\alpha)}$ turns out to be positive. In this latter case patterns can emerge, thus breaking the symmetry of the unperturbed initial condition. The condition of instability can be expressed in a compact form (provided $J^{-1}$ exists), as we prove in the SI. Specifically, we find that the instability sets in if one of the following condition holds: (i) if $\text{Tr}(J^R) < 0$ and provided $\Lambda^{(\alpha)} < -\frac{\text{Tr}(J)}{\text{Tr}(J_R)}$, for at least one choice of $\alpha$; (ii) if $\text{det}(J^R) < 0$ and provided $\Lambda^{(\alpha)} < \Lambda_-$, for at least one choice of $\alpha$; (iii) if $\text{det}(J^R) > 0$, $\text{Tr}(J^{-1} J^R) > 0$ and provided $\Lambda_- < \Lambda^{(\alpha)} < \Lambda_+$, for at least one choice of $\alpha$. Here, $\Lambda_{\pm} = \frac{1}{2} \left[ -\text{Tr}(J^{-1} J^R) \pm \sqrt{\text{Tr}(J^{-1} J^R)^2 - 4 \text{det}(J^{-1} J^R)} \right]$. The above conclusions hold for a two species model that displays a constant homogeneous equilibrium and, as such, generalize the renowned Turing instability conditions for reaction-diffusion models, to purely reactive systems subject to local and remote interactions. As already mentioned, the analysis extends to the setting where the homogeneous state is a synchronous collection of oscillators performing in unison. In this case, the Jacobian matrix is a periodic function of time and the stability can be eventually traced back to the Floquet exponents, following an identical logical path of that outlined above (see SI).

**Volterra model with remote pairwise interaction.** As a first example, we consider the reaction scheme known as the Volterra model [21], $f(x, y) = c_1 xy - dx$ and $g(x, y) = ry - sy^2 - c_2 xy$. The variable $x$ identifies the concentration of predators, while $y$ stands for the prey. Birth and death are accommodated for as self-reaction terms, while cross reaction terms substantiate the mutual interaction between competing species. The parameters are positive definite and control the relative strength of the implemented terms. The Volterra equations admit a fixed point, $x^* = \frac{c_1}{c_2}$, $y^* = \frac{r}{d}$, which

**FIG. 1. Volterra model with remote interactions.** Panels (a) and (b): node colors code for the asymptotic concentration of the species (predators, outer ring, and prey, inner ring), for the Volterra model for two distinct interaction networks. Panel (c): the associated dispersion relations $\lambda^{(\alpha)}$ vs. $-\Lambda^{(\alpha)}$. Red symbols refer to the one-dimensional lattice with periodic boundary conditions, and blue symbols follow from a ER network. Panel (d) shows predator (continuous line)-prey (dashed line) oscillations which can be in some cases triggered by the random inhomogeneous perturbation.
is meaningful and stable provided \( c_1 r - s d > 0 \). We now turn to considering \( N \) replicas of the model, by making the variables to depend on the node index \( i \), associated to different ecological niches. Following the above lines of reasoning, we assume that species can sense the remote interaction with other communities populating the neighboring nodes. For instance, the competition of prey for food and resources can be easily extended so as to account for a larger habitat which embraces adjacent patches. At the same time, predators can benefit from a coordinated action to hunt in teams. Assume that the linear terms in \( f(x, y) \) and \( g(x, y) \) stay local (death term for predators and birth term for prey), i.e. \( f_0(x, y) = -dx, \ g_0(x, y) = ry \). We generalize the terms \( f_1(x, y) = c_1 xy \) and \( g_1(x, y) = -sy^2 - c_2 xy \) to the case of remote interactions as:

\[
\begin{align*}
\dot{x}_i &= -dx_i + \beta \frac{c_1}{k_i} y_i \sum_j A_{ij} x_j + (1 - \beta) \frac{c_1}{k_i} x_i \sum_j A_{ij} y_j \\
\dot{y}_i &= ry_i - \frac{s}{k_i} y_i \sum_j A_{ij} y_j - \frac{c_2}{k_i} y_i y_j \sum_j A_{ij} x_j
\end{align*}
\]

(5)

where \( \beta \in (0, 1) \) modulates the relative strength of the non local terms that drive the evolution of the predators. By simple manipulations, we cast the previous equations so as to bring into evidence the dependence on the reactive Laplacian \( \mathcal{L}^R \). In formulae, one gets

\[
\dot{x}_i = c_1 x_i y_i - dx_i + \alpha \frac{c_1}{k_i} y_i \sum_j \mathcal{L}^R_{ij} x_j + (1 - \alpha) c_1 x_i \sum_j \mathcal{L}^R_{ij} y_j

\]

and

\[
\dot{y}_i = ry_i - s y_i^2 - c_2 x_i y_i - sy_i \sum_j \mathcal{L}^R_{ij} y_j - c_2 y_i \sum_j \mathcal{L}^R_{ij} x_j.
\]

The system can then be studied by resorting to the strategy developed above. The interaction parameters can be set so as to make the dispersion relation positive, as displayed in Fig. 1(c). Red symbols refer to the generalized Volterra model organized on a close lattice made of \( N = 30 \) nodes (panel (a) of Fig. 1), while the blue symbols are obtained when the sites are connected by an Erdős-Rényi (ER) network with \( \langle k \rangle = 3.3 \) (panel (b)). The colors of the nodes stand for the asymptotic state of the system across the networks, showing the formation of distinct patterns for predators (outer ring) and prey (inner ring), in the two cases. While the the lattice yields a regular, equally spaced, pattern, a disordered distribution of populated patches is instead obtained for the ER network, thus reflecting the randomness of the connections. We remark that in both cases, the extinction in a patch of one of the species is typically associated to the disappearance of the other one in the same node, resulting in a global habitat with populated patches alternated with uninhabited ones. These latter play the role of natural barriers separating colonized niches. The emerging patterns of coexistence differ from those observed from standard reaction-diffusion systems, where predators and prey tend to cluster in distinct sites. As a side result, we notice that in some cases the perturbation may trigger the emergence of regular oscillations, typical of a predator-prey cycle. This behavior cannot be reproduced for a deterministic Volterra model in absence of remote couplings [21].

**FIG. 2.** Stuart-Landau model with remote interactions. (a) The instability domain is depicted: \( c = \sigma_{Re} + \sigma_{Im} \beta_{Im}/\beta_{Re} \) is plotted at varying \( \sigma_{Im} \) and \( \beta_{Im} \), while \( \sigma_{Re} = \beta_{Re} = 1 \). The instability condition for the limit cycle \( w^*(t) \) coincides with the request \( c < 0 \). Panel (b) shows the dispersion relation for two different networks, a lattice with \( k = 6 \) (red empty circles) and a Watts-Strogatz network with the same mean degree (blue full circles). Panels (c) and (d) show the patterns of \( |w_i| \), in the space of the nodes and against time, corresponding to the previously mentioned network structures and ensuing dispersion relations.

**Linearly coupled Stuart-Landau oscillators and the Benjamin-Feir instability revisited.** As a second example, we consider a set of reactively coupled Stuart-Landau oscillators. The Stuart-Landau model is the normal form of a Hopf bifurcation and, as such, it bears a universal appeal[22][26]. The Stuart-Landau equation takes the form

\[
\dot{w} = \sigma w - \beta |w|^2 w + i w \omega \text{ where } \omega = \sigma_{Im} - \beta_{Im} \sigma_{Re}/\beta_{Re}.
\]

To determine the stability of the time dependent periodic solution \( w^* \), one can introduce a perturbation of \( w^* \) in the form \( w^*(1 + u) \exp(\nu) \), where \( u \) and \( \nu \) are small quantities. Expanding at the linear order of approximation yields a stable limit cycle which can be cast in the explicit form

\[
w^*(t) = \sqrt{\frac{2\nu}{\beta_{Re}}} \exp(i \omega t),
\]

where \( \omega = \sigma_{Im} - \beta_{Im} \sigma_{Re}/\beta_{Re} \). Interestingly, even if \( w^* \) is periodic in time, \( J \) is constant, owing to the specificity of the Stuart-Landau equation and to the form of the imposed perturbation. This observation allows us to proceed in the analysis without resorting to the Floquet machinery. The request of a stable limit cycle \( w^* \) translates into \( \sigma_{Re} > 0 \), which consequently implies \( \beta_{Re} > 0 \) (since \( \sigma_{Re}/\beta_{Re} > 0 \) for the solution to exist). Stuart-Landau oscillators are often coupled diffusively, either on a regular lattice or on a complex network, so as to result in the celebrated Ginzburg-Landau equation. For suitable
choices of the parameters, the oscillators evolve in unison, giving rise to a fully synchronized homogenous state. This latter can however break apart, upon injection of a tiny disturbance, if the parameters are assigned in the complementary reference domain. This modulational instability, known in the literature as the Benjamin-Feir instability, follows from the subtle interplay between reaction and diffusion terms. Inspired by the analyses carried out above, here we consider a collection of non-diffusive Stuart-Landau oscillators, interacting via their linear reaction term. This choice materializes in a variant of the traditional Ginzburg-Landau equation, ensuing a novel instability of the Benjamin-Feir type. Consider an ensemble made of $i = 1, ..., N$ oscillators at the nodes of a network, characterized by the complex amplitude $w_i$, with $i = 1, ..., N$. The family of Stuart-Landau oscillators evolves therefore as: $\dot{w}_i = \frac{\sigma}{\alpha} \sum_{j} A_{ij} w_j - \beta w_i |w_i|^2$ or, equivalently, $\dot{w}_i = \sigma w_i - \beta |w_i|^2 + \sum_{j} L_{ij} w_j$. A linear stability analysis which moves from the ansatz $w_i = w^* (1 + u_i) \exp(\nu_i)$ (with $u_i, \nu_i < 1$) and implements the above calculation strategy leads to the $\dot{J}_i = J + \Lambda^{(\alpha)} R_j$, where $R_j = \begin{pmatrix} \sigma_{Re} & -\sigma_{Im} \\ \sigma_{Im} & \sigma_{Re} \end{pmatrix}$. We emphasize that both $J_i$ and $J$ are time independent, thus allowing us to perform the calculation without invoking the Floquet formalism. As $\text{Tr} (J) = 2 \sigma_{Re} > 0$, the homogeneous solution turns unstable only if $\text{det} (J_i) < 0$. Since the Jacobian of the uncoupled Stuart-Landau system $J$ is not invertible, we cannot directly invoke the compact inequalities derived above. It is however easy to prove that $\text{det} (J_i) < 0$ given $\Lambda^{(\alpha)} > 2 \sigma_{Re}^2 + \sigma_{Re} \sigma_{Im} / \beta_{Re}$, for at least one choice of $\alpha$. Since the eigenvalues of the reactive Laplacian are by definition negative and $\sigma_{Re} > 0$, the instability request materializes in the compact necessary condition $\sigma_{Re} + \sigma_{Im} / \beta_{Re} < 0$, which constitutes the revisitation of the Benjamin-Feir instability to the present setting where the Stuart-Landau oscillators are subject to a reactive linear mean-field coupling.

Fig. 2(a) displays the region of instability in the reference plane $(\sigma_{Im}, \beta_{Im})$ (when setting $\sigma_{Re}$ and $\beta_{Re}$ to unit). The dashed white line marks the transition to the region of instability. Emerging patterns, and their associated dispersion relations, $\lambda(\alpha)$ vs. $-\Lambda^{(\alpha)}$, are depicted for the Stuart-Landau oscillators distributed on, respectively, a lattice with non-local couplings and a Watts-Strogatz graph. In the SI, we further assess the impact of the network topology on the ensuing instability, showing that the long-range couplings promotes the stability of the system.

Summing up, we have here introduced a novel mechanism for the emergence of coherent patterns in purely reactive systems. Remote interactions, treated in a mean-field approximation, lead to a reactive Laplacian, whose spectrum reflects back on the dispersion relation ultimately setting the conditions for the instability. Applications to reactive systems which display a constant or time dependent consensus state are discussed and confirm the widespread suitability of the proposed scheme. Taken all together, our theory paves the way for investigating novel mechanisms of pattern formation, by providing a flexible alternative to traditional reaction-diffusion schemes, first invoked, in this context, by Turing almost 70 years ago.

**SUPPLEMENTARY INFORMATION**

A. Characterizing the spectrum of the reactive Laplacian.

Recalling that $A_{ii} = 1$, let us introduce matrix $A = A - 1$, the adjacency matrix of the same network, after removal of the self-loops. Hence, $k_i^A = \sum_j A_{ij} = k_i^A - 1$ for all $i$. Define then $L_i^A = A_{ij} - k_i^A \delta_{ij}$ and $L_j^A = A_{ij} - k_i^A \delta_{ij}$. We can straightforwardly prove that $L_i^A = L_j^A$. Indeed, $L_i^A = A_{ii} - k_i^A = 1 - k_i^A = L_i^A$ and $\forall i \neq j, L_i^A = A_{ij} = L_j^A$. $L_i^A$ is by definition a Laplacian matrix, hence characterised by a non-negative spectrum. Based on the above the same conclusion applies to $L_{ij}^A$. In particular, $(1, \ldots, 1)^T$ is the eigenvector of $L^A$ associated to the 0 eigenvalue. We now turn to considering the reactive Laplacian $L$ and set to prove that it also displays a non-positive spectrum, thus providing an a posteriori justification to the name assigned to the operator. Denote by $D$ the diagonal matrix of the connectivities of $L, D_{ii} = k_i^A$. Then, introduce $L^{sym} = D^{-1/2} L^A D^{-1/2}$. By using the definition of $L^A$ we get $L_{ij}^{sym} = A_{ij} / \sqrt{k_i^A k_j^A} - \delta_{ij}$ from which it immediately follows that $L^{sym}$ is symmetric. We can then show that $L^{sym}$ is non-positive definite. Take any $x \in \mathbb{R}^N \setminus \{0\}$, $N$ standing for the dimension of the matrices, i.e. the size of the network. Then $(x, L^{sym} x) = (x, D^{-1/2} L^A D^{-1/2} x) = (D^{-1/2} x, L^A D^{-1/2} x)$ where we used the property of the scalar product $(x, M x) = (M^T x, x)$ and the fact the $D^{-1/2}$ is diagonal. By setting $y = D^{-1/2} x$, we get $(x, L^{sym} x) = (y, L^A y) \leq 0 \ \forall x$ where the last inequality follows from the fact that $L^A$ is non-positive definite. Hence $L^{sym}$ shares the same property. We are finally in a position to show that $L$ has the characteristic spectrum of a Laplacian matrix. Observe that $L = D^{-1/2} L^A D^{-1/2} (D^{-1/2} L^A D^{-1/2}) D^{1/2} = D^{-1/2} L^{sym} D^{1/2}$. Hence, $L$ is similar to $L^{sym}$ and, thus, the two operators display the same non-positive spectrum. Finally, by the very first definition, it follows that $(1, \ldots, 1)^T$ is the eigenvector associated to the 0 eigenvalue of $L$, which ends the proof.

B. The dispersion relation and the conditions for instability

In the following we provide a detailed procedure to characterize the linear stability of the homogeneous equilibria $(x^*, y^*)$ for systems in the general form of eqs. [2]

First of all, we introduce a small inhomogeneous perturbation, $x_i = x^* + u_i$, $y_i = y^* + v_i$, and expand the governing equations up to the linear order to eventually get:

\[
\begin{align*}
\dot{u}_i &= \partial_x f^* u_i + \partial_y f^* v_i + \sum_j L_{ij} [\partial_x f^*_R u_j + \partial_y f^*_R v_j] \\
\dot{v}_i &= \partial_x g^* u_i + \partial_y g^* v_i + \sum_j L_{ij} [\partial_x g^*_R u_j + \partial_y g^*_R v_j]
\end{align*}
\]

(6)

where the symbols $\partial_2$ and $\partial_4$ indicate that the derivatives are computed with respect to the second and fourth arguments of the function to which they are applied. In matrix form,

\[
\begin{pmatrix}
\dot{u} \\
\dot{v}
\end{pmatrix} = J \otimes 1 \begin{pmatrix} u \\ v \end{pmatrix} + J_R \otimes L \begin{pmatrix} u \\ v \end{pmatrix}
\]

(7)

where

\[
J_R = \begin{pmatrix}
\partial_x f^*_R \\
\partial_x g^*_R
\end{pmatrix}.
\]

(8)

Introduce the eigenvectors and eigenvalues of the Laplacian $L$, as $\sum_j L_{ij} \phi_j^{(\alpha)} = \Lambda^{(\alpha)} \phi_i^{(\alpha)}$. Expand the perturbations on the basis of the reactive Laplacian to eventually yield:

\[
u_i = \sum_\alpha c_\alpha \phi_i^{(\alpha)}, \quad v_i = \sum_\alpha d_\alpha \phi_i^{(\alpha)}.
\]

(9)
We can therefore write equation (7) as
\[
\sum_{\alpha} \left( \frac{c_{\alpha}}{d_{\alpha}} \right) \phi^{(\alpha)} = J \otimes 1 \sum_{\alpha} \left( \frac{c_{\alpha}}{d_{\alpha}} \right) \phi^{(\alpha)} + J_R \otimes L \sum_{\alpha} \left( \frac{c_{\alpha}}{d_{\alpha}} \right) \phi^{(\alpha)},
\]
and by diagonalizing the reactive Laplacian:
\[
\sum_{\alpha} \left( \frac{c_{\alpha}}{d_{\alpha}} \right) \phi^{(\alpha)} = [J + \Lambda^{(\alpha)} J_R] \otimes 1 \sum_{\alpha} \left( \frac{c_{\alpha}}{d_{\alpha}} \right) \phi^{(\alpha)}.
\]
(11)

The above linear system is ruled by a $2 \times N$ block-diagonal Jacobian matrix. Each block is the $2 \times 2$ reduced Jacobian $J_\alpha \equiv J + \Lambda^{(\alpha)} J_R$. By making use of the fact that the eigenvectors are linearly independent one eventually gets system
\[
\left( \frac{c_{\alpha}}{d_{\alpha}} \right) = [J + \Lambda^{(\alpha)} J_R] \left( \frac{c_{\alpha}}{d_{\alpha}} \right).
\]
(12)

Starting from this setting we can elaborate on the conditions that drive the system unstable. The eigenvalues of the reduced Jacobian $J_\alpha$ are given by:
\[
\lambda_{\pm}(\alpha) = \frac{1}{2} \left[ \text{Tr}(J_\alpha) \pm \sqrt{\text{Tr}(J_\alpha)^2 - 4 \det(J_\alpha)} \right].
\]
(13)

It is straightforward to verify that, in absence of couplings, i.e. for $\Lambda^{(\alpha)} = 0$, the real part of $\lambda_{\pm}$ is always negative, as it should be because of the stability of the uncoupled equilibrium. We now seek to find the condition for which there exists at least one eigenvalue of the reactive Laplacian, that corresponds to a positive entry of the dispersion relation, i.e. $\text{Re}(\lambda_{\pm}) > 0$, so signaling the instability. This condition is clearly met if $\text{Tr}(J_\alpha) > 0$ or if $\det(J_\alpha) < 0$.

The first condition can be written as $\text{Tr}(J) + \Lambda^{(\alpha)} \text{Tr}(J_R) > 0$. By recalling that the Laplacian eigenvalues are negative and that $\text{Tr}(J) < 0$, one finds that the latter condition is matched only if $\text{Tr}(J_R) < 0$, for $\Lambda^{(\alpha)} < -\frac{\text{Tr}(J)}{\text{Tr}(J_R)}$.

The second condition can be reformulated as $\det(J) \det(1 + \Lambda^{(\alpha)} J^{-1} J_R) < 0$, if $J$ is invertible, which is equivalent to requiring $\det(1 + \Lambda^{(\alpha)} J^{-1} J_R) = \Lambda^{(\alpha)}^2 \det(J^{-1} J_R) + \Lambda^{(\alpha)} \text{Tr}(J^{-1} J_R) + 1 \equiv H(\Lambda^{(\alpha)}) < 0$. By observing that $\det(J^{-1} J_R) = \frac{\det(J_R)}{\det(J)}$ and that $\text{det}(J) > 0$, we can isolate two distinct scenarios: if $\det(J_R) < 0$, the curve $H(\Lambda^{(\alpha)})$ draws a parabola like the one depicted with a green line in Fig 3. The sought condition is hence matched only if there exists an eigenvalue of the reactive Laplacian smaller than the value where the (continuous) parabola intersects the x-axis. If instead $\det(J_R) > 0$, the curve $H(\Lambda^{(\alpha)})$ is negative defined over a finite interval (blue curve in fig 3), provided $\text{Tr}(J^{-1} J_R) > 0$ and, at the same time, $\Delta \equiv \left[ \text{Tr}(J^{-1} J_R) \right]^2 - 4 \det(J^{-1} J_R) > 0$. It is however easy to prove that the latter inequality is always true. Indeed, one can always write $\Delta = \left[ \text{Tr}(\Gamma) \right]^2 - 4 \text{det}(\Gamma)$ and, by denoting with $\mu_1, \mu_2$ the eigenvalues of the generic matrix $\Gamma$, we can write $\Delta = (\mu_1 + \mu_2)^2 - 4 \mu_1 \mu_2 = (\mu_1 - \mu_2)^2$, which is always positive.

In summary, the homogeneous equilibrium $(x^*, y^*)$ can be unstable in the following cases:

- if $\text{Tr}(J_R) < 0$ and provided $\Lambda^{(\alpha)} < -\frac{\text{Tr}(J)}{\text{Tr}(J_R)}$, for at least one choice of $\alpha$.

- if $\det(J_\alpha) < 0$ which, if $J$ is invertible, is verified in the following alternative cases:
  - if $\det(J_R) < 0$ and provided $\Lambda^{(\alpha)} < \Lambda_-$, for at least one choice of $\alpha$
  - if $\det(J_R) > 0$, $\text{Tr}(J^{-1} J_R) > 0$ and provided $\Lambda_- < \Lambda^{(\alpha)} < \Lambda_+$, for at least one choice of $\alpha$.

where $\Lambda_{\pm}$ identifies the points where the curve $H(\Lambda^{(\alpha)})$ is equal to zero, namely:
\[
\Lambda_{\pm} = \frac{1}{2} \left[ -\text{Tr}(J^{-1} J_R) \pm \sqrt{\left[ \text{Tr}(J^{-1} J_R) \right]^2 - 4 \det(J^{-1} J_R)} \right].
\]
C. Network topology affecting pattern formation: the case of the coupled Stuart-Landau equations.

As an addition to the analysis carried out in the main body of the paper, we here get back to considering the system of coupled Stuart-Landau oscillators and elaborate on the role of long-range interactions for the onset of the instability. To this end we start from a lattice with \( k-1 \) nearest neighbors and perturb it with the inclusion of remote links assigned with a given probability. In particular, the generic element \( A_{ij} \) is one with probability \( |i-j|^{-\gamma} \), where \( |\cdot| \) measures the shortest distance on the circle between node \( i \) and node \( j \). The rewiring is implemented in such a way that the average connectivity is preserved. The exponent \( \gamma \) quantifies the range of the interaction, \( \gamma_c = 1 \) setting the threshold between short and long ranged systems, in one dimension.

The network displayed in the panel of fig. 4(a) is a ring with \( k = 7 \), including self-edges. The associated dispersion relation is characterized by a collection of unstable modes that populate the region at small \( |\Lambda^{(a)}| \), where the instability localizes. The emerging patterns are plotted in Fig. 4(d). For \( \gamma = 2 \), the process of network generation is biased to short range couplings, see Fig. 4(b), and the ensuing patterns are depicted in Fig. 4(e). When reducing \( \gamma \), the spectral gap (the distance from zero of the first non negative eigenvalue of the Laplacian) opens. For sufficiently small values of \( \gamma \) (\( \gamma = 0.6 < \gamma_c \), in Fig. 4(c)), all Laplacian eigenvalues are associated to negative entries of the dispersion relation. The fully synchronous state is hence stable and the imposed perturbation gets re-absorbed after a transient in time, see figs. 4(f).

As a further check, we consider the Stuart-Landau oscillators coupled via a weighted adjacency matrix that implements the above strategy for interpolating from a short to a long-ranged scenario. The assigned weights scale as a power law of the nodes distance, with exponent \( \gamma \). Stated differently, the dependence on the inter-nodes distance lies in the intensity of the connections. As clearly illustrated in Fig. 5, the spectral gap increases when progressively strengthening the connections among distant nodes (i.e. by decreasing \( \gamma \)), and the system gains a stable configuration characterized by the synchronous oscillators. By adding long-range couplings, one favors a mean-field homogenization of the dynamics, the system behaving hence as a tightly connected uniform component.
FIG. 4. Instability and observed patterns for the model of Stuart-Landau oscillators coupled via (i) a unidimensional lattice (first column) and (ii) two rewired versions of it, respectively second and third columns. First row: dispersion relations and networks; second row: modulus of $|w_i|$ for every node, over a finite time window of observation. Self-loops are not represented in the network images.
FIG. 5. Instability and observed patterns for the model of coupled Stuart-Landau oscillators. Here, the long-range effect is obtained by weighting the links in the adjacency matrix, according to a decaying power-law function with exponent $\gamma$. First row: scatter plot of the adjacency matrix weights, second row: dispersion relation, third row: modulus of $|w_i|$ for every node, over a finite time window of observation.
