Abstract

Recursive loops in a logic program present a challenging problem to the PLP framework. On the one hand, they loop forever so that the PLP backward-chaining inferences would never stop. On the other hand, they generate cyclic influences, which are disallowed in Bayesian networks. Therefore, in existing PLP approaches logic programs with recursive loops are considered to be problematic and thus are excluded. In this paper, we propose an approach that makes use of recursive loops to build a stationary dynamic Bayesian network. Our work stems from an observation that recursive loops in a logic program imply a time sequence and thus can be used to model a stationary dynamic Bayesian network without using explicit time parameters. We introduce a Bayesian knowledge base with logic clauses of the form $A \leftarrow A_1, \ldots, A_l, true, Context, Types$, which naturally represents the knowledge that the $A_i$s have direct influences on $A$ in the context $Context$ under the type constraints $Types$. We then use the well-founded model of a logic program to define the direct influence relation and apply

*A preliminary version appears in the 15th International Conference on Inductive Logic Programming.
SLG-resolution to compute the space of random variables together with their parental connections. We introduce a novel notion of influence clauses, based on which a declarative semantics for a Bayesian knowledge base is established and algorithms for building a two-slice dynamic Bayesian network from a logic program are developed.

**Key words:** Probabilistic logic programming (PLP), the well-founded semantics, SLG-resolution, stationary dynamic Bayesian networks.

### 1 Introduction

Probabilistic logic programming (PLP) is a framework that extends the expressive power of Bayesian networks with first-order logic [20, 23]. The core of the PLP framework is a backward-chaining procedure, which generates a Bayesian network graphic structure from a logic program in a way quite like query evaluation in logic programming. Therefore, existing PLP methods use a slightly adapted *SLD- or SLDNF-resolution* [18] as the backward-chaining procedure.

Recursive loops in a logic program are SLD-derivations of the form

\[ A_1 \leftarrow ... \leftarrow A_2 \leftarrow ... \leftarrow A_3 \leftarrow \] (1)

where for any \( i \geq 1 \), \( A_i \) is the same as \( A_{i+1} \) up to variable renaming. Such loops present a challenging problem to the PLP framework. On the one hand, they loop forever so that the PLP backward-chaining inferences would never stop. On the other hand, they may generate cyclic influences, which are disallowed in Bayesian networks.

Two representative approaches have been proposed to avoid recursive loops. The first one is by Ngo and Haddawy [20] and Kersting and De Raedt [17], who restrict to considering only acyclic logic programs [1]. The second approach, proposed by Glesner and Koller [13], uses explicit time parameters to avoid occurrence of recursive loops. It enforces acyclicity using time parameters in the way that every predicate has a time argument such that the time argument in the clause head is at least one time step later than the time arguments of the predicates in the clause body. In this way, each predicate \( p(X) \) is changed to \( p(X, T) \) and each clause \( p(X) \leftarrow q(X) \) is rewritten into \( p(X, T1) \leftarrow T2 = T1 - 1, q(X, T2) \), where \( T, T1 \) and \( T2 \) are time parameters.

In this paper, we propose a solution to the problem of recursive loops under the PLP framework. Our method is not restricted to acyclic logic programs, nor does it rely on explicit time parameters. Instead, it makes use of recursive loops to derive a stationary dynamic Bayesian network. We will make two novel contributions. First, we introduce the *well-founded semantics* [33] of logic programs to the PLP framework; in particular, we use the well-founded model of a logic program to define the direct influence relation and apply

---

1The *left-most computation rule* [18] is assumed in this paper.
\( SLG\)-resolution \( \text{[3]} \) (or \( SLTNF\)-resolution \( \text{[29]} \)) to make the backward-chaining inferences. As a result, termination of the PLP backward-chaining process is guaranteed. Second, we observe that under the PLP framework recursive loops (cyclic influences) define feedbacks, thus implying a time sequence. For instance, the clause \( \text{aids}(X) \leftarrow \text{aids}(Y), \text{contact}(X,Y) \) introduces recursive loops

\[
\text{aids}(X) \leftarrow \text{aids}(Y) \ldots \leftarrow \text{aids}(Y_1) \ldots
\]

Together with some other clauses in a logic program, these recursive loops may generate cyclic influences of the form

\[
\text{aids}(p_1) \leftarrow \ldots \leftarrow \text{aids}(p_1) \ldots \leftarrow \text{aids}(p_1) \ldots
\]

Such cyclic influences represent feedback connections, i.e., that \( p_1 \) is infected with aids (in the current time slice \( t \)) depends on whether \( p_1 \) was infected with aids earlier (in the last time slice \( t - 1 \)). Therefore, recursive loops of form (1) imply a time sequence of the form

\[
A \leftarrow \ldots \leftarrow A \ldots \leftarrow A \ldots
\]

where \( A \) is a ground instance of \( A_1 \). It is this observation that leads us to viewing a logic program with recursive loops as a special temporal model. Such a temporal model corresponds to a stationary dynamic Bayesian network and thus can be compactly represented as a two-slice dynamic Bayesian network.

The paper is structured as follows. In Section 2, we review some concepts concerning Bayesian networks and logic programs. In Section 3, we introduce a new PLP formalism, called Bayesian knowledge bases. A Bayesian knowledge base consists mainly of a logic program that defines a direct influence relation over a space of random variables. In Section 4, we establish a declarative semantics for a Bayesian knowledge base based on a key notion of influence clauses. Influence clauses contain only ground atoms from the space of random variables and define the same direct influence relation as the original Bayesian knowledge base does. In Section 5, we present algorithms for building a two-slice dynamic Bayesian network from a Bayesian knowledge base. We describe related work in Section 6 and summarize our work in Section 7.

## 2 Preliminaries and Notation

We assume the reader is familiar with basic ideas of Bayesian networks \( \text{[21]} \) and logic programming \( \text{[18]} \). In particular, we assume the reader is familiar with the well-founded semantics \( \text{[33]} \) as well as \( SLG\)-resolution \( \text{[3]} \). Here we review some basic concepts concerning dynamic Bayesian networks (DBNs). DBNs are introduced to model the evolution of the state of the
environment over time \[10\]. Briefly, a DBN is a Bayesian network whose random variables are subscripted with time steps (basic units of time) or time slices (i.e., intervals). In this paper, we use time slices. For instance, \(\text{Weather}_{t-1}, \text{Weather}_t\) and \(\text{Weather}_{t+1}\) are random variables representing the weather situations in time slices \(t - 1, t\) and \(t + 1\), respectively. We can then use a DBN to depict how \(\text{Weather}_{t-1}\) influences \(\text{Weather}_t\).

A DBN is represented by describing the intra-probabilistic relations between random variables in each individual time slice \(t\) \((t > 0)\) and the inter-probabilistic relations between the random variables of each two consecutive time slices \(t - 1\) and \(t\). If both the intra- and inter-probabilistic relations are the same for all time slices (in this case, the DBN is a repetition of a Bayesian network over time; see Figure 1), the DBN is called a stationary DBN \[24\]; otherwise it is called a flexible DBN \[13\]. As far as we know, most existing DBN systems reported in the literature are stationary DBNs.

\begin{figure}[h]
\centering
\begin{tikzpicture}
\node (A) at (0,0) {$A_t$};
\node (B) at (-1,-1) {$B_t$};
\node (C) at (-2,-2) {$C_t$};
\node (D) at (-3,-3) {$D_t$};
\node (E) at (1,0) {$A_{t-1}$};
\node (F) at (2,-1) {$B_{t-1}$};
\node (G) at (3,-2) {$C_{t-1}$};
\node (H) at (4,-3) {$D_{t-1}$};
\draw[->] (A) -- (E);
\draw[->] (B) -- (F);
\draw[->] (C) -- (G);
\draw[->] (D) -- (H);
\end{tikzpicture}
\caption{A stationary DBN structure.}
\end{figure}

In a stationary DBN as shown in Figure 1, the state evolution is determined by random variables like \(C, B\) and \(A\), as they appear periodically and influence one another over time (i.e., they produce cycles of direct influences). Such variables are called state variables. Note that \(D\) is not a state variable. Due to the characteristic of stationarity, a stationary DBN is often compactly represented as a two-slice DBN.

**Definition 2.1** A two-slice DBN for a stationary DBN consists of two consecutive time slices, \(t - 1\) and \(t\), which describes (1) the intra-probabilistic relations between the random variables in slice \(t\) and (2) the inter-probabilistic relations between the random variables in slice \(t - 1\) and the random variables in slice \(t\).

A two-slice DBN models a feedback system, where a cycle of direct influences establishes a feedback connection. For convenience, we depict feedback connections with dashed edges. Moreover, we refer to nodes coming from slice \(t - 1\) as state input nodes (or state input variables).\(^2\)

**Example 2.1** The stationary DBN of Figure 1 can be represented by a two-slice DBN as shown in Figure 2, where \(A, C\) and \(B\) form a cycle of direct influences and thus establish a feedback connection. This stationary DBN can also be represented by a two-slice DBN starting from a different state input node such as \(C_{t-1}\) or \(B_{t-1}\). These two-slice DBN structures are equivalent in the sense that they model the same cycle of direct influences and can be unrolled into the same stationary DBN (Figure 1).
Observe that in a two-slice DBN, all random variables except state input nodes have the same subscript $t$. In the sequel, the subscript $t$ is omitted for simplification of the structure. For instance, the two-slice DBN of Figure 2 is simplified to that of Figure 3.

In the rest of this section, we introduce some necessary notation for logic programs. Variables begin with a capital letter, and predicate, function and constant symbols with a lower-case letter. We use $p(\cdot)$ to refer to any predicate/atom whose predicate symbol is $p$ and use $p(\overline{X})$ to refer to $p(X_1, ..., X_n)$ where all $X_i$s are variables. There is one special predicate, $true$, which is always logically true. A predicate $p(\overline{X})$ is typed if its arguments $\overline{X}$ are typed so that each argument takes on values in a well-defined finite domain. A (general) logic program $P$ is a finite set of clauses of the form

$$A \leftarrow B_1, ..., B_m, \neg C_1, ..., \neg C_n$$

where $A$, the $B_i$s and $C_j$s are atoms. We use $HU(P)$ and $HB(P)$ to denote the Herbrand universe and Herbrand base of $P$, respectively, and use $WF(P) = \langle I_t, I_f \rangle$ to denote the well-founded model of $P$, where $I_t, I_f \subseteq HB(P)$, and every $A$ in $I_t$ is true and every $A$ in $I_f$ is false in $WF(P)$. By a (Herbrand) ground instance of a clause/atom $C$ we refer to a ground instance of $C$ that is obtained by replacing all variables in $C$ with some terms in $HU(P)$.

A logic program $P$ is a positive logic program if no negative literal occurs in the body of any clause. $P$ is a Datalog program if no clause in $P$ contains function symbols. $P$ is an acyclic logic program if there is a mapping $map$ from the set of ground instances of atoms in $P$ into the set of natural numbers such that for any ground instance $A \leftarrow B_1, ..., B_k, \neg B_{k+1}, ..., \neg B_n$ of any clause in $P$, $map(A) > map(B_i)$ $(1 \leq i \leq n)$ \[1\]. $P$ is said to have the bounded-term-size property w.r.t. a set of predicates \( \{ p_1(\cdot), ..., p_t(\cdot) \} \) if there is a function $f(n)$ such that for any $1 \leq i \leq t$ whenever a top goal $G_0 \leftarrow p_i(\cdot)$ has no argument whose term size exceeds $n$, no atoms in any SLDNF- (or SLG-) derivations for $G_0$ have an argument whose term size exceeds $f(n)$ (this definition is adapted from \[32\]).

\[2\]When no confusion would occur, we will refer to nodes and random variables exchangeably.
3 Definition of a Bayesian Knowledge Base

In this section, we introduce a new PLP formalism, called Bayesian knowledge bases. Bayesian knowledge bases accommodate recursive loops and define the direct influence relation in terms of the well-founded semantics.

**Definition 3.1** A Bayesian knowledge base is a triple \( <PB \cup CB, T_x, CR> \), where

- \( PB \cup CB \) is a logic program, each clause in \( PB \) being of the form

\[
p(.) \leftarrow p_1(.), ..., p_l(.), \text{true}, B_1, ..., B_m, \neg C_1, ..., \neg C_n, \]

where (i) the predicate symbols \( p, p_1, ..., p_l \) only occur in \( PB \) and (ii) \( p(.) \) is typed so that for each variable \( X_i \) in it with a finite domain \( DOM_i \) (a list of constants) there is an atom \( \text{member}(X_i, DOM_i) \) in the clause body.

- \( T_x \) is a set of conditional probability tables (CPTs) of the form \( P(p.)|p_1(.), ..., p_l(.) \), each being attached to a clause in \( PB \).

- \( CR \) is a combination rule such as noisy-or, min or max.

A Bayesian knowledge base contains a logic program that can be divided into two parts, \( PB \) and \( CB \). \( PB \) defines a direct influence relation, each clause saying that the atoms \( p_1(.), ..., p_l(.) \) have direct influences on \( p(.) \) in the context that \( B_1, ..., B_m, \neg C_1, ..., \neg C_n, \text{member}(X_1, DOM_1), ..., \text{member}(X_s, DOM_s) \) is true in \( PB \cup CB \) under the well-founded semantics. Note that the special literal \( \text{true} \) is used in clause to mark the beginning of the context; it is always true in the well-founded model \( WF(PB \cup CB) \). For each variable \( X_i \) in the head \( p(.) \), \( \text{member}(X_i, DOM_i) \) is used to enforce the type constraint on \( X_i \); i.e. the value of \( X_i \) comes from its domain \( DOM_i \). \( CB \) assists \( PB \) in defining the direct influence relation by introducing some auxiliary predicates (such as \( \text{member}(.) \)) to describe contexts. Clauses in \( CB \) do not describe direct influences.

Recursive loops are allowed in \( PB \) and \( CB \). In particular, when some \( p_i(.) \) in clause is the same as the head \( p(.) \), a cyclic direct influence occurs. Such a cyclic influence models a feedback connection and is interpreted as \( p(.) \) at present depending on itself in the past.

In this paper, we focus on Datalog programs, although the proposed approach applies to logic programs with the bounded-term-size property (w.r.t. the set of predicates appearing in the heads of clauses in \( PB \)) as well. Datalog programs are widely used in database and knowledge base systems and have a polynomial time complexity in computing their

---

3The predicate \( \text{true} \) can be defined in \( CB \) using a unit clause.
well-founded models \[33\]. In the sequel, we assume that except for the predicate \textit{member}(.), \(PB \cup CB\) is a Datalog program.

For each clause \(\text{I}\) in \(PB\), there is a unique CPT, \(P(p(.)|p_1(.),...,p_l(.))\), in \(T_x\) specifying the degree of the direct influences. Such a CPT is shared by all instances of clause \(\text{I}\).

A Bayesian knowledge base has the following important property.

**Theorem 3.1** (1) All unit clauses in \(PB\) are ground. (2) Let \(G_0 = \leftarrow p(.)\) be a goal with \(p\) being a predicate symbol occurring in the head of a clause in \(PB\). Then all answers of \(G_0\) derived from \(PB \cup CB \cup \{G_0\}\) by applying SLG-resolution are ground.

**Proof:** (1) If the head of a clause in \(PB\) contains variables, there must be atoms of the form \textit{member}(\(X_i\), DOM\(_i\)) in its body. This means that clauses whose head contains variables are not unit clauses. Therefore, all unit clauses in \(PB\) are ground.

(2) Let \(A\) be an answer of \(G_0\) obtained by applying SLG-resolution to \(PB \cup CB \cup \{G_0\}\). Then \(A\) must be produced by applying a clause in \(PB\) of form \(\text{I}\) with a most general unifier (mgu) \(\theta\) such that \(A = p(.)\theta\) and the body \((p_1(.),...,p_l(.),true,B_1,...,B_m,\neg C_1,...,\neg C_n,\text{member}(X_1,DOM_1),...,\text{member}(X_s,DOM_s))\theta\) is evaluated true in the well-founded model \(WF(PB \cup CB)\). Note that the type constraints \((\text{member}(X_1,DOM_1),...,\text{member}(X_s,DOM_s))\theta\) being evaluated true by SLG-resolution guarantees that all variables \(X_i\)'s in the head \(p(.)\) are instantiated by \(\theta\) into constants in their domains DOM\(_i\)s. This means that \(A\) is ground. \(\Box\)

For the sake of simplicity, in the sequel for each clause \(\text{I}\) in \(PB\), we omit its type constraints \textit{member}(\(X_i\), DOM\(_i\)) \((1 \leq i \leq s)\). Therefore, when we say that the context \(B_1,...,B_m,\neg C_1,...,\neg C_n\) is true, we assume that the related type constraints are true as well.

**Example 3.1** We borrow the well-known AIDS program from \[13\] (a simplified version) as a running example to illustrate our PLP approach. It is formulated by a Bayesian knowledge base \(KB_1\) with the following logic program:\(\footnote{This Bayesian knowledge base \(KB_1 = \langle PB_1 \cup CB_1, T_{x_1}, CR_1\rangle\) may well contain contexts that describe a person’s background information. The contexts together with \(CB_1, T_{x_1}\) and \(CR_1\) are omitted here for the sake of simplicity.}

\[
PB_1 : \begin{align*}
1. & \text{aids}(p1). \\
2. & \text{aids}(p3). \\
3. & \text{aids}(X) \leftarrow \text{aids}(X). \\
4. & \text{aids}(X) \leftarrow \text{aids}(Y), \text{contact}(X,Y). \\
5. & \text{contact}(p1,p2). \\
6. & \text{contact}(p2,p1).
\end{align*}
\]

Note that both the 3rd and the 4-th clause produce recursive loops. The 3rd clause also has a cyclic direct influence. Conceptually, the two clauses model the fact that the direct
influences on $aids(X)$ come from whether $X$ was infected with aids earlier (the feedback connection induced from the 3rd clause) or whether $X$ has contact with someone $Y$ who is infected with aids (the 4-th clause).

4 Declarative Semantics

In this section, we formally describe the space of random variables and the direct influence relation defined by a Bayesian knowledge base $KB$. We then define probability distributions induced by $KB$.

4.1 Space of Random Variables and Influence Clauses

A Bayesian knowledge base $KB$ defines a direct influence relation over a subset of $HB(PB)$. Recall that any random variable in a Bayesian network is either an input node (with no parent nodes) or a node on which some other nodes (i.e. its parent nodes) in the network have direct influences. Since an input node can be viewed as a node whose direct influences come from an empty set of parent nodes, we can define a space of random variables from a Bayesian knowledge base $KB$ by taking all unit clauses in $PB$ as input nodes and deriving the other nodes iteratively based on the direct influence relation defined by $PB$. Formally, we have

Definition 4.1 The space of random variables of $KB$, denoted $S(KB)$, is recursively defined as follows:

1. All unit clauses in $PB$ are random variables in $S(KB)$.

2. Let $A ← A_1, ..., A_l, true, B_1, ..., B_m, ¬C_1, ..., ¬C_n$ be a ground instance of a clause in $PB$. If the context $B_1, ..., B_m, ¬C_1, ..., ¬C_n$ is true in the well-founded model $WF(PB∪CB)$ and $\{A_1, ..., A_l\} ⊆ S(KB)$, then $A$ is a random variable in $S(KB)$. In this case, each $A_i$ is said to have a direct influence on $A$.

3. $S(KB)$ contains only those ground atoms satisfying the above two conditions.

Definition 4.2 For any random variables $A$, $B$ in $S(KB)$, we say $A$ is influenced by $B$ if $B$ has a direct influence on $A$, or for some $C$ in $S(KB)$ $A$ is influenced by $C$ and $C$ is influenced by $B$. A cyclic influence occurs if $A$ is influenced by itself.

Example 4.1 (Example 3.1 continued) The clauses 1, 2, 5 and 6 are unit clauses, thus random variables. $aids(p2)$ is then derived applying the 4-th clause. Consequently, $S(KB_1) = \{aids(p1), aids(p2), aids(p3), contact(p1,p2), contact(p2,p1)\}$. $aids(p1)$ and $aids(p2)$ have a direct influence on each other. There are three cyclic influences: $aids(pi)$ is influenced by itself for each $i = 1, 2, 3$. 

8
Let $WF(PB \cup CB) = \langle I_t, I_f \rangle$ be the well-founded model of $PB \cup CB$ and let $I_{PB} = \{ p(.) \in I_t | p \text{ occurs in the head of some clause in } PB \}$. The following result shows that the space of random variables is uniquely determined by the well-founded model.

**Theorem 4.1** $S(KB) = I_{PB}$.

**Proof:** First note that all unit clauses in $PB$ are both in $S(KB)$ and in $I_{PB}$. We prove this theorem by induction on the maximum depth $d \geq 0$ of backward derivations of a random variable $A$.

($\implies$) Let $A \in S(KB)$. When $d = 0$, $A$ is a unit clause in $PB$, so $A \in I_{PB}$. For the induction step, assume $B \in I_{PB}$ for any $B \in S(KB)$ whose maximum depth $d$ of backward derivations is below $k$. Let $d = k$ for $A$. There must be a ground instance $A \leftarrow A_1, ..., A_l, true, B_1, ..., B_m, \neg C_1, ..., \neg C_n$ of a clause in $PB$ such that the $A_i$s are already in $S(KB)$ and $B_1, ..., B_m, \neg C_1, ..., \neg C_n$ is true in the well-founded model $WF(PB \cup CB)$. Since the head $A$ is derived from the $A_i$s in the body, the maximum depth for each $A_i$ must be below the depth $k$ for the head $A$. By the induction hypothesis, the $A_i$s are in $I_{PB}$. By definition of the well-founded model, $A$ is true in $WF(PB \cup CB)$ and thus $A \in I_{PB}$.

($\impliedby$) Let $A \in I_{PB}$. When $d = 0$, $A$ is a unit clause in $PB$, so $A \in S(KB)$. For the induction step, assume $B \in S(KB)$ for any $B \in I_{PB}$ whose maximum depth $d$ of backward derivations is below $k$. Let $d = k$ for $A$. There must be a ground instance $A \leftarrow A_1, ..., A_l, true, ...$ of a clause in $PB$ such that the body is true in $WF(PB \cup CB)$. Note that the predicate symbol of each $A_i$ occurs in the head of a clause in $PB$. Since the head $A$ is derived from the literals in the body, the maximum depth of backward derivations for each $A_i$ in the body must be below the depth $k$ for the head $A$. By the induction hypothesis, the $A_i$s are in $S(KB)$. By Definition 4.1 $A \in S(KB)$. □

Theorem 4.1 suggests that the space of random variables can be computed by applying an existing procedure for the well-founded model such as SLG-resolution or SLTNF-resolution. Since SLG-resolution has been implemented as the well-known XSB system [25], in this paper we apply it for the PLP backward-chaining inferences. SLG-resolution is a tabling mechanism for top-down computation of the well-founded model. For any atom $A$, during the process of evaluating a goal $\leftarrow A$, SLG-resolution stores all answers of $A$ in a space called table, denoted $T_A$.

Let $\{ p_1, ..., p_t \}$ be the set of predicate symbols occurring in the heads of clauses in $PB$, and let $GS_0 = \{ \leftarrow p_1(\overline{X}_1), ..., \leftarrow p_t(\overline{X}_t) \}$.

**Algorithm 1: Computing random variables.**

1. $S'(KB) = \emptyset$.
2. For each $\leftarrow p_i(\overline{X}_i)$ in $GS_0$
(a) Compute the goal $\leftarrow p_i(\overline{X}_i)$ by applying SLG-resolution to $PB \cup CB \cup \{\leftarrow p_i(\overline{X}_i)\}$. 
(b) $S'(KB) = S'(KB) \cup T_{p_i(\overline{X}_i)}$.

3. Return $S'(KB)$.

**Theorem 4.2** Algorithm 1 terminates, yielding a finite set $S'(KB) = S(KB)$.

**Proof:** Let $WF(PB \cup CB) = <I_t, I_f>$ be the well-founded model of $PB \cup CB$. By the soundness and completeness of SLG-resolution, Algorithm 1 will terminate with a finite output $S'(KB)$ that consists of all answers of $p_i(\overline{X}_i)$ ($1 \leq i \leq t$). By Theorem 3.1, all answers in $S'(KB)$ are ground. This means $S'(KB) = I_{PB}$. Hence, by Theorem 4.1, $S'(KB) = S(KB)$. □

We introduce the following principal concept.

**Definition 4.3** Let $A \leftarrow A_1, \ldots, A_l, true, B_1, \ldots, B_m, \neg C_1, \ldots, \neg C_n$ be a ground instance of the k-th clause in $PB$ such that its body is true in the well-founded model $WF(PB \cup CB)$. We call

$$k. \ A \leftarrow A_1, \ldots, A_l$$

(5) an influence clause.\(^5\) All influence clauses derived from all clauses in $PB$ constitute the set of influence clauses of $KB$, denoted $\mathcal{I}_{\text{clause}}(KB)$.

The following result is immediate from Definition 4.1 and Theorem 4.1.

**Theorem 4.3** For any influence clause (5), $A$ and all $A_i$s are random variables in $S(KB)$.

Influence clauses have the following principal property.

**Theorem 4.4** For any $A_i$ and $A$ in $HB(PB)$, $A_i$ has a direct influence on $A$, which is derived from the k-th clause in $PB$, if and only if there is an influence clause in $\mathcal{I}_{\text{clause}}(KB)$ of the form $k. A \leftarrow A_1, \ldots, A_l, A_i$.

**Proof:** ($\implies$) Assume $A_i$ has a direct influence on $A$, which is derived from the k-th clause in $PB$. By Definition 4.1, the k-th clause has a ground instance of the form $A \leftarrow A_1, \ldots, A_i, \ldots, A_l, true, B_1, \ldots, B_m, \neg C_1, \ldots, \neg C_n$ such that $B_1, \ldots, B_m, \neg C_1, \ldots, \neg C_n$ is true in $WF(PB \cup CB)$ and $\{A_1, \ldots, A_l, A_i\} \subseteq S(KB)$. By Theorem 4.1, $A_1, \ldots, A_l, A_i$ is true in $WF(PB \cup CB)$. Thus, $k. A \leftarrow A_1, \ldots, A_l, A_i$ is an influence clause in $\mathcal{I}_{\text{clause}}(KB)$.

($\impliedby$) Assume that $\mathcal{I}_{\text{clause}}(KB)$ contains an influence clause $k. A \leftarrow A_1, \ldots, A_l, A_i$. Then the k-th clause in $PB$ has a ground instance of the form $A \leftarrow A_1, \ldots, A_i, \ldots, A_l, true, B_1, \ldots, B_m, \neg C_1, \ldots, \neg C_n$ such that its body is true in $WF(PB \cup CB)$ and (by Theorem 4.3) $\{A_1, \ldots, A_i, \ldots, A_l\} \subseteq S(KB)$. By Definition 4.1, $A \in S(KB)$ and $A_i$ has a direct influence on $A$. □

\(^5\)The prefix “k,” would be omitted sometimes for the sake of simplicity.
Corollary 4.5 For any atom $A$, $A$ is in $S(KB)$ if and only if there is an influence clause in $I_{\text{clause}}(KB)$ whose head is $A$.

Theorem 4.4 shows the significance of influence clauses: they define the same direct influence relation over the same space of random variables as the original Bayesian knowledge base does. Therefore, a Bayesian network can be built directly from $I_{\text{clause}}(KB)$ provided the influence clauses are available.

Observe that to compute the space of random variables (see Algorithm 1), SLG-resolution will construct a proof tree rooted at the goal $← p_i(X_i)$ for each $1 \leq i \leq t$. For each answer $A$ of $p_i(X_i)$ in $S(KB)$ there must be a success branch (i.e. a branch starting at the root node and ending at a node marked with success) in the tree that generates the answer. Let $p_i(.) ← A_1, ..., A_l, true, ...$ be the $k$-th clause in $PB$ that is applied to expand the root goal $← p_i(X_i)$ in the success branch and let $\theta$ be the composition of all mgus along the branch. Then $A = p_i(.)\theta$ and the body $A_1, ..., A_l, true, ...$ is evaluated true, with the mgu $\theta$, in $WF(PB \cup CB)$ by SLG-resolution. This means that for each $1 \leq j \leq l$, $A_j\theta$ is an answer of $A_j$ that is derived by applying SLG-resolution to $PB \cup CB \cup \{← A'_j\}$ where $A'_j$ is $A_j$ or some instance of $A_j$. By Theorem 4.6 all $A_j\theta$s are ground atoms. Therefore, $k. p_i(.)\theta ← A_1\theta, ..., A_l\theta$ is an influence clause. Hence we have the following result.

Theorem 4.6 Let $B_r$ be a success branch in a proof tree of SLG-resolution, $p_i(.) ← A_1, ..., A_l, true, ...$ be the $k$-th clause in $PB$ that expands the root goal in $B_r$, and $\theta$ be the composition of all mgus along $B_r$. $B_r$ produces an influence clause $k. p_i(.)\theta ← A_1\theta, ..., A_l\theta$.

Every success branch in a proof tree for a goal in $GS_0$ produces an influence clause. The set of influence clauses can then be obtained by collecting all influence clauses from all such proof trees in SLG-resolution.

Algorithm 2: Computing influence clauses.

1. For each goal $← p_i(X_i)$ in $GS_0$, compute all answers of $p_i(X_i)$ by applying SLG-resolution to $PB \cup CB \cup \{← p_i(X_i)\}$ while for each success branch starting at the root goal $← p_i(X_i)$, collecting an influence clause from the branch into $I'_{\text{clause}}(KB)$.

2. Return $I'_{\text{clause}}(KB)$.

Theorem 4.7 Algorithm 2 terminates, yielding a finite set $I'_{\text{clause}}(KB) = I_{\text{clause}}(KB)$.

Proof: That Algorithm 2 terminates is immediate from Theorem 4.2, as except for collecting influence clauses, Algorithm 2 makes the same derivations as Algorithm 1. The termination of Algorithm 2 then implies $I'_{\text{clause}}(KB)$ is finite.

By Theorem 4.6 any clause in $I'_{\text{clause}}(KB)$ is an influence clause in $I_{\text{clause}}(KB)$. We now prove the converse. Let $k. A ← A_1, ..., A_l$ be an influence clause in $I_{\text{clause}}(KB)$. Then...
the $k$-th clause in $PB$ $A' \leftarrow A_1',...,A_l',true,...$ has a ground instance of the form $A \leftarrow A_1,...,A_l,true,...$ whose body is true in $WF(PB \cup CB)$. By the completeness of SLG-resolution, there must be a success branch in the proof tree rooted at a goal $\leftarrow p_i(X_i)$ in $GS_0$ where (1) the root goal is expanded by the $k\theta$ the branch is $\theta$, and (3) $A \leftarrow A_1,...,A_l,true,...$ is an instance of $(A' \leftarrow A_1',...,A_l',true,...)\theta$. By Theorem 4.6 $k$. $A'\theta \leftarrow A_1',...,A_l',\theta$ is an influence clause. Since any influence clause is ground, $k$. $A'\theta \leftarrow A_1',...,A_l',\theta$ is the same as $k$. $A \leftarrow A_1,...,A_l$. This influence clause from the success branch will be collected into $T'_{\text{clause}}(KB)$ by Algorithm 2. Thus, any clause in $T_{\text{clause}}(KB)$ is in $T'_{\text{clause}}(KB)$. □

Example 4.2 (Example 4.1 continued) There are two predicate symbols, $aids$ and $contact$, in the heads of clauses in $PB_1$. Let $GS_0 = \{\leftarrow aids(X), \leftarrow contact(Y,Z)\}$. Algorithm 2 will generate two proof trees rooted at $\leftarrow aids(X)$ and $\leftarrow contact(Y,Z)$, respectively, as shown in Figures 4 and 5. In the proof trees, a label $C_i$ on an edge indicates that the $i$-th clause in $PB$ is applied, and the other labels like $X = p1$ on an edge show that an answer from a table is applied. Each success branch yields an influence clause. For instance, expanding the root goal $\leftarrow aids(X)$ by the 3rd clause produces a child node $\leftarrow aids(X)$ (Figure 4). Then applying the answers of $aids(X)$ from the table $T_{aids(X)}$ to the goal of this node leads to three success branches. Applying the mgu $\theta$ on each success branch to the 3rd clause yields three influence clauses of the form $3$. $aids(pi) \leftarrow aids(pi)$ ($i = 1,2,3$). As a result, we obtain the following set of influence clauses:

$$T'_{\text{clause}}(KB_1) : 1. \ aids(p1).$$
$$2. \ aids(p3).$$
$$3. \ aids(p1) \leftarrow aids(p1).$$
$$3. \ aids(p2) \leftarrow aids(p2).$$
$$3. \ aids(p3) \leftarrow aids(p3).$$
$$4. \ aids(p2) \leftarrow aids(p1), contact(p2,p1).$$
$$4. \ aids(p1) \leftarrow aids(p2), contact(p1,p2).$$
$$5. \ contact(p1,p2).$$
$$6. \ contact(p2,p1).$$

For the computational complexity, we observe that the cost of Algorithm 2 is dominated by applying SLG-resolution to evaluate the goals in $GS_0$. It has been shown that for a Datalog program $P$, the time complexity of computing the well-founded model $WF(P)$ is polynomial $O(12)$. More precisely, the time complexity of SLG-resolution is $O(|P| \times N^{\Pi P+1} \times \log N)$, where $|P|$ is the number of clauses in $P$, $\Pi P$ is the maximum number of literals in the body of a clause, and $N$, the number of atoms of predicates in $P$ that are not variants of each other, is a polynomial in the number of ground unit clauses in $P$. $P \cup CB$ is a Datalog program except for the $member(X_i, DOM_i)$ predicates (see Definition 3.1). Since each domain $DOM_i$ is a finite list of constants, checking if $X_i$ is
in $DOM_i$ takes time linear in the size of $DOM_i$. Let $K_1$ be the maximum number of $member(X_i, DOM_i)$ predicates used in a clause in $P$ and $K_2$ be the maximum size of a domain $DOM_i$. Then the time of handling all $member(X_i, DOM_i)$ predicates in a clause is bounded by $K_1 \times K_2$. Since each clause in $P$ is applied at most $N$ times in SLG-resolution, the time of handling all $member(X_i, DOM_i)$s in all clauses in $P$ is bounded by $|P| \times N \times K_1 \times K_2$. This is also a polynomial, hence SLG-resolution computes the well-founded model $WF(PB \cup CB)$ in polynomial time. Therefore, we have the following result.

**Theorem 4.8** The time complexity of Algorithm 2 is polynomial.

### 4.2 Probability Distributions Induced by $KB$

For any random variable $A$, we use $pa(A)$ to denote the set of random variables that have direct influences on $A$; namely $pa(A)$ consists of random variables in the body of all influence clauses whose head is $A$. Assume that the probability distribution $P(A|pa(A))$ is available (see Section 5.2). Furthermore, we make the following independence assumption.

**Assumption 1** For any random variable $A$, we assume that given $pa(A)$, $A$ is probabilistically independent of all random variables in $S(KB)$ that are not influenced by $A$.

We define probability distributions induced by $KB$ in terms of whether there are cyclic influences.

**Definition 4.4** When no cyclic influence occurs, the probability distribution induced by $KB$ is $P(S(KB))$. 

---

Figure 4: The proof tree for $\leftarrow ailments(X)$.

![Proof Tree 1](image1)

Figure 5: The proof tree for $\leftarrow contact(Y, Z)$.

![Proof Tree 2](image2)
\textbf{Theorem 4.9} \( P(S(KB)) = \prod_{A_i \in S(KB)} P(A_i|pa(A_i)) \) under the independence assumption.

\textbf{Proof:} When no cyclic influence occurs, the random variables in \( S(KB) \) can be arranged in a partial order such that if \( A_i \) is influenced by \( A_j \) then \( j > i \). By the independence assumption, we have

\[ P(S(KB)) = P(\bigwedge_{A_i \in S(KB)} A_i) = P(A_1|\bigwedge_{i=2} A_i) \cdot P(\bigwedge_{i=2} A_i) = P(A_1|pa(A_1)) \cdot P(\bigwedge_{i=3} A_i) \cdot P(\bigwedge_{i=3} A_i) = \ldots = \prod_{A_i \in S(KB)} P(A_i|pa(A_i)) \square \]

When there are cyclic influences, we cannot have a partial order on \( S(KB) \). By Definition 4.2 and Theorem 4.4, any cyclic influence, say “\( A_1 \) is influenced by itself,” must be resulted from a set of influence clauses in \( I_{\text{clause}}(KB) \) of the form

\[
\begin{align*}
A_1 & \leftarrow \ldots, A_2, \\
A_2 & \leftarrow \ldots, A_3, \\
& \ldots \\
A_n & \leftarrow \ldots, A_1 \\
\end{align*}
\]

These influence clauses generate a chain (cycle) of direct influences

\[ A_1 \leftarrow A_2 \leftarrow A_3 \leftarrow \ldots \leftarrow A_n \leftarrow A_1 \]  

which defines a feedback connection. Since a feedback system can be modeled by a two-slice DBN (see Section 2), the above influence clauses represent the same knowledge as the following ones do:

\[
\begin{align*}
A_1 & \leftarrow \ldots, A_2, \\
A_2 & \leftarrow \ldots, A_3, \\
& \ldots \\
A_n & \leftarrow \ldots, A_{l-1}, \\
\end{align*}
\]

Here the \( A_i \)s are state variables and \( A_{l-1} \) is a state input variable. As a result, \( A_1 \) being influenced by itself becomes \( A_1 \) being influenced by \( A_{l-1} \). By applying this transformation (from influence clauses (6) to (8)), we can get rid of all cyclic influences and obtain a \textit{generalized set} \( I_{\text{clause}}(KB)_g \) of influence clauses from \( I_{\text{clause}}(KB) \).

\textbf{Example 4.3 (Example 4.2 continued)} \( I_{\text{clause}}(KB_1) \) can be transformed to the following generalized set of influence clauses by introducing three state input variables \( aids(p1)_{t-1} \), \( aids(p2)_{t-1} \) and \( aids(p3)_{t-1} \).

\footnote{Depending on starting from which influence clause to generate an influence cycle, a different generalized set containing different state input variables would be obtained. All of them are equivalent in the sense that they define the same feedbacks (cycles of direct influences) and can be unrolled into the same stationary DBN.}
\[ \mathcal{I}_{\text{clause}}(KB_1)_g : 1. \text{aids}(p1). \]
\[ 2. \text{aids}(p3). \]
\[ 3. \text{aids}(p1) \leftarrow \text{aids}(p1)_{t-1}. \]
\[ 3. \text{aids}(p2) \leftarrow \text{aids}(p2)_{t-1}. \]
\[ 3. \text{aids}(p3) \leftarrow \text{aids}(p3)_{t-1}. \]
\[ 4. \text{aids}(p2) \leftarrow \text{aids}(p1)_{t-1}, \text{contact}(p2,p1). \]
\[ 4. \text{aids}(p1) \leftarrow \text{aids}(p2), \text{contact}(p1,p2). \]
\[ 5. \text{contact}(p1,p2). \]
\[ 6. \text{contact}(p2,p1). \]

When there is no cyclic influence, \( KB \) is a non-temporal model, represented by \( \mathcal{I}_{\text{clause}}(KB) \). When cyclic influences occur, however, \( KB \) becomes a temporal model, represented by \( \mathcal{I}_{\text{clause}}(KB)_g \). Let \( S(KB)_g \) be \( S(KB) \) plus all state input variables introduced in \( \mathcal{I}_{\text{clause}}(KB)_g \).

**Definition 4.5** When there are cyclic influences, the probability distribution induced by \( KB \) is \( P(S(KB)_g) \).

By extending the independence assumption from \( S(KB) \) to \( S(KB)_g \), we obtain the following result.

**Theorem 4.10** \( P(S(KB)_g) = \prod_{A_i \in S(KB)_g} P(A_i | pa(A_i)) \) under the independence assumption.

**Proof:** Since \( \mathcal{I}_{\text{clause}}(KB)_g \) produces no cyclic influences, the random variables in \( S(KB)_g \) can be arranged in a partial order such that if \( A_i \) is influenced by \( A_j \) then \( j > i \). The proof then proceeds in the same way as that of Theorem [1.3] \( \square \)

### 5 Building a Bayesian Network from a Bayesian Knowledge Base

#### 5.1 Building a Two-Slice DBN Structure

From a Bayesian knowledge base \( KB \), we can derive a set of influence clauses \( \mathcal{I}_{\text{clause}}(KB) \), which defines the same direct influence relation over the same space \( S(KB) \) of random variables as \( PB \cup CB \) does (see Theorem [1.3]). Therefore, given a probabilistic query together with some evidences, we can depict a network structure from \( \mathcal{I}_{\text{clause}}(KB) \), which covers the random variables in the query and evidences, by backward-chaining the related random variables via the direct influence relation.

Let \( Q \) be a probabilistic query and \( E \) a set of evidences, where all random variables come from \( S(KB) \) (i.e., they are heads of some influence clauses in \( \mathcal{I}_{\text{clause}}(KB) \)). Let \( TOP \)
consist of these random variables. An influence network of $Q$ and $E$, denoted $\mathcal{I}_{\text{net}}(KB)_{Q,E}$, is constructed from $\mathcal{I}_{\text{clause}}(KB)$ using the following algorithm.

**Algorithm 3: Building an influence network.**

1. Initially, $\mathcal{I}_{\text{net}}(KB)_{Q,E}$ has all random variables in $TOP$ as nodes.

2. Remove the first random variable $A$ from $TOP$. For each influence clause in $\mathcal{I}_{\text{clause}}(KB)$ of the form $k. A \leftarrow A_1, ..., A_l$, if $l = 0$ then add to $\mathcal{I}_{\text{net}}(KB)_{Q,E}$ an edge $A \leftarrow$. Otherwise, for each $A_i$ in the body
   
   (a) If $A_i$ is not in $\mathcal{I}_{\text{net}}(KB)_{Q,E}$ then add $A_i$ to $\mathcal{I}_{\text{net}}(KB)_{Q,E}$ as a new node and add it to the end of $TOP$.

   (b) Add to $\mathcal{I}_{\text{net}}(KB)_{Q,E}$ an edge $A \leftarrow A_i$.

3. Repeat step 2 until $TOP$ becomes empty.

4. Return $\mathcal{I}_{\text{net}}(KB)_{Q,E}$.

**Example 5.1 (Example 4.2 continued)** To build an influence network from $KB_1$ that covers $aids(p1)$, $aids(p2)$ and $aids(p3)$, we apply Algorithm 3 to $\mathcal{I}_{\text{clause}}(KB_1)$ while letting $TOP = \{aids(p1), aids(p2), aids(p3)\}$. It generates an influence network $\mathcal{I}_{\text{net}}(KB_1)_{Q,E}$ as shown in Figure 6.

![Figure 6: An influence network built from the AIDS program KB1.](image)

An influence network is a graphical representation for influence clauses. This claim is supported by the following properties of influence networks.

**Theorem 5.1** For any $A_i, A_j$ in $\mathcal{I}_{\text{net}}(KB)_{Q,E}$, $A_j$ is a parent node of $A_i$, connected via an edge $A_i \leftarrow A_j$, if and only if there is an influence clause of the form $k. A_i \leftarrow A_1, ..., A_j, ..., A_l$ in $\mathcal{I}_{\text{clause}}(KB)$.

---

Note the differences between influence networks and influence diagrams. Influence diagrams (also known as decision networks) are a formalism introduced in decision theory that extends Bayesian networks by incorporating actions and utilities [24].
Proof: First note that termination of Algorithm 3 is guaranteed by the fact that any random variable in $S(KB)$ will be added to $TOP$ no more than one time (line 2a). Let $A_i, A_j$ be nodes in $I_{net}(KB)_{Q,E}$. If $A_j$ is a parent node of $A_i$, connected via an edge $A_i \leftarrow A_j$, this edge must be added at line 2b due to applying an influence clause in $I_{clause}(KB)$ of the form $k. A_i \leftarrow A_1, ..., A_j, ..., A_l$ (line 2). Conversely, if $I_{clause}(KB)$ contains such an influence clause, it must be applied at line 2 with edges of the form $A_i \leftarrow A_j$ added to the network at line 2a. □

Theorem 5.2 For any $A_i, A_j$ in $I_{net}(KB)_{Q,E}$, $A_i$ is a descendant node of $A_j$ if and only if $A_i$ is influenced by $A_j$.

Proof: Assume $A_i$ is a descendant node of $A_j$, with a path

$$A_i \leftarrow B_1 \leftarrow ... B_m \leftarrow A_j$$

(9)

By Theorem 5.1 $I_{clause}(KB)$ must contain the following influence clauses

$$k. A_i \leftarrow ..., B_1, ...$$
$$k_1. B_1 \leftarrow ..., B_2, ...$$
$$.....$$
$$k_m. B_m \leftarrow ..., A_j, ...$$

(10)

By Theorem 4.4 and Definition 1.2 $A_i$ is influenced by $A_j$. Conversely, if $A_i$ is influenced by $A_j$, there must be a chain of influence clauses of the form as above. Since $A_i, A_j$ are in $I_{net}(KB)_{Q,E}$, by Theorem 5.1 there must be a path of form (9) in the network. □

Theorem 5.3 Let $V$ be the set of nodes in $I_{net}(KB)_{Q,E}$ and let $W = \{A_j \in S(KB) |$ for some $A_i \in TOP, A_i$ is influenced by $A_j\}$. $V = TOP \cup W$.\(^8\)

Proof: That $I_{net}(KB)_{Q,E}$ covers all random variables in $TOP$ follows from line 1 of Algorithm 3. We first prove that if $A_j \in W$ then $A_j \in V$. Assume $A_j \in W$. There must be a chain of influence clauses of form (10) with $A_i \in TOP$. In this case, $B_1, B_2, ..., B_m, A_j$ will be recursively added to the network (line 2). Thus $A_j \in V$. We then prove that if $A_j \in V$ and $A_j \not\in TOP$ then $A_j \in W$. Assume $A_j \in V$ and $A_j \not\in TOP$. $A_j$ must not be added to $V$ at line 1. Instead, it is added to $V$ at line 2a. This means that for some $A_i \in TOP, A_i$ is a descendant of $A_j$. By Theorem 5.2 $A_i$ is influenced by $A_j$. Hence $A_j \in W$. □

Theorem 4.9 shows that the probability distribution induced by $KB$ can be computed over $I_{clause}(KB)$. Let $I_{net}(KB)_{S(KB)}$ denote an influence network that covers all random variables in $S(KB)$. We show that the same distribution can be computed over

\(^8\)This result suggests that an influence network is similar to a supporting network introduced in [20].
For any node $A_i$ in $\mathcal{I}_{net}(KB)_{S(KB)}$, let $\text{parents}(A_i)$ denote the set of parent nodes of $A_i$ in the network. Observe the following facts: First, by Theorem 5.1, $\text{parents}(A_i) = \text{pa}(A_i)$. Second, by Theorem 5.2, $A_i$ is a descendant node of $A_j$ in $\mathcal{I}_{net}(KB)_{S(KB)}$ if and only if $A_i$ is influenced by $A_j$ in $\mathcal{I}_{clause}(KB)$. This means that the independence assumption (Assumption 1) applies to $\mathcal{I}_{net}(KB)_{S(KB)}$ as well, and that $\mathcal{I}_{clause}(KB)$ produces a cycle of direct influences if and only if $\mathcal{I}_{net}(KB)_{S(KB)}$ contains the same (direct) loop. Combining these facts leads to the following immediate result.

**Theorem 5.4** When no cyclic influence occurs, the probability distribution induced by $KB$ can be computed over $\mathcal{I}_{net}(KB)_{S(KB)}$. That is, $\textbf{P}(S(KB)) = \prod_{A_i \in S(KB)} \textbf{P}(A_i | \text{pa}(A_i)) = \prod_{A_i \in S(KB)} \textbf{P}(A_i | \text{parents}(A_i))$ under the independence assumption.

Theorem 5.4 implies that an influence network without loops is a Bayesian network structure. Let us consider influence networks with loops. By Theorem 5.2, loops in an influence network are generated from recursive influence clauses of form (6) and thus they depict feedback connections of form (7). This means that an influence network with loops can be converted into a two-slice DBN, simply by converting each loop of the form

\[
\begin{array}{c}
\vdots \\
A_1 \rightarrow k_1 \rightarrow A_2 \rightarrow k_2 \rightarrow \ldots \rightarrow k_{n-1} \rightarrow A_n \\
\end{array}
\]

into a two-slice DBN path

\[
A_1 \leftarrow k_1 \ldots \leftarrow A_{n-1} \leftarrow k_{n-1} \leftarrow A_n \leftarrow A_1
\]

by introducing a state input node $A_{1_{n-1}}$.

As illustrated in Section 2, a two-slice DBN is a snapshot of a stationary DBN across any two time slices, which can be obtained by traversing the stationary DBN from a set of state variables backward to the same set of state variables (i.e., state input nodes). This process corresponds to generating an influence network $\mathcal{I}_{net}(KB)_{Q,E}$ from $\mathcal{I}_{clause}(KB)$ incrementally (adding nodes and edges one at a time) while wrapping up loop nodes with state input nodes. This leads to the following algorithm for building a two-slice DBN structure, $2\mathcal{S}_{net}(KB)_{Q,E}$, directly from $\mathcal{I}_{clause}(KB)$, where $Q$, $E$ and $TOP$ are the same as defined in Algorithm 3.

**Algorithm 4: Building a two-slice DBN structure.**

1. Initially, $2\mathcal{S}_{net}(KB)_{Q,E}$ has all random variables in $TOP$ as nodes.

2. Remove the first random variable $A$ from $TOP$. For each influence clause in $\mathcal{I}_{clause}(KB)$ of the form $k$. $A \leftarrow A_1, \ldots, A_l$, if $l = 0$ then add to $2\mathcal{S}_{net}(KB)_{Q,E}$ an edge $A \leftarrow k$. Otherwise, for each $A_i$ in the body

   (a) If $A_i$ is not in $2\mathcal{S}_{net}(KB)_{Q,E}$ then add $A_i$ to $2\mathcal{S}_{net}(KB)_{Q,E}$ as a new node and add it to the end of $TOP$. 

18
(b) If adding $A \leftarrow A_i$ to $2S_{\text{net}}(KB)_{Q,E}$ produces a loop, then add to $2S_{\text{net}}(KB)_{Q,E}$ a node $A_{i-1}$ and an edge $A \leftarrow A_{i-1}$, else add an edge $A \leftarrow A_i$ to $2S_{\text{net}}(KB)_{Q,E}$.

3. Repeat step 2 until TOP becomes empty.

4. Return $2S_{\text{net}}(KB)_{Q,E}$.

Example 5.2 (Example 5.1 continued) To build a two-slice DBN structure from $KB_1$ that covers $\text{aids}(p_1)$, $\text{aids}(p_2)$ and $\text{aids}(p_3)$, we apply Algorithm 4 to $I_{\text{clause}}(KB_1)$ while letting $TOP = \{\text{aids}(p_1), \text{aids}(p_2), \text{aids}(p_3)\}$. It generates $2S_{\text{net}}(KB_1)_{Q,E}$ as shown in Figure 7. Note that loops are cut by introducing three state input nodes $\text{aids}(p_1)_{t-1}$, $\text{aids}(p_2)_{t-1}$ and $\text{aids}(p_3)_{t-1}$. The two-slice DBN structure concisely depicts a feedback system where the feedback connections are as shown in Figure 8.

Figure 7: A two-slice DBN structure built from the AIDS program $KB_1$.

Algorithm 4 is Algorithm 3 enhanced with a mechanism for cutting loops (item 2b), i.e. when adding the current edge $A \leftarrow A_i$ to the network forms a loop, we replace it with an edge $A \leftarrow A_{i-1}$, where $A_{i-1}$ is a state input node. This is a process of transforming influence clauses (6) to (8). Therefore, $2S_{\text{net}}(KB)_{Q,E}$ can be viewed as an influence network built from a generalized set $I_{\text{clause}}(KB)_g$ of influence clauses. Let $S(KB)_g$ be the set of random variables in $I_{\text{clause}}(KB)_g$, as defined in Theorem 4.10. Let $2S_{\text{net}}(KB)_{S(KB)}$ denote a two-slice DBN structure (produced by applying Algorithm 4) that covers all random variables in $S(KB)_g$. We then have the following immediate result from Theorem 5.4.

Theorem 5.5 When $I_{\text{clause}}(KB)$ produces cyclic influences, the probability distribution induced by $KB$ can be computed over $2S_{\text{net}}(KB)_{S(KB)}$. That is, $P(S(KB)_g) = \prod_{A_i \in S(KB)_g} P(A_i | \text{pa}(A_i)) = \prod_{A_i \in S(KB)_g} P(A_i | \text{parents}(A_i))$ under the independence assumption.
Remark 5.1 Note that Algorithm 4 produces a DBN structure without using any explicit time parameters. It only requires the user to specify, via the query and evidences, what random variables are necessarily included in the network. Algorithm 4 builds a two-slice DBN structure for any given query and evidences whose random variables are heads of some influence clauses in $I_{\text{clause}}(KB)$. When no query and evidences are provided, we may apply Algorithm 4 to build a complete two-slice DBN structure, $2S_{\text{net}}(KB)_Q,E$, which covers the space $S(KB)$ of random variables, by letting $\text{TOP}$ consist of all heads of influence clauses in $I_{\text{clause}}(KB)$. This is a very useful feature, as in many situations the user may not be able to present the right queries unless a Bayesian network structure is shown.

Also note that when there is no cyclic influence, Algorithm 4 becomes Algorithm 3 and thus it builds a regular Bayesian network structure.

5.2 Building CPTs

After a Bayesian network structure $2S_{\text{net}}(KB)_Q,E$ has been constructed from a Bayesian knowledge base $KB$, we associate each (non-state-input) node $A$ in the network with a CPT. There are three cases. (1) If $A$ (as a head) only has unit clauses in $I_{\text{clause}}(KB)$, we build from the unit clauses a prior CPT for $A$ as its prior probability distribution. (2) If $A$ only has non-unit clauses in $I_{\text{clause}}(KB)$, we build from the clauses a posterior CPT for $A$ as its posterior probability distribution. (3) Otherwise, we prepare for $A$ both a prior CPT (from the unit clauses) and a posterior CPT (from the non-unit clauses). In this case, $A$ is attached with the posterior CPT; the prior CPT for $A$ would be used, if $A$ is a state variable, as the probability distribution of $A$ in time slice 0 (only in the case that a two-slice DBN is unrolled into a stationary DBN starting with time slice 0).

Assume that the parent nodes of $A$ are derived from $n$ ($n \geq 1$) different influence clauses in $I_{\text{clause}}(KB)$. Suppose these clauses share the following CPTs in $T_x$: $P(A_1|B^1_1, ..., B^1_{m_1})$, ..., and $P(A_n|B^n_1, ..., B^n_{m_n})$. (Recall that an influence clause prefixed with a number $k$ shares the CPT attached to the $k$-th clause in $P_B$.) Then the CPT for $A$ is computed by combining the $n$ CPTs in terms of the combination rule $CR$ specified in Definition 3.1.

Example 5.3 (Example 5.2 continued) Let $CPT_i$ denote the CPT attached to the $i$-th clause in $PB_1$. Consider the random variables in $2S_{\text{net}}(KB_1)_Q,E$. Since aids($p1$) has three parent nodes, derived from the 3rd and 4-th clause in $PB_1$ respectively, the posterior CPT for aids($p1$) is computed by combining $CPT_3$ and $CPT_4$. aids($p1$) has also a prior CPT, $CPT_1$, derived from the 1st clause in $PB_1$. For the same reason, the posterior CPT for aids($p2$) is computed by combining $CPT_3$ and $CPT_4$. The posterior CPT for aids($p3$) is $CPT_3$ and its prior CPT is $CPT_2$. contact($p1,p2$) and contact($p2,p1$) have only prior CPTs, namely $CPT_5$ and $CPT_6$. Note that state input nodes, aids($p1$)$_{t-1}$, aids($p2$)$_{t-1}$ and aids($p3$)$_{t-1}$, do not need to have a CPT; they will be expanded, during the process of unrolling the two-slice DBN into a stationary DBN, to cover the time slices involved in the given query.
and evidence nodes. If the resulting stationary DBN starts with time slice 0, the prior CPTs, CPT_{aids(p1)_0} and CPT_{aids(p3)_0}, for aids(p1) and aids(p3) are used as the probability distributions of aids(p1)_0 and aids(p3)_0.

Note that aids(p2) is a state variable, but there is no unit influence clause available to build a prior CPT for it. We have two ways to derive a prior CPT, CPT_{aids(p2)_0}, for aids(p2) from some existing CPTs. (1) CPT_{aids(p2)_0} comes from averaging CPT_{aids(p1)_0} and CPT_{aids(p3)_0}. For instance, let the probability of aids(p1) = yes be 0.7 in CPT_{aids(p1)_0} and the probability of aids(p3) = yes be 0.74 in CPT_{aids(p3)_0}. Then the probability of aids(p2) = yes is (0.7 + 0.74)/2 = 0.72 in CPT_{aids(p2)_0}. (2) CPT_{aids(p2)_0} comes from averaging the posterior probability distributions of aids(p2). For instance, let {0.9, 0.7, 0.4, 0.8} be the posterior probabilities of aids(p2) = yes in the posterior CPT for aids(p2). Then the probability of aids(p2) = yes is (0.9 + 0.7 + 0.4 + 0.8)/4 = 0.7 in CPT_{aids(p2)_0}.

6 Related Work

A recent overview of existing representational frameworks that combine probabilistic reasoning with logic (i.e. logic-based approaches) or with relational representations (i.e. non-logic-based approaches) is given by De Raedt and Kersting [8]. Typical non-logic-based approaches include probabilistic relational models (PRM), which are based on the entity-relationship (or object-oriented) model [12, 15, 22], and relational Markov networks, which combine Markov networks and SQL-like queries [30]. Representative logic-based approaches include frameworks based on the KBMC (Knowledge-Based Model Construction) idea [3, 4, 10, 13, 14, 17, 20, 23], stochastic logic programs (SLP) based on stochastic context-free grammars [7, 19], parameterized logic programs based on distribution semantics (PRISM) [26], and more. Most recently, a unifying framework, called Markov logic, has been proposed by Domingos and Richardson [9]. Markov logic subsumes first-order logic and Markov networks. Since our work follows the KBMC idea focusing on how to build a Bayesian network directly from a logic program, it is closely related to three representative existing PLP approaches: the context-sensitive PLP developed by Haddawy and Ngo [20], Bayesian logic programming proposed by Kersting and Raedt [17], and the time parameter-based approach presented by Glesner and Koller [13]. In this section, we make a detailed comparison of our work with the three closely related approaches.

6.1 Comparison with the Context-Sensitive PLP Approach

The core of the context-sensitive PLP is a probabilistic knowledge base (PKB). In order to see the main differences from our Bayesian knowledge base (BKB), we reformulate its definition here.

Definition 6.1 A probabilistic knowledge base is a four tuple <PD, PB, CB, CR>, where
• PD defines a set of probabilistic predicates (p-predicates) of the form $p(T_1, ..., T_m, V)$ where all arguments $T_i$s are typed with a finite domain and the last argument $V$ takes on values from a probabilistic domain $DOM_p$.

• PB consists of probabilistic rules of the form

\[ P(A_0|A_1, ..., A_l) = \alpha \leftarrow B_1, ..., B_m, \neg C_1, ..., \neg C_n \]  

(11)

where $0 \leq \alpha \leq 1$, the $A_i$s are p-predicates, and the $B_j$s and $C_k$s are context predicates (c-predicates) defined in CB.

• CB is a logic program, and both PB and CB are acyclic.

• CR is a combination rule.

In a probabilistic rule (11), each p-predicate $A_i$ is of the form $q(t_1, ..., t_m, v)$, which simulates an equation $q(t_1, ..., t_m) = v$ with $v$ being a value from the probabilistic domain of $q(t_1, ..., t_m)$. For instance, let $D_{color} = \{red, green, blue\}$ be the probabilistic domain of $color(X)$, then the p-predicate $color(X, red)$ simulates $color(X) = red$, meaning that the color of $X$ is red. The left-hand side $P(A_0|A_1, ..., A_l) = \alpha$ expresses that the probability of $A_0$ conditioned on $A_1, ..., A_l$ is $\alpha$. The right-hand side $B_1, ..., B_m, \neg C_1, ..., \neg C_n$ is the context of the rule where the $B_j$s and $C_k$s are c-predicates. Note that the sets of p-predicate and c-predicate symbols are disjoint. A separate logic program $CB$ is used to evaluate the context of a probabilistic rule. As a whole, the above probabilistic rule states that for each of its (Herbrand) ground instances

\[ P(A'_0|A'_1, ..., A'_l) = \alpha \leftarrow B'_1, ..., B'_m, \neg C'_1, ..., \neg C'_n \]

if the context $B'_1, ..., B'_m, \neg C'_1, ..., \neg C'_n$ is true in CB under the program completion semantics, the probability of $A'_0$ conditioned on $A'_1, ..., A'_l$ is $\alpha$.

PKB and BKB have the following important differences.

First, probabilistic rules of form (11) in PKB contain both logic representation (right-hand side) and probabilistic representation (left-hand side) and thus are not logic clauses. The logic part and the probabilistic part of a rule are separately computed against $CB$ and $PB$, respectively. In contrast, BKB uses logic clauses of form (4), which naturally integrate the direct influence information, the context and the type constraints. These logic clauses are evaluated against a single logic program $PB \cup CB$, while the probabilistic information is collected separately in $T_x$.

Second, logic reasoning in PKB relies on the program completion semantics and is carried out by applying SLDNF-resolution. But in BKB, logic inferences are based on the well-founded semantics and are performed by applying SLG-resolution. The well-founded semantics resolves the problem of inconsistency with the program completion semantics,
while SLG-resolution eliminates the problem of infinite loops with SLDNF-resolution. Note that the key significance of BKB using the well-founded semantics lies in the fact that a unique set of influence clauses can be derived, which lays a basis on which both the declarative and procedural semantics for BKB are developed.

Third, most importantly PKB has no mechanism for handling cyclic influences. In PKB, cyclic influences are defined to be inconsistent (see Definition 9 of the paper [20]) and thus are excluded (PKB excludes cyclic influences by requiring its programs be acyclic). In BKB, however, cyclic influences are interpreted as feedbacks, thus implying a time sequence. This allows us to derive a stationary DBN from a logic program with recursive loops.

Recently, Fierens, Blockeel, Ramon and Bruynooghe [11] introduced logical Bayesian networks (LBN). LBN is similar to PKB except that it separates logical and probabilistic information. That is, LBN converts rules of form (11) into the form

\[ A_0 | A_1, ..., A_l \leftarrow B_1, ..., B_m, \neg C_1, ..., \neg C_n \]

where the \( A_i \)'s are p-predicates with the last argument \( V \) removed, and the \( B_j \)'s and \( C_k \)'s are c-predicates defined in \( CB \). This is not a standard clause of form (3) as defined in logic programming [15]. Like PKB, LBN differs from BKB in the following: (1) it has no mechanism for handling cyclic influences (see Section 3.2 of the paper [11]), and (2) although the well-founded semantics is also used for the logic contexts, neither declarative nor procedural semantics for LBN has been formally developed.

6.2 Comparison with Bayesian Logic Programming

Building on Ngo and Haddawy’s work, Kersting and De Raedt [17] introduce the framework of Bayesian logic programs. A Bayesian logic program (BLP) is a triple \( <P, T_x, CR> \) where \( P \) is a well-defined logic program, \( T_x \) consists of CPTs associated with each clause in \( P \), and \( CR \) is a combination rule. A distinct feature of BLP over PKB is its separation of probabilistic information (\( T_x \)) from logic clauses (\( P \)). According to [17], we understand that a well-defined logic program is an acyclic positive logic program satisfying the range restriction. 9 For instance, a logic program containing clauses like \( r(X) \leftarrow r(X) \) (cyclic) or \( r(X) \leftarrow s(Y) \) (not range-restricted) is not well-defined. BLP relies on the least Herbrand model semantics and applies SLD-resolution to make backward-chaining inferences.

BLP has two important differences from BKB. First, it applies only to positive logic programs. Due to this, it cannot handle contexts with negated atoms. (In fact, no contexts are considered in BLP.) Second, it does not allow cyclic influences. BKB can be viewed as an extension of BLP with mechanisms for handling contexts and cyclic influences in terms of the well-founded semantics. Such an extension is clearly nontrivial.

---

9A logic program is said to be range-restricted if all variables appearing in the head of a clause appear in the body of the clause.
6.3 Comparison with the Time Parameter-Based Approach

The time parameter-based framework (TPF) proposed by Glesner and Koller [13] is also a triple $<P, T_x, CR>$, where $CR$ is a combination rule, $T_x$ is a set of CPTs that are represented as decision trees, and $P$ is a logic program with the property that each predicate contains a time parameter and that in each clause the time argument in the head is at least one time step later than the time arguments in the body. This framework is implemented in Prolog, i.e. clauses are represented as Prolog rules and goals are evaluated applying SLDNF-resolution. Glesner and Koller [13] state: “... In principle, this free variable $Y$ can be instantiated with every domain element. (This is the approach taken in our implementation.)” By this we understand that they consider typed logic programs with finite domains.

We observe the following major differences between TPF and BKB. First, TPF is a temporal model and its logic programs contain a time argument for every predicate. It always builds a DBN from a logic program even if there is no cyclic influence. In contrast, logic programs in BKB contain no time parameters. When there is no cyclic influence, BKB builds a regular Bayesian network from a logic program (in this case, BKB serves as a non-temporal model); when cyclic influences occur, it builds a stationary DBN, represented by a two-slice DBN (in this case, BKB serves as a special temporal model). Second, TPF uses time steps to describe direct influences (in the way that for any $A$ and $B$ such that $B$ has a direct influence on $A$, the time argument in $B$ is at least one time step earlier than that in $A$), while BKB uses time slices (implied by recursive loops of form (1)) to model cycles of direct influences (feedbacks). Time-steps based frameworks like TPF are suitable to model flexible DBNs, whereas time-slices based approaches like BKB apply to stationary DBNs. Third, most importantly TPF avoids recursive loops by introducing time parameters to enforce acyclicity of a logic program. A serious problem with this method is that it may lose and/or produce wrong answers to some queries. To explain this, let $P$ be a logic program and $P_t$ be $P$ with additional time arguments added to each predicate (as in TPF). If the transformation from $P$ to $P_t$ is correct, it must hold that for any query $p(.)$ over $P$, an appropriate time argument $N = 0, 1, 2, ...$ can be determined such that the query $p(., N)$ over $P_t$ has the same set of answers as $p(.)$ over $P$ when the time arguments in the answers are ignored. It turns out, however, that this condition does not hold in general cases. Note that finding an appropriate $N$ for a query $p(.)$ such that evaluating $p(., N)$ over $P_t$ (applying SLDNF-resolution) yields the same set of answers as evaluating $p(.)$ over $P$ corresponds to finding an appropriate depth-bound $M$ such that cutting all SLDNF-derivations for the query $p(.)$ at depth $M$ does not lose any answers to $p(.)$. The latter is the well-known loop problem in logic programming [2]. Since the loop problem is undecidable in general, there is no algorithm for automatically determining such a depth-bound $M$ (rep. a time argument $N$) for an arbitrary query $p(.)$ [2] 27 28. We further illustrate this claim using the following example.
Example 6.1 The following logic program defines a path relation; i.e. there is a path from X to Y if either there is an edge from X to Y or for some Z, there is a path from X to Z and an edge from Z to Y.

\[ P : 1. e(s, b1). \\
2. e(b1, b2). \\
...... \\
99. e(b98, b99). \\
100. e(b99, g). \\
101. path(X, Y) ← e(X, Y). \\
102. path(X, Y) ← path(X, Z), e(Z, Y). \]

To avoid recursive loops, TPF may transform P into the following program.

\[ P_t : 1. e(s, b1, 0). \\
2. e(b1, b2, 0). \\
...... \\
99. e(b98, b99, 0). \\
100. e(b99, g, 0). \\
101. e(X, Y, T1) ← T2 = T1 − 1, e(X, Y, T2). \\
102. path(X, Y, T1) ← T2 = T1 − 1, e(X, Y, T2). \\
103. path(X, Y, T1) ← T2 = T1 − 1, path(X, Z, T2), e(Z, Y, T2). \]

\( P_t \) looks more complicated than \( P \). In addition to having time arguments and time formulas, it has a new clause, the 101st clause, formulating that \( e(X, Y) \) being true at present implies it is true in the future.

Let us see how to check if there is a path from \( s \) to \( g \). In the original program \( P \), we simply pose a query \(? − path(s, g)\). In the transformed program \( P_t \), however, we have to determine a specific time parameter \( N \) and then pose a query \(? − path(s, g, N)\), such that evaluating \( path(s, g) \) over \( P \) yields the same answer as evaluating \( path(s, g, N) \) over \( P_t \). Interested readers can practice this query evaluation using different values for \( N \). The answer to \( path(s, g) \) over \( P \) is \( yes \). However, we would get an answer \( no \) to the query \( path(s, g, N) \) over \( P_t \) if we choose any \( N < 100 \).

7 Conclusions and Discussion

We have developed a novel theoretical framework for deriving a stationary DBN from a logic program with recursive loops. We observed that recursive loops in a logic program imply a time sequence and thus can be used to model a stationary DBN without using explicit time parameters. We introduced a Bayesian knowledge base with logic clauses of form (4). These logic clauses naturally integrate the direct influence information, the context and the
type constraints, and are evaluated under the well-founded semantics. We established a
declarative semantics for a Bayesian knowledge base and developed algorithms that build a
two-slice DBN from a Bayesian knowledge base.

We emphasize the following three points.

1. Recursive loops (cyclic influences) and recursion through negation are unavoidable in
modeling real-world domains, thus the well-founded semantics together with its top-
down inference procedures is well suitable for the PLP application.

2. Recursive loops define feedbacks, thus implying a time sequence. This allows us to
derive a two-slice DBN from a logic program containing no time parameters. We point
out, however, that the user is never required to provide any time parameters during
the process of constructing such a two-slice DBN. A Bayesian knowledge base defines
a unique space of random variables and a unique set of influence clauses, whether it
contains recursive loops or not. From the viewpoint of logic, these random variables
are ground atoms in the Herbrand base; their truth values are determined by the well-
founded model and will never change over time. Therefore, a Bayesian network is
built over these random variables, independently of any time factors (if any). Once a
two-slice DBN has been built, the time intervals over it would become clearly specified,
thus the user can present queries and evidences over the DBN using time parameters
at his/her convenience.

3. Enforcing acyclicity of a logic program by introducing time parameters is not an ef-
fective way to handle recursive loops. Firstly, such a method transforms the original
non-temporal logic program into a more complicated temporal program and builds a
dynamic Bayesian network from the transformed program even if there exist no cyclic
influences (in this case, there is no state variable and the original program defines
a regular Bayesian network). Secondly, it relies on time steps to define (individual)
direct influences, but recursive loops need time slices (intervals) to model cycles of
direct influences (feedbacks). Finally, to pose a query over the transformed program,
an appropriate time parameter must be specified. As illustrated in Example there
is no algorithm for automatically determining such a time parameter for an arbitrary
query.

Promising future work includes (1) developing algorithms for learning BKB clauses to-
gether with their CPTs from data and (2) applying BKB to model large real-world problems.
We intend to build a large Bayesian knowledge base for traditional Chinese medicine, where
we already have both a large volume of collected diagnostic rules and a massive repository
of diagnostic cases.

---

10However, from the viewpoint of Bayesian networks the probabilistic values of these random variables
(i.e. values from their probabilistic domains) may change over time.
