A theory of superconductivity is presented where the effect of anharmonicity, as entailed in the acoustic phonon damping, is explicitly considered in the pairing mechanism. The gap equation is solved including diffusive Akhiezer damping for longitudinal acoustic phonons, with a damping coefficient which can be directly related to the Grüneisen parameter and hence to the anharmonic coefficients in the interatomic potential. The results show that the increase of anharmonicity has a strikingly non-monotonic effect on the critical temperature $T_c$. The optimal damping coefficient yielding maximum $T_c$ is set by the velocity of the bosonic mediator. This theory may open up unprecedented opportunities for material design where $T_c$ may be tuned via the anharmonicity of the interatomic potential, and presents implications for the superconductivity in the recently discovered hydrides, where anharmonicity is very strong and for which the Akhiezer damping is especially relevant.

Introduction

Atomic vibrations in solids are inevitably affected by the shape of the interatomic potential. For all real materials, the shape of the interatomic potential is far from being quadratic, i.e. harmonic. The intrinsic anharmonicity of solids has many well known consequences such as thermal expansion, soft modes and instabilities, sound absorption, identification of stable crystalline phases etc. [1] A well established approach to anharmonicity is the self-consistent method introduced by Born and Hooton [2], leading to the concept of renormalization of phonon frequencies in the quasiharmonic or self-consistent phonon approximation, where the renormalized phonon frequencies arise from an effective vibrational dynamics within a region about equilibrium, which takes anharmonic terms of the potential into account via adjustable parameters obtained from a self-consistent solution to the many-body problem [3].

However, the effect of anharmonicity extends to far greater areas, including electron-phonon coupling, where traditionally the effect of anharmonicity has always been neglected, and where instead recent first-principle calculations demonstrate an important effect of anharmonicity on band-structure [4, 5].

In the context of superconductors, a fundamental understanding of the effect of anharmonicity on phonon-mediated superconductivity and e.g. on $T_c$ is absent due to the lack of analytical approaches to this problem. Yet, this is a fundamental issue in the context of high-T superconductors where anharmonicity becomes important due to the significant temperature values, since in general anharmonicity in solids grows roughly linear in $T$ [1]. Even more urgent is the problem of the effect of anharmonicity in hydrogen-based materials, which have recorded the highest $T_c$ values so far: in these systems the presence of a light element such as hydrogen induces a huge anharmonicity due to the large oscillation amplitudes of the hydrogen atoms [6–11].

Numerical studies and first-principle calculations can assess the effect of anharmonicity in an empirical way for a specific material by benchmarking against harmonic calculations, but a systematic fundamental understanding of the role of anharmonicity on conventional superconductivity is missing. This would be highly beneficial to obtain system-independent guidelines to not only estimate the effect of anharmonicity in general cases, but also to develop generic guidelines for material design. For example, by relating anharmonicity to the interatomic potential it could become possible to design materials with ad-hoc or tunable electron-phonon coupling and superconducting properties.

Here we take a first step in this direction by studying the effect of phonon anharmonicity on superconductivity beyond the quasi-harmonic approximation. We do this by explicitly taking into account the phonon damping due to anharmonicity in the mediator for the electron pairing. The theory shows that, unexpectedly, the effect of the anharmonicity (as represented by the damping coefficient) on $T_c$ is non-monotonic, i.e. $T_c$ first increases then goes through a maximum and then decreases.
upon increasing the anharmonic damping. This occurs because electron-phonon scattering processes involving energy-loss and energy-gain (Stokes and anti-Stokes) act constructively to increase the effective attraction driving the formation of Cooper pairs. The enhancement is most efficient for a window of critical damping parameter \(D_{\text{max}}\) set by the bosonic velocity and correlated with the Ioffe-Regel scale. Outside this window, the strength of pairing deteriorates leading a reduction in \(T_c\).

The theoretical framework – The displacement field of an anharmonic solid obeys the following dynamical equation [12]:

\[
\rho \frac{\partial^2 u_i}{\partial t^2} = C_{ijkl}^T \frac{\partial^2 u_k}{\partial x_j \partial x_l} - C_{ijkl}^T \alpha_{kl} \frac{\partial \Delta T}{\partial x_j} + \nu_{ijkl} \frac{\partial u_k}{\partial x_j} \frac{\partial x_l}{\partial x_i} \tag{1}
\]

which is coupled to Fourier’s law for heat transfer and to the energy balance equation for the thermal gradient \(\Delta T\). In Eq. (1), \(u_i\) denotes the \(i\)-th Cartesian component of the atomic displacement field, \(C_{ijkl}^T\) is the isothermal elastic constant tensor, \(\alpha_{kl}\) is the thermal expansion tensor, and \(\nu_{ijkl}\) is the viscosity tensor. The dot indicates derivative with respect to time of the elastic field \(u_i\) in the last dissipative term.

For solids, where acoustic excitations can be split into longitudinal (LA) and transverse (TA), Eq. (1) can be split into two decoupled equations for LA and TA displacements, leading to the following Green’s function in Fourier space [13]:

\[
G_{\lambda}(\omega, q) = \frac{1}{\omega^2 - \Omega^2_{\lambda}(q) + i \omega \Gamma_{\lambda}(q)} \tag{2}
\]

where \(\lambda = TA, LA\) is the branch label, and \(\Gamma_{\lambda}(q) = D q^2\) represents the damping, which coincides with the acoustic absorption coefficient [12], while \(\Omega_{\lambda}(q) = \nu_{\lambda} q\) is the acoustic eigenfrequency, already renormalized to account for the shift induced by anharmonicity [14], with \(\nu_{\lambda}\) the speed of sound for branch \(\lambda\).

The quadratic dependence \(\Gamma_{\lambda}(q) = D q^2\) of the damping stems directly from the viscous term in Eq. (1) and is typical of Akhiezer damping [12, 15]. In particular, it has been shown [15] that \(\Gamma\) takes the following general form for longitudinal excitations (see also [16]):

\[
\Gamma_L = \frac{q^2}{2 \rho} \left[ \frac{4}{3} \eta + \zeta \right] + \frac{\kappa T \alpha^2 \rho^2 v_L^2}{C_p} \left( 1 - \frac{4 v_L^2}{3 v_T^2} \right)^2 \tag{3}
\]

where \(\eta \equiv \nu_{xy} x y\) is the shear viscosity, \(\zeta\) is the bulk viscosity, \(\rho\) is the solid density, \(\kappa\) is the thermal conductivity, \(\alpha\) is the longitudinal thermal expansion coefficient, and \(C_p\) is the specific heat at constant pressure. The second term in Eq. (3), \(\sim \alpha^2\), represents the phonon damping due to heat exchange between the compressed and the rarefied regions of the longitudinal wave. This second contribution, in practice, represents only a few percent of the first viscous contribution in Eq. (3) and is therefore negligible.

The above derivation follows a hydrodynamic approach [17]; by comparing with the result of a microscopic approach based on the Boltzmann transport equation for phonons, it has been shown that [12]

\[
D_L = \frac{C_v T}{2 \rho} \left( \frac{4}{3} \langle \gamma_{zy} \rangle - \langle \gamma_{zy} \rangle^2 \right) \approx \frac{C_v T}{2 \rho} \langle \gamma_{zy} \rangle^2 \tag{4}
\]

where we neglected the contribution from bulk viscosity \(\zeta\), since normally \(\eta \gg \zeta\). Furthermore, \(\langle \ldots \rangle\) indicates averaging with respect to the Bose-Einstein distribution as a weight, while \(\gamma_{zy}\) is the \(xy\) component of the tensor of Grüneisen constants. Also, \(C_v\) is the specific heat at constant volume, while \(\tau\) is the phonon life-time. Since \(\tau \sim T^{-1}\) (which is an experimental observation for most solids [12, 18]), the diffusion constant \(D_L\) is independent of temperature, i.e., a well-known experimental fact [18].

A substantially equivalent expression for the damping of longitudinal phonons, in terms of an average Grüneisen constant of the material \(\gamma_{\text{av}}\), was derived by Boemmel and Dransfeld [18]

\[
D_L \approx \frac{C_v T}{2 \rho} \frac{\gamma_{av}^2}{2} \tag{5}
\]

and provides a good description of the Akhiezer damping measured experimentally in quartz at \(T > 60K\) [18].

In turn, the Grüneisen constant \(\gamma\), or at least the leading term [19] of \(\gamma_{av}\) or \(\gamma_{xy}\) above, can be directly related to the anharmonicity of the interatomic potential. For perfect crystals with pairwise nearest-neighbour interaction, the following relation holds [19]

\[
\gamma = -\frac{1}{\tilde{V}} \frac{1}{6} \sqrt{\frac{V''(a) a^2 + 2 V'(a) a - V'(a)}} \tag{6}
\]

where \(a\) is the equilibrium lattice spacing between nearest-neighbours, and \(V''(a)\) denotes the third derivative of the interatomic potential \(V(r)\) evaluated in \(r = a\). Hence, the phonon damping coefficient \(D_L\) can be directly related to the anharmonicity of the interatomic potential via the Grüneisen coefficient and Eq. (6).

Results – Because in crystals momentum is always conserved during electron-phonon scattering events, only longitudinal phonons contribute to pairing [20, 21], therefore we will focus on the LA phonon, \(\lambda = LA\), and we will drop the \(\lambda\) index in the following. According to Eq. (2) we thus choose a phonon propagator written in Matsubara frequency of the form

\[
\Pi(q, i\Omega_n) = \frac{1}{(\Omega^2 + \Omega_n D) q^2 + \Omega_n^2} \tag{7}
\]

with \(\Gamma(q) = D q^2\) and \(v\) is the phonon velocity. We define the Bosonic Matsubara frequency \(\Omega_n = 2 n \pi T\) where \(n\) is an integer number and \(T\) the temperature. The superconducting gap equation for a generic gap at momentum \(k\) and Fermionic Matsubara frequency \(\omega_n = (2n+1)\pi T\)
takes the form (see Ref. [22] for example)
\[
\Delta(i\omega_n, k) = \frac{g^2}{\beta V} \sum_{q, \omega_m} \frac{\Delta(i\omega_m, k + q)\Pi(q, i\omega_n - i\omega_m)}{\omega_m^2 + \xi_{k+q}^2 + \Delta(i\omega_m, k + q)^2},
\]
(8)
for a constant attractive interaction \(g\) and volume \(V\). Here \(\xi_k\) is the free electron dispersion which we choose to be quadratic with a chemical potential \(\mu\). The inverse temperature is denoted by \(\beta\) and we work in simplified units where twice the electron mass is set to unity. For analytical tractability, we also choose an isotropic gap function independent of frequency, i.e., \(\Delta(i\omega_m, k + q) \equiv \Delta\). Converting the momentum summation into energy integral with variable \(\xi\) and assuming a constant density of states, the gap equation reduces to
\[
1 = \sum_{\omega_m} \int_{-\mu}^{\infty} d\xi \left[ \frac{\lambda T d\xi}{(v^2 - D\omega_m)(\xi + \mu) + \omega_m^2} \right]^{\omega_m^2 + \xi^2 + \Delta^2}.
\]
(9)
where \(\lambda = N(0)g^2\) and \(N(0)\) is the density of states at the Fermi level. To begin the discussion, we confine ourselves to small \(D\) so that we can ignore \(D\mu \ll T \sim T_c\), even though the chemical potential is allowed to be large compared to \(T_c\). This implies that the linear term in \(\omega_m\) can be neglected. The remaining constant \(\mu v^2\) acts like a mass term and reduces \(T_c\) for all \(D\) [23]. As this effect is only quantitative, this term can also be ignored, as a first approximation, without affecting the central claims of the paper. The full effect of the chemical potential term will be included in the upcoming paragraphs. With these assumptions and using the energy integral identity
\[
\int_{-\infty}^{\infty} \frac{d\xi}{(\xi + s)(\xi + r)^2} = \frac{\pi}{r(s^2 + r^2)},
\]
we obtain
\[
1 = \sum_{\omega_m} \frac{\lambda \pi T_\omega_m^2}{\sqrt{\omega_m^2 + \Delta^2}(\omega_m^4 + (\omega_m^2 + \Delta^2)(v^2 - D\omega_m)^2)}.
\]
(10)
To determine the condition for \(T_c\), we set the superconducting gap \(\Delta = 0\). We can then perform the infinite sum over Matsubara frequencies [24] to obtain the simplified gap equation
\[
1 = -\frac{1}{\bar{v}^4} \left[ \psi \left( \frac{1}{2} \right) + \frac{i(i + D)}{4} \psi \left( 1 - \frac{\bar{v}^2}{2\pi T_\omega_m(i + D)} \right) \right. \\
+ \left. \frac{i(i + D)}{4} \psi \left( \frac{1}{2} + \frac{\bar{v}^2}{2\pi T_\omega_m(i + D)} \right) + c.c. \right],
\]
(11)
where, henceforth, the barred quantities are normalized by \(\sqrt{\lambda}\), i.e., \(\bar{v} = v/\sqrt{\lambda}\) and \(\psi(x)\) is the digamma function. A solution for \(T_c\) can be obtained from Eq. (11) and is plotted in Fig. 1 (Top) as a function of the anharmonic damping parameter \(D\). The plot shows that \(T_c\) enhanced quadratically for small \(D\), reaches a maximum at an optimal anharmonicity parameter \(D_{max}\) (set by the dimensionless phonon velocity \(\bar{v}\)), and falls off as a power law for larger \(D\). The optimal parameter \(D_{max}\) increases with \(\bar{v}\) as shown in Fig. 1 (Bottom). The Supplemental material [24] (see also Refs. [25–30] quoted therein), we discuss the behavior of \(D_{max}\) for larger values of \(\bar{v}\) where it saturates to a value \(D_{max} \sim v^2/T_c\) (not shown in Fig. 1). This condition for resonance can be obtained from the denominator in Eq. (10). Note that the enhancement of the transition temperature occurs only above a critical value of the phonon velocity that is set by the interaction parameter \(\sqrt{\lambda}\). The reason for the non-monotonic behavior of \(T_c\) can be understood from Eq.(10) and the anti-symmetry in \(\omega\) of the phonon damping term. Because of this property, Stokes and anti-Stokes processes \((\omega_m < \bar{v}, \bar{v} > 0\text{, respectively})\) add up constructively to increase the effective attraction driving the formation of Cooper pairs. This constructive interference grows with \(D\) which gets to the numerator upon adding the two processes. Eventually, however, for sufficiently large anharmonic damping \(D \gg v^2/\omega_m\), the quadratic term \(\sim D^2\omega_m^2\) in the denominator of Eq.(10) becomes the dominant contribution, the Stokes and anti-Stokes processes now add up in a destructive way and superconductivity gets suppressed. In the regime where \(\bar{v}\) is very small, the last term in the denominator of Eq.(10) can be approximated as \((v^2 - D\omega_m)^2 \sim D^2\omega_m^2\). The position of the maximum temperature as a function of the dimensionless longitudinal sound speed. In both plots we fixed \(\bar{\mu} = 0.1\).
where we have the definitions $a \equiv \frac{z}{D+1}$, $b_\pm \equiv \frac{\sqrt{2 + \frac{4v^2}{D^2}}}{2(D-1)}$ and $z \equiv \frac{v^2}{2D} + iD\frac{\bar{\mu}}{2\pi T_c}$. A plot of the numerical solution for $T_c$ versus $D$ is shown in Fig. 2 (Top). Many of the features appearing in Fig. 1 (Top) are reproduced when the chemical potential is introduced – a non-monotonic dependence on the anharmonicity parameter, a quadratic rise and power-law fall off for small and large $D$ respectively. This reaffirms the assumptions made on the chemical potential in deriving Eq. (11). However, the chemical potential has an additional non-trivial effect of reducing $T_c$ at small and large $D$, but enhances its peak value at optimal $D$. Furthermore, the $T_c$ peak position ($D_{\text{max}}$) changes substantially for small $\bar{\mu}$ and remains virtually unchanged for larger $\bar{\mu}$. A plot of $D_{\text{max}}$ as a function of $\bar{\mu}$ is shown in Fig. 2 (Bottom).

**Chemical potential effects** – In the following paragraphs, we relax the assumptions made previously on the chemical potential. We restrict ourselves to the BCS/quasi-BCS regime where the chemical potential is positive and not below the band bottom. This assumption ignores effects where the pairing scale becomes comparable to the band-width and hence keeping the BCS-BEC cross-over regime inaccessible. Following the same steps of the previous section, we obtain the simplified formula

$$1 = \sum_{\omega_m} \frac{\lambda \pi T_c (\omega_{mc}^2 + (v^2 - D \omega_{mc}) \mu)}{(\omega_{mc}^2 + (v^2 - D \omega_{mc}) \mu)^2 + \omega_{mc}^2} \frac{1}{|\omega_{mc}|^{-1}} \frac{1}{\omega_{mc}^2 + (v^2 - D \omega_{mc})^2}$$

(12)

where $\omega_{mc}$ is the fermionic Matsubara frequency at $T = T_c$. After algebraic manipulations of the Matsubara sum [24], the final equation for $T_c$ with a finite chemical potential reduces to

$$1 = \frac{1}{2v^2} \bar{\mu} \left[ -\psi \left( \frac{1}{2} \right) + \psi \left( \frac{1}{2} - \beta \right) \right] + \frac{a - b}{2(b_+ - b_-)} \psi \left( \frac{1}{2} - \beta \right) + c.c \right] + [D \leftrightarrow -D],$$

(13)

(see [31] and references therein); however, only a few theoretical works have examined directly the effects of damping on the superconducting properties, mostly in terms of glassiness [23, 32–34]. Ref. [33] finds an enhancement of superconducting transition driven by a spin-glass phase formed from paramagnetic spins interacting through Ruderman-Kittel-Kasuya-Yosida exchange couplings. On the other hand, Ref. [32] finds that a glassy phase leads to monotonically decreasing $T_c$ but does not take into account the role of anharmonic phonon damping explicitly. The dissipative aspect of the glass phase was considered at a phenomenological level in Ref. [23] in the context of the under-doped high-$T_c$ cuprates. While a similar non-monotonic behavior in $T_c$ is found, its mechanism does not arise from the time-reversal symmetry breaking in the dissipation term. This is reflected in the linear rise of $T_c$ for small viscosities as opposed to the quadratic rise as found in this work. Furthermore, as alluded to earlier, the parameter $D$ is a characteristic of anharmonic damping and originates from the viscosity
term in Eq. (1) describing anharmonic phonons. It can be directly related to the Grüneisen constant, which, in turn, can be determined via first-principle calculations of the inter-atomic potential through Eq. (6); therefore, this relation provides a microscopic handle for tuning $D$ giving rise to significant control in designing real materials.

To conclude, we have developed superconducting gap equations which account for the effect of anharmonicity in the Akhiezer damping of phonons. The phonon viscosity parameter $D$ can be related directly to the Grüneisen coefficient and to the shape of the interatomic potential. Upon solving the gap equation, it is found that the $T_c$ depends non-monotonically upon the anharmonic damping parameter $D$ and features a maximum as a function of $D$. The value of the critical damping parameter ($D_{\text{max}}$) around which Cooper pairing is the strongest is set by the velocity $v$ of the phonon. Within this optimal range of damping, Stokes and anti-Stokes electron-phonon scattering processes act constructively to increase the effective coupling constant. Outside this window, the strength of pairing deteriorates leading to a reduction in $T_c$. The prominence of the peak is enhanced when the Fermi energy is large compared to the electron-phonon coupling. Since the phonon damping corresponds to the phonon linewidth, which can be measured experimentally with inelastic neutron or X-ray scattering, or with ultrasonic techniques, these predictions may be further tested and investigated experimentally. Also, the presented framework may lead to new guidelines for material design to optimize $T_c$ in conventional superconductors, including high-$T_c$ hydrides.

Details on the computations – To obtain Eq. 9 from
the gap equation (Eq. 8; see Fig. 3 for the associated self-energy diagram) we make the assumption of an isotropic gap function independent of frequency, i.e., $\Delta(\omega_n, k + q) \equiv \Delta$. This allows us to cancel the order parameter in the numerator on both sides of Eq. 8 and eliminate the $\omega_n$ dependence to yield

$$1 = \frac{g^2}{\beta V} \sum_{q, \omega_n} \frac{1}{((v^2 - D\omega_m)q^2 + \omega_n^2)} \left( \omega_n^2 + \xi_q^2 + \Delta^2 \right).$$

(14)

We can now convert the $q$ momentum sum into an integral by replacing $\frac{1}{v} \sum_q \rightarrow \frac{1}{(2\pi)^2} \int d^q q \rightarrow \int N(\xi)d\xi$, where $N(\xi)$ is the density of states at energy $\xi$. For quadratic bands with chemical potential $\mu$, we have $\xi_q = q^2 - \mu$ written in units stated in the main text. We now further assume a featureless density of states and approximate $N(\xi) \simeq N(0)$ as in a BCS superconductor. This is exact in two dimensions and works well when the chemical potential is far away from the band bottom in three dimensions. Defining $\lambda = g^2 N(0)$, we finally obtain Eq. 9. To obtain Eq. 11 from Eq. 10, we can simplify the Matsubara sum by summing over only positive frequencies and writing the equation for $T_c$ as

$$1 = \frac{\lambda}{2(2\pi T_c)^2} \sum_{m=0}^{\infty} \left[ \frac{1}{x(x^2 + (v^2' + Dx)^2)} + \frac{1}{x(x^2 + (v^2' - Dx)^2)} \right].$$

(15)

where $x \equiv m + \frac{1}{2}$ and the primed quantities are dimensionless variables normalized by $2\pi T_c$ (i.e., $v^2' = v^2/2\pi T_c$). One can then use partial fractions to simplify the denominators and use the identity $\psi(z) = \lim_{k \rightarrow \infty} \left\{ -\sum_{m=0}^{k-1} \frac{1}{n+z} + \ln k \right\}$. The logarithmic terms cancel to yield Eq. 11. Similarly, one can obtain Eq. 13 from Eq. 12 by shifting the summation over positive frequencies and writing the equation for $T_c$ as

$$1 = \frac{\lambda \pi T_c}{(2\pi T_c)^3} \sum_{m=0}^{\infty} \left[ \frac{(x^2 + (v^2' - Dx)\mu') x^{-1}}{(x^2 + (v^2' - Dx)\mu')^2 + x^2(v^2' - Dx)^2} + \frac{(x^2 + (v^2' + Dx)\mu') x^{-1}}{(x^2 + (v^2' + Dx)\mu')^2 + x^2(v^2' + Dx)^2} \right].$$

(16)

The resonance condition – In this last paragraph, we provide more details about the resonance condition discussed in the main text. The idea is that at a specific frequency, sometimes referred to as the Ioffe-Regel frequency [25], the boson mediator for the phonons undergoes a crossover from a ballistic propagation to a diffusive incoherent motion. More precisely, this happens at:

$$\omega_{IR} \sim \frac{v^2}{\pi D}$$

(17)

This value is of fundamental importance in the realm of amorphous systems, because of its correlation with the boson peak frequency, where the vibrational density of states (VDOS), normalized by the Debye law $\sim \omega^2$, displays a maximum value [26–28]. The same boson peak phenomenology, however, is also at play in strongly anharmonic crystals [29, 30].

Physically, this means that the density of the boson mediators is maximal around the boson peak frequency. As a consequence, one would expect the effects of the mediators to be enhanced at such energy scale. By estimating that:

$$\omega_{IR} \sim T_c$$

(18)

we arrive at the following phenomenological resonance condition:

$$T_c \sim \frac{v^2}{\pi D_{max}}$$

(19)

which is quoted in the main text. Here $D_{max}$ is the value of the phonon viscosity at which $T_c$ is maximized.

In order to validate this expression, we plot the ratio $\pi DT_c/v^2$ in figure 4 for the same curves shown in the
main text in fig.1. We observe, that, especially for large values of the sound speed (compared to the phonon viscosity $D$), the resonance condition (19) holds to good accuracy. This observation provides a useful correlation between the energy scale of the boson peak (induced by anharmonicity) and the maximum critical temperature that can be reached.

Figure 4. A validation of the resonance condition (19) using the data of fig.1.
