Abstract

Objective: Compensatory mechanisms are responsible for the clinical signs of suppression of neurodegeneration. Intervention into their mechanisms on an example of the ratio of excitatory and depressor synaptic responses will contribute to the development of therapeutic strategies.

Methods: After 12-28 weeks (w) of experiment on the model of Alzheimer’s disease (AD), an activity of single neurons of hippocampus (H), Amygdala (Am) and, nucleus basalis of Meynert (NBM) to high frequency stimulation (HFS) of entorhinal cortex (EC) was recorded. The high frequency stimulation of H resulted in an activity of single neurons of the Am and NBM. By means of on-line selection and special mathematical analysis, tetanic potentiation (TP) and depression (TD) with further combination into posttetanic uni and multidirectional sequences, were revealed. In morpho- and histochemical study, the method of revelation of Ca2+ dependent phosphorylation was used.

Results: After 12 weeks of experiment on the model of AD, a heavy TD of NBM and Am neurons to HFS of H, as well as a weak (TD) in H and NBM neurons to HFS of EC were found. TP occurred by the activation of EC in the H (TP PT) and in Am (TP PDT) neurons, equal to and above the norm in neurons of Am to HFS of H. In the neurons of NBM to HFS of EC, the weakest excitation to HFS of H was detected. In the neurons H to HFS of EC, Am and NBM to HFS of H, after 12-28 weeks, TD and tetanic excitation in all cases were low, which indicating on depletion of compensatory opportunities. Morpho- and histo-chemical changes of H, Am and NBM neurons on the model of AD were characterized by total tendency to structural-metabolic dysfunctions, with distortion of forms, central chromatolysis, presence of light ectopic nucleus with increased nucleolus, change reaction of neurofibrills, lack of reaction processes, accumulation of hyper phosphorylated entities and, presence of spaces with the lack of cellular reaction.

Conclusion: The absence of expressed depression, presupposed by us as a protector in the present study, makes it necessary to involve pharmacological interventions with a view to its strengthening, and therefore is the subject of the next reports. Electrophysiological data have been confirmed morphologically.

Introduction

Accumulation of β-amyloid (Aβ) in the brain is a hallmark of Alzheimer’s disease (AD) and studies have demonstrated that it can induce synapse dysregulation, altered neuronal activity [1-5] and in early AD hallmark of the aberrant regulation in synaptic function including AMPA receptor (AMPAR) synaptic accumulation and synaptic plasticity [6,7]. Previous findings have demonstrated that synaptic plasticity, regarded as the cellular basis for learning and memory [8], is vulnerable to exposure to high levels of Aβ; hippocampal long-term potentiation (LTP) is impaired following exogenous exposure to soluble oligomeric Aβ [2,9,10]. To understand how memory function in AD becomes deregulated, a vast number of studies have looked to determine the mechanisms underlying the Aβ-mediated impairment of synaptic plasticity [11]. Synaptic plasticity is one of the most important properties of the mammalian brain as it underlies learning and memory processes. One of the main forms of synaptic plasticity found at the excitatory synapses is the long-term potentiation (LTP), which requires the activation of postsynaptic glutamate receptors (NMDA and AMPA) and is altered in neurodegenerative diseases [12]. Soluble Aβ potently and selectively disrupts synaptic plasticity causing inhibition of LTP and enhancement of long-term depression (LTD) of glutamatergic transmission in normal rodent hippocampus and future clinical trials of drugs acting through the glutamatergic and cholinergic systems [10,13]. In vivo injection of Aβ is reported to facilitate LTD and LTP reversal (depotentiation) in the CA1 region of the hippocampus [1]. Synapse vulnerability strongly correlates with cognitive decline before detectable neuronal death [14,15] and might contribute to the subsequent neuronal degeneration. The correlation between AD dementia and synaptic degeneration, investigated the ability of soluble Aβ-derived oligomers (ADHDs) to affect synapse composition, structure and abundance, attaching to presumed excitatory pyramidal neurons but not GABAergic neurons [16]. Moreover, in vitro studies performed in hippocampal neurons have reported that application of Aβ peptides, at concentrations below neurotoxic levels, can inhibit LTP induction without affecting basal synaptic transmission [17-19]. Although some downstream targets of Aβ have been identified [20-23], only a
limited number of studies has shown the ability of these molecules to fully restore function after significant synapse degeneration [21,22]. The identity of the signaling pathways that could restore synapse function remains poorly understood. On the other hand, as apoptotic death in CA3 and neurogenesis in dentate gyrus is modulated by glutamatergic neurotransmission resulting from NMDA receptor activation and Ca²⁺ levels fluctuations when interaction with corticosteroids [24]. Homeostatic synaptic plasticity (HSP) serves to restrain neuronal activity within a physiological range. The studies have provided great insight into Hebbian plasticity in AD, however the role of Aβ in HSP remains largely unknown [25]. A major function of HSP is to regulate neuronal activity in a negative feedback manner, thus maintaining neuronal activity or synaptic function [26,27] within a physiological range after changes in network activity [28-31]. Finally, increasing evidence suggests a link between a deficiency in Wnt signaling and AD. The findings demonstrate the remarkable capacity of adult neurons to regenerate functional circuits after substantial synapse loss and highlights that Wnt signaling is a targetable pathway in neurodegenerative diseases [32].

The aim of the study was the micro electrophysiological study the mechanisms of development of synaptic processes in neural structures not only the short-term H, but also the long-term (Rostral amygdalopiform area - Am and NBM) memory of the brain evoked by activation of the Entorhinal cortex (EC) and H in the form of synaptic potentiation and depression on amyloid model of AD induced by Aβ 25-35.

Materials and Methods

Experiments were performed on 26 male adult albino rats, weighing 200-250 g in 2 series of experiments: 1) on intact (n=10) and 2) on AD model (n=16), induced by bilateral intra cerebroventricular (i.c.v) injection of Aβ 25-35. The neuronal activity of H, Am and NBM to high frequency stimulation (HFS) (1 s) of EC, Am and NBM to HFS of H are studied. All experiments were performed according to the "rules of laboratory animal care" (NIH publication for no 85-23, revised 1985; experiments, the authors certify that they were carried out in accordance with the National Institute of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No. 80-23) revised 1996 or the UK Animals (Scientific Procedures) Act 1986 and associated guidelines, or the European Communities Council Directive of 24 November 1986 (86/609/EEC)). To create a model of AD bilaterally and i.c.v was injected toxic oligomer Aβ 25-35 according to the stereotaxic coordinates of the rat atlas [33] (AP-1, L ± 1.5, DV+3.5 mm) by 3mc of its 9-10 M fragments (1 mg/ml at 37°C), aggregated for 4 days) [34] and sustained up to 12-28 weeks till acute experiment. Surgeries under pentobarbital anesthesia (40 mg/kg, i.p.) are carried out. The operative field was treated with 0.1% bicillin (Renazhtne benzylpenicillin). In acute experiments animals were additionally immobilized by 1% dilitin (Suxamethonium iodide) (25 mg/kg, i.p) and transferred to artificial respiration. After craniotomy stereotactically oriented stimulating electrodes were implanted in the ipsilateral EC (AP-11, L ± 3.5, DV+4.0 mm) and H (AP-3.5, L ± 2.0, DV+4.0 mm) and glass recording microelectrode with tip diameter of 1 μm, filled with 2 M NaCl solution, were inserted in H (AP-3.5, L ± 2.0, DV+4.0 mm), Am (AP-3.25, L ± 5.4-5.8, DV+9.5-10.2 mm) and NBM (AP-1.8, L ± 3.0, DV+7.4 mm). In general was recorded the activity of 876 neurons from H (236), Am (382) and NBM (258). HFS (100 Hz for 1 s) of EC and CA1 of H was performed by rectangular current shocks of duration 0.05 ms, 0.10-0.16 and 0.16-0.18mA. We performed software analysis of the single spike activity of H (88), Am (89) and NBM (90) neurons in the norm and H (205), Am (293) and NBM (178) neurons on the model of AD. On-line recording is made on the basis of the program, which provides a selection of spikes by amplitude discrimination, followed by the "raster" of pre- and post-stimulus spiking from numerous neurons, as well as diagrams of the averaged spike frequency (developed by Kamenetski). After selection the pulse flow was subjected to programmed mathematical analysis. For selected and comparable groups of neuronal activity spiking were built summed and averaged (PETH Average) and frequency histograms (Frequency Average). To determine the statistical significance of differences in the duration of inter spike intervals before and after the stimulus was used nonparametric test the homogeneity of two independent samples - two-sample "Wilcoxon-Mann-Whitney" test. Since the number of recorded spikes were quite large (up to several hundreds of spikes per 20 s interval after the stimulus), was used a modification of this test, taking into account its asymptotic normality - z-test. Critical values comparing to tabulated values of a normal distribution with a significance level of 0.05, 0.01 and 0.001 (for different tests) are shows, that after the HFS for most samples of neuronal activity spiking there is a statistically significant alteration at least 0.05 level of significance.

Morphohistochemical studies were carried out by the method of detecting the activity of Ca²⁺-dependent acid phosphatase (AP) [35] on the basis of the Hamori method. The morphological approach is based on the identification of intracellular phosphorus-containing compounds having key positions in metabolic energy processes for preservation and self-reproduction of vital systems. The method is reproducible, adequate and selectively identifies AP, which is the most important Ca²⁺-dependent marker of neuron activity. And that is an important criterion of reliability of its use and in a comparative aspect, it is highly reproducible both on intact and on pathological material. In addition to the histochemical value, the method represents a definite morphological interest. The resulting picture is adequate, has a great informativeness and allows to judge about certain links in the metabolism of the structures under investigation and about morphohistochemical changes in the brain. On the light-colored background of the preparation, neural structures are clearly identified, constantly reproducible, that is an important criterion for the reliability of the method. The pieces of the brain were fixed in 5% neutral formalin prepared on 0.1 M phosphate buffer pH 7.4. For better stabilization of phosphorus and in order to prevent autolysis, fixation was performed at 4°C for 48 h. Frozen slices 60 μ thick were prepared from pieces of the brain, washed in distilled water and transferred to an incubation mixture for selective detection of nerve cells. 20 ml of a 0.38% solution of lead acetate, 5 ml of 1 M acetate buffer pH 5.6 and 5 ml of a 2% solution of sodium β-glycerophosphate. The incubation was carried out in a thermostat at 37°C for 1 to 2 h. Then, the washing of the sections in distilled water, the development in sodium sulfate solution and after repeated washing, the embedding in the balsam with the subsequent description of the preparations.

Results

Comparative analysis of the impulsive activity of single H, Am and NRM neurons in norm (n=322), on the model of AD after 12 (n=581) and 13-28 (n=197) weeks revealed the formation of excitatory and depressor responses in neurons of H, Am and NBM to HFS of EC, in neurons of Am and NBM to HFS of H as tetanization potential (TP) and depression (TD), followed by post-tetanic mixed unit (PT PD, TP PTP) and multidirectional (TP TP, TP PTP) manifestations of activity. On the basis of the average number of spikes (PETH), with conversion into inter spike intervals and frequency in Hz (Frequency Average) and compared with pre-stimulus level the depressor post-stimulus manifestations of neuronal activity to HFS of EC identified in the following ranges. A 12 weeks later after the injection of Aβ 25-35 tetanic depression in depressor sequences in H neurons to HFS of EC within a 3-fold underestimated of pre-stimulus activity, twice less than norm (6-fold) (Figure 1A); in the depressor-excitatory sequence about...
Figure 1: A-E- integrated averaged peristimulus (PETH Average) and frequency histograms (Frequency Average) of tetanic and post-tetanic depressor (TD PTD, depressor-excitatory (TD PTP), excitatory (TP PTP) and excitatory-depressor spike activity of neurons in the H (А, F), the Am (B, G) and NBM (C, H) to HFS of ЕС, in Am (D, I) and NBM (E, J) to HFS of H on AD model 12 weeks after the administration of Аβ 25-35, compared with the norm. The remaining marks are in the figure.
4-fold and also below the norm (Figure 1B). After 12 weeks TD in the TD PTD in Am neurons to HFS of EC were within 23-fold underestimated, while in the norm it reached only 4.25-fold, i.e., much higher and in TD PTP - 22 times also above norm (4.66-fold) (Figure 1C). In NBM neurons to HFS of EC after 12 weeks TD in the TD PTD determined by the order of 2.3-fold underestimation, respectively, which was much lower than norm (15-fold); TD in TD PTP - within 3-fold underestimated, respectively, is also much lower than the norm (Figure 1D). In Am neurons to HFS of H TD in TD PTD after 12 weeks reached 3.5-fold underestimation but above the norm (2-fold) (Figure 1E); TD in TD PTP after 12 weeks - 3-fold underestimation, also exceeding the norm (about 2-fold) (Figure 1F).

Finally, after 12 weeks on the model of AD in NBM neurons TD in TD PTP and PTP to HFS of H underestatement was within 4 and 2.5-fold underestimation, respectively, which turned out to be somewhat higher than norm (4- and 2-fold, respectively) (Figures 1G and 1H). Thus, in the corresponding posttetanic sequences tetanic depression in the model of AD 12 weeks later in H neurons to HFS of EC did not reach the norm, in Am neurons to HFS of EC significantly exceeded the norm, and in NBM neurons to HFS of EC also significantly, but did not reach the norm, and in NBM neurons to HFS of H was equal to it (Figure 1).

The excitatory post-stimulus tetanic reaction (Figure 2) changed as follows: TP in excitatory s sequences (TP PTP) in H neurons to HFS of EC later 12 weeks after β 25-35 injection reached exceeded of pre-stimulus level 8-fold, that turned out to be higher than normal (4.5-fold) (Figure 2A); TP in excitatory-depressor sequences (TP PTD) in this period of testing reached 2.5-fold exceeding, much below normal (10-fold) (Figure 2B). In Am neurons to HFS of EC after 12 weeks TP in TP PTP is calculated within the 10.25-fold higher and above the norm (7.83-fold); TP in TP PTD reached 14-fold elevation, much higher than the norm (2.25-fold); TP in TP PTP - 1.2-fold, far below the norm (13.0-fold) (Figure 2C). In NBM neurons, to HFS of EC reached only the 1.38-fold elevation and lower than the norm (2.25-fold); TP in TP PTD - 1.2-fold, which was below the norm (3.0-fold) (Figures 2E and 2F). In NBM neurons, to HFS of H TP in TP PTP after 12 weeks was within the 1.12-fold elevation, higher than normal (2.66-fold); TP in TP PTD in the same period is calculated within a 1.14-fold, which was below the norm (3-fold) (Figures 2E and 2F). In NBM neurons, to HFS of H TP in TP PTP after 12 weeks was within the 1.12-fold elevation, higher than normal (2.66-fold); TP in TP PTD in the same period had 1.5-fold excess and equal the norm (1.5-fold) (Figures 2G and 2H). In other words, in the H neurons to HFS of EC excitatory tetanic effects after 12 weeks in both sequences were higher and significantly below the norm, respectively. In Am neurons to HFS of EC after 12 weeks the situation was the reverse - with some excess and a much higher than norm. In NBM neurons, to HFS of EC after 12 weeks in excitatory sequence excess was below the norm, and in excitatory-depressor - much lower. In Am and NBM neurons to HFS of H generally changes were in insignificant ranges. In Am neurons to HFS of H TP in both sequences did not reach the norm.

Finally, in NBM neurons to HFS of H at 12 week, on the contrary, the excess did not reach the norm in the exciting sequence, and in excitatory-depressor - was in the normal range.

At the norm and model of AD at 12 weeks after administration of Aβ 25-35 constructed the histograms of spikes sum and diagrams of averaged spike frequency the pre- and post-stimulus displays of activity of structures studied in real time (20 seconds before and after stimulation) on the basis of raster of pre- and post-stimulus depressor and excitatory manifestations of spike activity, with details of the numerical values, including the time of HFS (Figures 2-5). This type of analysis give possibility to judge on relative intensity of pathology, compared with the norm of above-mentioned uni- and multidirectional post-stimulus tetanic and post-tetanic manifestations of activity of these structures in the frequency terms against the pre-stimulus level.

For a final conclusion, based on the corresponding calculations the degree of relative manifestation of the indices of decrease and increase of tetanic depression and excitation frequency in uni- and multi-directional post-stimulus depressor and excitatory manifestations in the mentioned period of testing in the pathology and for comparison with the norm were composed disk diagrams (Figures 6 and 7), in which they are presented graphically for all of the above mentioned cases.

According to mention diagrams, we may come to the following conclusion (Figure 6). On the model of AD of 12 weeks remoteness recorded the most powerful deepening of tetanic depression as an example of both sequences in Am neurons to HFS of EC and approaching to the norm in NBM neurons to HFS of H. Expressed but almost half do not reach the norm in Am neurons to HFS of H. There's even is less expressed in H neurons to HFS of EC. Considerably less pronounced in NBM neurons to HFS of EC diametrically opposite to neurons of Am evoked by HFS of EC. Tetanic excitation in these experimental conditions, compared with the norm, changes in the following proportions (Figure 7). Powerful tetanic excitation took place by activation of EC in neuron of H (excitatory sequence) and Am (in excitatory-depressor sequences), equal to and above the norm in the Am neurons. HFS of H on the contrary, in NM neurons to HFS of EC were detected weakest excitation and relatively weak - to HFS of H in both sequences.

Of interest the quantitative correlation, compare with norm, post-stimulus depressor and excitatory reactions. To 12 weeks trials on the model of AD depressor effects (including aggregate with post-tetanic excitatory) experienced the sharp increase in neurons of Am and NBM at HFS EC and in neurons Am at HFS H, but fell in neurons H at HFS EC (especially in depressor-excitatory sequences), as well as - NBM at HFS H, but in inverse proportion (more in excitatory sequences).

As regards post-stimulus excitatory reactions, then it in all studied structures predominantly was sharply increased, with the exception of NBM at HFS of H. In other words, depressor effects up to 12 weeks increased with protective function in excitatory – compensatory order. However with increase of the trial's time on the model of AD from 12 weeks to 28 weeks of both depressor and excitatory reactions sharply fell, that indicates about depletion of compensatory possibilities, what it was expected.

On rats in norm and when i.c.v. introduction of amyloid peptide Aβ 25-35 a comparative study of the morphohistochemical state of the H, amygdala complex (AM) and NBM was performed.

In intact rats on frontal sections of H a layered pattern of alternating white and gray matter is visible. Pyramidal cells of H differ in size, shape, branching nature of the processes. The largest neurons are distinguished in the dentate gyrus, they are scattered and characterized by high activity of AP (Figure 8A). The neurons of the fields CA1 and CA3 are arranged in rows, and very crowded, are distinguished by the intensity of staining and the very dense arrangement of the neurons (Figures 8B and 8C). In form they are polygonal, triangular and oval and they clearly stand out basal dendrites. Their apical dendrites are thickened and traced without branches at some distance from the body (Figures 8A and 8C).

In the AD model, the morphological pattern of neurodegenerative changes in H was characterized by the absence of continuity of the
Figure 2: A-J - from the top – the histograms of the spikes sum of pre- and post-stimulus activity displays in real time (20 seconds before and after stimulation) and spikes frequency diagrams of the H, Am, NBM single neurons in norm, evoked by HFS of EC (A-F) and H (G-J), respectively: depressor - TD PTD (A-E), in conjunction with the excitatory - TD PTP (F-J) manifestations of post-stimulus activation. In here and in the following figures: in the bottom - spikes frequency diagrams, presented in the histograms with mean values (M) for time intervals before stimulation (BE - before event), at the time of tetanization (TT - time tetanization) and after stimulation (PE - post event). Right of the charts - the number of trials (n). The rest of the symbols are in the figure.
Figure 3: A-J: The histograms of the spikes sum of pre- and post-stimulus activity displays in real time (20 s before and after stimulation) and spikes frequency diagrams of the H, Am, NBM single neurons in norm, evoked by HFS of EC (A-F) and H (G-J), respectively: excitatory - TP PTP (A-E), in conjunction with the depressor - TP PTD (F-J) manifestations of post-stimulus activation. The rest of the symbols are in the figure.

ranges (Figures 8D-8H), some regions of H were more intensely affected, while others remained intact. In the initial stage of cellular lesions, in the cytoplasm a gradual disappearance of the lead phosphate sediment is observed. There is a violation of the structural nature of neurons, complete lack of response of neurofibrils. Neurons lose their characteristic shape and are rounded, swollen, and in most of them stop reacting the processes (Figures 8D-8H), although some large pyramidal cells still have preserved thickened apical dendrites (Figures 8D and 8H). In the cytoplasm of swollen neurons devoid of processes, a gradual disappearance of the granular sediment is occurs. This process begins with the central part of the cell body (Figures 8D-8H) and resembles the picture of central chromatolysis observed in the Nissl method.

In some neurons, it is found in the form of a “rosette,” creating a picture of a split neuron (Figure 8E). At the end, it gives a picture of the cell shadow (Figure 8D) or completes disappearance (Figures 8G and 8H). The process recalls the “disappearance of cells”, described by Nissle in “Zellschwund”, and therefore Fünfgeld gave it the name “cell disease in the form of their disappearance” [36].

Expressed degenerative changes are noted in the field CA1. There is a complete absence of the reaction of the processes, violation of the shape and size of the neurons, very characteristic are circular “devastated” from the neurons sites (Figure 8G). In the intercellular space of the dentate gyrus and in the fields CA3 and CA1, glial cell nuclei are found (Figures 8D-8H). In the field CA3, the bodies of neurons are rounded and swollen. The morphological picture is characterized by uneven granularity in the cytoplasm of cells, a decrease in phosphatase activity of neurons in the fields CA1, CA3 H (Figures 8G and 8H), most of them are subjected to chromatolysis, although it is fair to note that the nuclei of neurons occupy a central location (Figure 8H). Large pyramidal cells of the dentate gyrus are more resistant to amyloid, but they also tend to clear the cytoplasm. In such swollen pyramidal cells, an ectopic, disproportionately large swollen nucleus is found, surrounded as a rim by a dark layer of sediment (Hamori-positive granulation) (Figure 8D). It seems that the nucleus searches for optimal conditions for survival and often it is so strongly pressed under the cell membrane that the cell reminds a ring (Figure 8E). In such cases, the nuclear membrane disappears. It is necessary to note one more form of lesion, morphologically similar to the senile plaque. These are quite large round formations, inside of which are visible non-structural clumps surrounded by a light vitreous mass, which, in turn, is surrounded by a crown surrounded by thickened fibers and nuclei of neuroglia. Such single formations were found in the dentate gyrus of H (Figure 8F). Analysis of morphohistochemical data in neurons of Am showed that they are diverse in form in intact rats. The shape of the cells is round, oval, polygonal, the passage of processes is well traced, small nuclei are visible, mainly with one nucleolus. Part of the cytoplasm is filled with granules of the deposit; the other part is colored homogeneously and looks lighter. The cell membrane is richly littered with granules, and in the processes they are arranged in one row. There are neurons with low activity of AP. In general, no uniform staining of neurons is observed in Am (Figures 9A-9C). Dark and light cells, according to most researchers, are different functional states of the same cell. By their structural organization, they have features similar to neurosecretory cells of H [37]. Results of morphohistochemical study of Am rats have shown that with the i.c.v. of amyloid peptide Aβ 25-35, neurons lose their characteristic shape and are rounded, swollen, hypertrophied and in most of them the processes cease to respond (Figures 9D-9F).

The nuclei of cells that are in the swelling stage are also swollen and take an eccentric position. In such neurons clearly appears enlarged dark-colored nucleolus (Figures 9E and 9F). Characteristic is the uneven distribution of the AP sediment. In the cytoplasm of swollen neurons devoid of processes, a gradual disappearance of the granular sediment starts beginning from the central part of the cell body. Cells with centrally located swollen light nuclei and annular sub-membrane arrangement of AP are detected; the cell membrane of such neurons

Figure 9: Microphotographs of Am neurons of intact rats (A-C) and 12 weeks after the bilateral i.c.v. injection of Aβ 25-35 (D-F) (central chromatolysis - violation of the shape and size of neurons, the black arrow - ectopia of nuclei with an enlarged dark nucleolus in the neurons, the arrowhead - submembrane arrangement of the AP, the triangle - cells of the “shadow”). Identification of the activity of Ca2+-dependent AP. Magnification: 40 (a); 100 (A); 400 (B, b), 1000 (C-F).
is clearly expressed, at the expense of bordering with the deposit granules (Figures 9D and 9E). In some places, there is a picture of cell shadow or its complete disappearance (Figures 9D and 9F). Among the cells subjected to chromatolysis, neurons with AP activation in the cytoplasm and nucleus with a preserved apical dendrite are also occasionally found (Figure 8D).

On the frontal slices of intact rats NBM, very fine colored nerve cells of a triangular and polygonal shape with outgrowths emerging from acute angles and branching are detected, which can be traced on a quite long distance from the body (Figures 10A-10D). In intact rats in all neurons of the brain, the nuclei occupy a central location and characteristic is the presence of reactive phenomena from the glial elements. A similar morphological picture is observed in the neurons of the NBM (Figures 10B and 10C). The results of the morpho-histochemical study of NBM in rats with i.c.v. injections of Aβ 25-35 revealed lesions of the nervous tissue, primarily affecting the soma and the processes of nerve cells. There is a rarefaction in the density of the location of nerve cells, the shape of the neurons is disturbed, they wrinkle and the processes are not detected (Figures 10E and 10F). The process of lesion begins with the fact that the cell decreases from the very beginning in size, its lateral and basal surfaces are somewhat fall. Nerve cells have the appearance of black, angular or rod-like formations. The processes become thinner and shorten. The apical and lateral dendrites coil or disappear. Clumps of tigers approach, merge into a compact, darkly colored mass, the nucleus stretches (Figure 10F).

Discussion

It is possible that a deficit in neurogenesis may contribute to AD pathogenesis since at least one of the two regions ostensibly neurogenic in the adult human brain (the subgranular zone of the dentate gyrus and the ventriculo-olfactory neurogenic system) support high-level functions affected in early AD (associative memory and olfaction respectively). The results suggest that modestly reduced GABA(A) receptor function in immature neurons of the developing and adult brain can serve as a common molecular substrate for deficits in adult neurogenesis and behavior indicative of anxious and depressive-like mood states [38]. Neurogenesis is regulated by several extrinsic factors, many of which also induce the expression of neurotrophins (NF). NF (BDNF, CDNF, GDNF, NGF) and their receptors, which appear to be critical for neuronal degeneration. Indeed, NF prevents cell death in degenerative processes and can enhance the growth and function of affected neurons in these disorders. Several biochemical and molecular mechanisms are involved in the AD and Parkinson's disease (PD) pathogenesis, such as synaptic dysfunction, NF impairment, energetic deficit triggered by mitochondrial disorder, OS and neuroinflammation [39-41]. In both illnesses, NF play an essential role for the survival of neurons affected by degenerative processes [42,43], NFs prevent the cell death and support the neuronal proliferation.

![Figure 10](image_url)
Therefore, the main findings related to the NF support in the survival, proliferation and maturation of affected neurons in AD and PD, such as cholinergic and dopaminergic neurons, as well as their putative employment as new therapeutic strategy for management of these diseases [44]. Although neurogenesis can be modulated exogenously by growth factors, stimulation of neurogenesis as a mean to treat neurodegeneration is still for the most part speculative [45]. The rest of the disease process, including formation of neurofibrillary tangles containing tau protein (Tp), is proposed to result from an imbalance between Aβ production and Aβ clearance [46]. Outcomes from numerous studies indicate a vital role of physiological Tp in the synaptic biology including induction of LTP, LTD and dendritic activity. Put together, unlike previously assumed, Tp may have a significantly larger role in imparting synaptic instability and cognitive deficits in AD and other tauopathies [47]. In conclusion, importance should be given to compensatory mechanisms. These include increased activity and hyper perfusion of the affected brain structures, the formation of antibodies to the β-amyloid, synthesis of neuroprotective proteins, activation of antioxidant defense systems and pro-ontogenesis that inhibit neuronal apoptosis, induction of neurogenesis, sprouting of the neuronal terminals, increasing “density” of receptors for neurotransmitters. Even the process of plaque formation may be of a compensatory function, because it reduces the level GABAergic control and decrease of GABA (A) receptors function can serve as a universal molecular substrate for the deficit of neurogenesis in adult brain.

In these experiments, conducted on intact and semichronic (amyloid model of AD) rats after 12 weeks, compared with the norm, activity recordings from single neurons of H, AM and NBM to HFS of EC and H by on-line selection and mathematical analysis revealed the formation of excitatory and depressor responses in the form of tetanic potentiation and depression (TD, TP) to be combined into uni- (TD PTD, TP PTP) and multi-directional (TD PTP, TP PTD) post-tetanic sequence.

The analysis of the noted post-tetanic manifestations of impulse activity of these structures that are calculated based on the average number of spikes (PETH) with conversion into interpulse intervals and frequency in Hz (Frequency Average) revealed the following. Of particular interest are early manifestations of compensatory opportunity of the studied brain structures involved in this pathology. Tetanic depression on the model of AD, 12 weeks after i.c.v. administration of Aβ 25-35 and to HFS of EC, did not reach the norm in neurons of H, significantly exceeded it in Am neurons and in neurons of NBM as well, but did not reach the norm (Figures 10A-10C). To HFS of H in neurons of Am tetanic depression exceeded the norm, but in NBM neurons turned out to be equal to it (Figures 10D and 10E). Excitatory tetanic effects to HFS of EC after 12 weeks in H neurons were higher and significantly below the norm in uni- and multi-directional sequences, respectively. In neurons of Am situation was reversed - with some excess, and much higher than the norm, and in NBM neurons excess was lower and much lower than the norm (Figures 10F-10H). To HFS of H in neurons of Am and NBM, in general, tetanic excitation changed insignificantly: in Am and not reached the norm in both sequences, and in neurons of NBM did not reach the norm in excitatory and in excitatory-depressor case was in the normal range (Figures 101 and 10f).

According to the relative intensity of tetanic and post-tetanic post-stimulus rater of the depressor and excitatory manifestations of spikes activity, with details of the numerical values, including the time of HFS, one can come to the following conclusions (Figures 2-5). By this type of analysis it can be judged on relative intensity of disease, compared with the norm of aforementioned uni- and multi-directional post-stimulus tetanic and post-tetanic activity manifestations and of these structures in terms of frequency, relative to pre-stimulus level. On the model of AD of the 12 weeks duration the most powerful deepening of tetanic depression observed in Am neurons to HFS of EC approaching the norm - in NBM neurons to HFS of H, and almost half do not reaching it - in Am neurons to HFS of H, still less pronounced - in H neurons to HFS EC and much less pronounced - in NBM neurons to HFS of EC (diametrically opposed to Am neurons to HFS of EC) (Figure 6). Tetanic excitation changed in the following ratios. Powerful tetanic excitation occurred on the activation of EC in H (in excitatory sequence) and Am neurons (in both sequences), equal to and above the norm to HFS of H (Figure 5). On the contrary, in the neurons of NBM to HFS of EC were detected weakest excitation and relatively weak - to HFS of H in both sequences (Figure 7). In some cases, the absence of strong depression, which we accept as a protector, in this study creates the need to involve pharmacological interventions for its gain that is subject to the following message.

In the present morpho-histochemical studies with Aβ-induced neurodegeneration, the characteristic morphological feature was the “gaps” characterized by the disappearance of the neuronal response in H, Am, and NBM. The picture of neurons, from the view of their structure, was a morphological proof of the disorders of their metabolism. The morphological picture resembled the acute swelling of nerve cells, which refers to a fairly common type of cellular pathology. The cause of this process can be various pathological effects of exo-and endogenous origin. Probably, as a result of the unfolding of metabolic phenomena of the pericarion, the process of respiration of cells is disrupted and the activity of a number of enzymes decreases. In the NBM, the morphological picture resembles the wrinkling of nerve cells, which refers to one of the types of cellular pathology observed in a variety of chronic diseases. However, an important criterion for assessing the degree of cell damage is the degree of damage to the nucleus. However, an important criterion for assessing the degree of cell damage is the degree of damage to the nucleus. The present data indicate that, mainly the nucleus of neurons trend to preserve vital activity by moving to the periphery of the cell, where apparently more favorable conditions are observed. Degenerative processes mainly affect the ectodermic elements of the central nervous system. Senile platelets are a special form of degeneration of the ectodermal tissue. At the beginning of the last century, Eikelenboom et al. [48] found that the key step in plate formation is the extracellular deposition of a foreign substance that provokes an inflammatory reaction accompanied by a regenerative response of the surrounding nerve fibers. Modern findings lead to the view that the amloid plate is the focus of a non-immune mediated chronic inflammatory response locally caused by the deposition of fibrillar Aβ [49].

Conclusion

Deepening of tetanic depressor responses apparently is a consequence of their advancement as a protective. According to our own data, depressor response more intensively involved of both in the non-specific (peripheral and central) and specific neurodegeneration [50-52]. It is supposed the advancement deepening the tetanic depression as assisting the recovery of the initial ratio of excitatory and depressor
responses. It is shown that depressor post-stimulus manifestations in the form TD and PTD mediate GABA or glycine monoamines. Us shows the protective purpose of GABA in studies of non-specific neurodegeneration, especially in the Deiters’ nucleus (following unilateral labyrinthectomy) [51], in the spinal cord after lateral hemisection [53-56] on peripheral nerve injury [57-61], on amyloid model of AD [50,62,63] and also on the rotenone model of PD [64,65]; in neurons mainly the GABAergic nature, in which early involving depressor reactions are accompanied by the recovery process until its completion. Confirmation the assumption of the universal protective assignment of GABA-ergic inhibition is the fact that in some systems during development of the nervous system GABA promotes proliferation, migration, differentiation and maturation of the synapse, expression of the GABAA receptor [66]. According to recent data, it suggested that GABA and glycine can play an important in the developing and mature central vestibular system [67]. In turn, in neurons of the vestibular nuclei by the GABA receptor mediated vestibular compensation after unilateral labyrinthectomy [67-70]. In this paper, where besides H for the first time are studied of Am and NM on the model of AD and also it is possible the involvement of true GABAergic inhibition during tetanic depression, with the aim of its deepening in the structures studied, thus supposed need of protectors for therapeutic intervention in the process of de and regeneration. In confirmation, the modern studies on the cellular and network levels show that synaptic inhibition cannot be assessed only as opposed to synaptic excitation and additionally serves highly specific functions in the nervous system of mammals [71]. Moreover, sustained deepening of depression in our above-mentioned works is the result of involvement as a protective categories Galarmin or PRP-1 (proine-rich peptide), the hypothalamic signaling in the adult hippocampus [68].
