As a crucial metabolic intermediate, L-lactate is involved in redox balance, energy balance, and acid–base balance in organisms. Moderate exercise training transiently elevates plasma L-lactate levels and ameliorates obesity-associated type 2 diabetes. However, whether moderate L-lactate administration improves obesity-associated insulin resistance remains unclear. In this study, we defined 800 mg/kg/day as the dose of moderate L-lactate administration. In mice fed with a high-fat diet (HFD), moderate L-lactate administration for 12 weeks was shown to alleviate weight gain, fat accumulation, and insulin resistance. Along with the phenotype alterations, white adipose tissue thermogenesis was also found to be elevated in HFD-fed mice. Meanwhile, moderate L-lactate administration suppressed the infiltration and proinflammatory M1 polarization of adipose tissue macrophages (ATMs) in HFD-fed mice. Furthermore, L-lactate treatment suppressed the lipopolysaccharide-induced M1 polarization of bone marrow–derived macrophages (BMDMs). L-lactate can bind to the surface receptor GPR132, which typically drives the downstream cAMP–PKA signaling. As a nutrient sensor, AMP-activated protein kinase (AMPK) critically controls macrophage inflammatory signaling and phenotype. Thus, utilizing inhibitors of the kinases PKA and AMPK as well as siRNA against GPR132, we demonstrated that GPR132–PKA–AMPKα1 signaling mediated the suppression caused by L-lactate treatment on BMDM M1 polarization. Finally, L-lactate addition remarkably resisted the impairment of lipopolysaccharide-treated BMDM conditional media on adipocyte insulin sensitivity. In summary, moderate L-lactate administration suppresses ATM proinflammatory M1 polarization through activation of the GPR132–PKA–AMPKα1 signaling pathway to improve insulin resistance in HFD-fed mice, suggesting a new therapeutic and interventional approach to obesity-associated type 2 diabetes.

Mammalian cells and tissues execute their metabolic tasks through exchanging energy metabolites from the circulatory system, in which glucose and L-lactate are the major caloric carriers (1, 2). L-lactate is the dominant isomeric form compared with D-lactate in mammals and is mainly derived from glucose via glycolysis. Circulating L-lactate travels among the organs, cells, and organelles as an oxidative and gluconeogenic substrate, which is defined as “lactate shuttle,” and plays a critical role in preserving redox balance, energy balance, and acid–base balance (2). In normal physiological conditions of humans and rodents, the plasma L-lactate concentration is at 0.5 to 2 mM (2, 3). When the circulating L-lactate level exceeds the basal range, it may negatively or positively affect the health of the organism. On the one hand, the local L-lactate level is up to 40 mM in the malignant tumor microenvironment because of aerobic glycolysis, and the plasma L-lactate concentrations also persist higher levels than those in normal physiological conditions (4, 5). In some tumors, such as non–small-cell lung carcinoma and cutaneous squamous cell carcinoma, the higher local L-lactate levels help tumor cells evade the surveillance of T cells and natural killer cells and hence accelerate the tumorigenesis (6). On the other hand, it is widely known that moderate exercise has beneficial effects on the metabolic health of the organism (7). The plasma L-lactate concentration is approximately increased to 4 mM during moderate exercise training and rapidly returns to normal physiological level in 1 to 3 h after exercise training (2, 8). The transient increment of L-lactate concentration protects muscle from injury by delivering a neural signal that produces pain to reduce exercise intensity, rather than causing muscle fatigue (9, 10). Recent studies by Takahashi et al. (11) further indicated that exercise-induced L-lactate could promote the secretion of adipokine transforming growth factor β2 (TGF-β2), which improved glucose homeostasis in the mice fed with a high-fat diet (HFD). Thus, the moderate elevation of plasma L-lactate concentration may positively affect the health of the organism. It deserves to explore whether exogenous moderate L-lactate administration could ameliorate diet-induced obesity and associated insulin resistance.

Obesity and associated insulin resistance are essentially because of persistent caloric absorption exceeding caloric expenditure. Therapeutic targeting of brown adipocyte–mediated thermogenesis to increase caloric expenditure has been regarded as a viable approach to combat obesity and associated insulin resistance (12). In addition, excess nutrition
**Moderate L-lactate administration reduces insulin resistance**

Absorption results in adipocyte hypertrophy and adipose tissue inflammation during the development of diet-induced obesity (13, 14). Meanwhile, the proportions of multiple immune cell populations are altered in adipose tissues, and adipose tissue macrophages (ATMs) are regarded as the primary contributors to adipose tissue inflammation and systemic insulin resistance (14, 15). Compared with those of lean individuals, obese adipose tissues have an increased proportion of total macrophages and a decreased ratio of the M2-like anti-inflammatory macrophages to the M1-like proinflammatory macrophages, which exacerbates local and systemic insulin resistance (15). Conversely, a series of endogenous molecules have been reported to modify the M1/M2 ratio of ATMs and reverse insulin resistance in obese individuals (11, 16–20). For instance, several cytokines, such as interleukin 4 (IL-4), IL-13, and TGF-β2 (11, 16), were shown to suppress ATM M1 polarization and improve adipose tissue inflammation. Some neurotransmitters, such as catecholamine and ceramide (17, 18), were suggested to restrict the proinflammatory polarization of ATMs and the synthesis of inflammatory cytokines. Recently, two energy metabolites, glutamine and succinate (19, 20), were found to participate in mitochondrial metabolism and boost the secretion of type 2 cytokines in ATMs. However, the functional correlation between L-lactate treatment and ATM polarization in the development of obesity-associated insulin resistance remains unclear.

Among multiple signals regulating energy metabolism homeostasis, AMP-activated protein kinase (AMPK) is a master sensor of glucose uptake, fatty acid oxidation, and mitochondrial biogenesis (21). In addition, AMPK is a critical molecule that suppresses macrophage inflammatory signals and transforms macrophages into an anti-inflammatory phenotype (22–24). As a catalytic subunit of AMPK, the activation of AMPKα1 inhibits several inflammatory transcription factors and ultimately reduces the secretion of proinflammatory cytokines, such as tumor necrosis factor alpha (TNF-α), monocye chemoattractant protein 1 (MCP-1), IL-1β, and interferon gamma (25, 26). Moreover, AMPKα1 could be activated by L-lactate, participating in mitochondrial uncoupling and lipid deposition in muscle cells and hepatocytes, respectively (27, 28). Therefore, whether L-lactate activates AMPKα1 and relevant signals to suppress macrophage proinflammatory polarization merits further investigation.

In this study, we first affirmed the appropriate dose of moderate L-lactate administration in HFD-fed mice. In the mice fed with either a low-fat diet (LFD) or an HFD, the effects of moderate L-lactate administration for 12 weeks on mouse body weight gain, fat accumulation, and glucose tolerance were examined. Subsequently, we detected the actions of moderate L-lactate administration on adipose tissue thermogenesis, total ATM populations, and ATM subpopulations in the mice. Furthermore, the molecular mechanism of L-lactate affects macrophage M1 polarization, which was explored in bone marrow–derived macrophages (BMDMs). Finally, we identified that L-lactate inhibited proinflammatory M1 polarization in BMDMs and improved associated glucose uptake in 3T3-L1 adipocytes through activating the BMDM AMPKα1 signal.

**Results**

**L-lactate administration reduced diet-induced weight gain in mice**

To affirm the dose of moderate L-lactate administration, HFD-fed mice were given with a gradient i.p. injection of L-lactate. L-lactate administration reduced the weight gain in the range of 400 mg/kg/day to 3200 mg/kg/day (Fig. 1A). When the dose was higher than 800 mg/kg/day, the mice sharply lost their weight instead of gaining weight (Fig. 1A). To avoid the acidosis induced by L-lactate overdose injection, we adopted 800 mg/kg/day as the dose of moderate L-lactate administration in the subsequent animal studies. At this dose, the plasma L-lactate concentration was elevated to 6 mM in 0.5 to 1 h after L-lactate injection and returned to the normal physiological level in 3 h (Fig. 1B). Therefore, 5 and 10 mM of L-lactate were used as the treatment concentrations in the subsequent cell studies.

**Moderate L-lactate administration ameliorated obesity-associated insulin resistance in mice**

The 6-week-old mice were fed on LFD or HFD. To evaluate the effects of moderate L-lactate administration on obesity and associated insulin resistance, the LFD-fed mice or HFD-fed mice were injected with L-lactate solution and named by LL group or HL group. As controls, the other LFD-fed mice or HFD-fed mice were injected with saline and named by LS group or HS group. After 12 weeks, the mice from HS group had higher body weight, fat mass, and serum lipid level than those from LS group (Fig. 1, C–F). Correspondingly, compared with LS group, HS group also had the increased adipocyte size of white adipose tissue (WAT), including epididymal adipose tissue (WAT), including epididymal adipose tissue (EAT) and subcutaneous adipose tissue (SAT) (Fig. 1G). Intriguingly, moderate L-lactate administration resisted these phenotype alterations in HFD-fed mice, although it did not affect body weight gain, fat mass, serum lipid level, and adipocyte size in LFD-fed mice (Fig. 1, C–G).

Obesity is often accompanied by numerous metabolic dysfunctions, especially insulin resistance (13). As expected, the mice from HS group had lower glucose tolerance and insulin tolerance than those from LS group. However, moderate L-lactate administration remarkably alleviated glucose and insulin intolerance in HFD-fed mice (Fig. 1, H and I). During the development of obesity, visceral adipose tissue has greater inflammatory changes than SAT and hence promotes local and systemic insulin resistance (13, 14). In adipocytes with normal insulin sensitivity, insulin stimulation can induce AKT phosphorylation and leads to glucose transporter type 4 (GLUT4) translocation to the plasma membrane and promotes glucose uptake (29, 30). And EAT is a common visceral adipose tissue in mouse studies (13). Thus, in EATs, we examined the mRNA levels of several classical proinflammatory cytokines, including MCP-1, TNF-α, IL-1β, and...

The GLUT4 translocation in EATs and quantification of plasma membrane GLUT4 to total GLUT4; immunoblots for phospho-AKT (Ser-473) and total AKT in EATs and quantification of phosphorylated AKT to total AKT. Data are presented as mean ± SD of eight mice per group, one-way ANOVA with Mann–Whitney test; *p < 0.05, **p < 0.01, and ***p < 0.001. EAT, epididymal adipose tissue; GLUT4, glucose transporter type 4; GTT, glucose tolerance test; HFD, high-fat diet; HS, HFD-saline (i.p.); HL, HFD-lactate (i.p.); ITT, insulin tolerance test; LFD, low-fat diet; LL, LFD-lactate (i.p.); LS, LFD-saline (i.p.); PM, plasma membrane.
interferon gamma, and detected the protein levels of phospho-AKT, AKT, and GLUT4. The mice from HS group have higher expressions of the cytokines (Fig. 1J) and lower levels of AKT phosphorylation and GLUT4 translocation (Fig. 1K) than those from LS group. Supporting the improvement of moderate L-lactate administration on mouse insulin resistance (Fig. 1, H and I), the alterations of cytokine level, AKT phosphorylation, and GLUT4 translocation were obviously restored in the mice from HL group (Fig. 1, J and K). Besides adipose tissues, the expression and activity of insulin signaling molecules were also detected in livers and muscles.

In either LFD-fed or HFD-fed mice, moderate L-lactate administration did not alter liver and muscle AKT phosphorylation and liver GLUT2 and muscle GLUT4 translocation (Fig. S1, A and B). Thus, moderate L-lactate administration ameliorated obesity-associated adipose tissue and systemic insulin resistance in HFD-fed mice.

High plasma L-lactate levels may decrease serum pH value and have a risk of hyperlactatemia or lactic acidosis (31). The hyperlactatemia or lactic acidosis would induce a series of adverse events, such as reduced appetite, hepatosplenomegaly, and hepatic injury (31). Therefore, serum pH value, food and energy intake, liver and spleen weight, liver and spleen morphology, and serum alanine aminotransferase and aspartate transaminase levels were examined in the mice. Of note, there were no differences in serum pH value, food intake, and energy intake among the experimental groups (Fig. S2, A–C). In LFD-fed mice, moderate L-lactate administration did not affect liver and spleen weight and their morphologies (Fig. S2, D–H). And even in HFD-fed mice, moderate L-lactate administration reversed HFD-induced liver lipid accumulation and serum alanine aminotransferase and aspartate transaminase elevations (Fig. S2, F–H). In conclusion, moderate L-lactate administration alleviates obesity-associated insulin resistance, but it does not lead to the development of hyperlactatemia or lactic acidosis.

**Moderate L-lactate administration reduces insulin resistance**

Contrastingly, moderate L-lactate administration promoted adipose tissue thermogenesis in HFD-fed mice

Persistent imbalance of energy intake and expenditure leads to abnormal body weight gain and metabolic dysfunction (32). Since the mouse energy intake in four groups was comparable (Fig. S2C), we evaluated energy expenditure among the groups. Despite there were no differences in O2 consumption and CO2 production between the mice from HS group and HL group when the metabolic data were normalized per animal (Fig. S3, A and B), HL group mice had a higher metabolic rate than HS group mice when the data were normalized to body weight (Fig. S3, C and D). To determine the short-term effects of moderate L-lactate administration on metabolic rate, we performed a moderate L-lactate injection at 9 AM and 18 PM and detected the metabolic fluctuation during a 24 h light–dark cycle. As expected, when the metabolic data were normalized to body weight, moderate L-lactate administration elevated metabolic rate in HFD-fed mice (Fig. S3, E and F). Interestingly, compared with LS group, the mice from LL group had an increased metabolic rate within 2 h after moderate L-lactate administration at 9 AM (Fig. S3, E and F).

And then, we measured the body temperature of four groups of mice. Moderate L-lactate administration turned back HFD-induced body temperature reduction in mice (Fig. 2A). In mammals, the maintenance of body temperature needs the involvement of adaptive thermogenesis (12, 32). As two distinct adaptive thermogenic adipocytes, brown and beige adipocytes express uncoupling protein 1 (UCP1) and transform chemical energy into heat energy by the action of UCP1 (12). Thus, we investigated the effect of moderate L-lactate administration on the expressions of some important thermogenic genes, including Ucp1, Pgc-1α, Cidea, and Prdm16. Relative to LFD, HFD significantly reduced Ucp1 expression in WAT, including EAT and SAT (Fig. 2, B and C). In addition, the mice from LS group had higher WAT Pgc-1α and Cidea levels than those from HS group (Fig. 2, B and C). Moderate L-lactate administration reversed the alterations of these thermogenic genes in EAT and SAT (Fig. 2, D and E). The relative mRNA level of Pgc-1α and Cidea in EAT and SAT was measured by qRT-PCR. The mRNA expression levels of Ucp1, Pgc-1α, and Cidea were determined by qRT-PCR. The results showed that moderate L-lactate administration significantly increased the expression of Ucp1, Pgc-1α, and Cidea in both EAT and SAT compared to the control group. Therefore, moderate L-lactate administration promoted adipose tissue thermogenesis in HFD-fed mice.
Moderate L-lactate administration remarkably elevated WAT thermogenic programs in HFD-fed mice (Fig. 2, B and C). However, in mouse brown adipose tissue, both HFD and L-lactate administration did not affect Ucp1 expression (Fig. 2D). Supporting the real-time PCR results, immunoblots revealed that moderate L-lactate administration reversed the depression of HFD on WAT UCP1 levels (Fig. 2E).

Furthermore, the expressions of genes involved in fatty acid oxidation (Cpt1a, Cpt1b, Cpt2, peroxisome proliferator–activated receptor alpha [PPARα], and Pgc-1α) and glucose catabolism (Pkm2 and G6pc) were also tested in the livers and skeletal muscles. After moderate L-lactate administration, there were no significant differences in these gene expressions in either LFD-fed or HFD-fed mice (Fig. S4, A and B). These observations suggest that moderate L-lactate administration promotes WAT thermogenesis. However, given that moderate L-lactate administration did not alter O2 consumption and CO2 production in HFD-fed mice when the metabolic data were normalized per animal (Fig. S3, A and B), whether the improvement of obesity-associated insulin resistance in the mice can be attributed to increased WAT thermogenesis remains in doubt. Therefore, other possible mechanisms affecting adipose tissue and systemic insulin resistance deserve careful investigation.

Moderate L-lactate administration suppressed obesity-induced ATM infiltration and proinflammatory M1 polarization in EATs

In addition to adipocytes, adipose tissue also contains abundant immune cells, in which macrophages have a crucial effect on regulating adipose tissue inflammation and glucose homeostasis in the development of obesity (14). Therefore, we further focused on the impacts of moderate L-lactate administration on ATM infiltration and polarization in EATs. Flow cytometry showed that HFD-fed mice have a higher proportion of total ATMs than LFD-fed mice (Fig. 3, A and B). Moreover, HFD also increased the percentage of CD11c-positive M1-like macrophages and decreased those of CD206-positive M2-like macrophages (Fig. 3, A and C), which resulted in an increment in the M1/M2 ratio of ATMs (Fig. 3D). Remarkably, in HFD-fed mice, moderate L-lactate administration blocked these changes in total populations and subpopulations of ATMs and reversed the M1/M2 ratio (Fig. 3, A–D). Consistent with the reversion of the M1/M2 ratio in HFD-fed mice, moderate L-lactate administration also modified the mRNA levels of several characteristic macrophage markers, including total macrophage marker F4/80, M1-like macrophage marker Nos2, and M2-like macrophage marker Arg1 (Fig. 3, E–G). Together, the results show that moderate L-lactate administration reduces ATM contents and suppresses proinflammatory M1 polarization in EATs in HFD-fed mice.

L-lactate treatment suppressed lipopolysaccharide-induced M1 polarization in BMDMs

During the development of diet-induced obesity, serum lipopolysaccharide (LPS) level increased gradually and is positively correlated to adipose tissue inflammation and insulin resistance (13). In addition, LPS treatment could induce M1 polarization in BMDMs (33), which simulated ATMs proinflammatory polarization in vivo. Here, LPS treatment upregulated the expressions of NOS2, TNF-α, MCP-1, and IL-1β (Fig. 4, A–D) and elevated the fluorescence intensities of M1 macrophage surface markers CD38 and CD274 (Fig. 4, E and F). However, 5 mM or 10 mM L-lactate significantly reversed the actions of LPS treatment (Fig. 4, A–F). These results indicated that L-lactate addition directly inhibited M1 polarization in BMDMs.

AMPKα1 mediated the inhibition of L-lactate on macrophage M1 polarization

To reveal the underlying mechanisms of L-lactate inhibiting macrophage M1 polarization, we sorted out macrophages from mouse EAT and detected the protein and phosphorylated levels of AMPKα1 in EATs and EAT macrophages. Compared with the mice from LS group, the mice from HS group have the decreased level of AMPKα1 phosphorylation in EATs (Fig. 5A). However, the decline in AMPKα1 phosphorylation was significantly reversed by moderate L-lactate administration in HFD-fed mice (Fig. 5A). And the similar reversion of AMPKα1 phosphorylation was also found in EAT macrophages from HFD-fed mice (Fig. 5B). The results implied that moderate L-lactate administration might inhibit ATM M1 polarization through activating AMPKα1 signaling.

To confirm the involvement, AMPK agonist, 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR), and inhibitor compound C were introduced in LPS-stimulated BMDMs. LPS treatment resulted in a decline in AMPKα1 phosphorylated level in BMDMs (Fig. 5C), along with the elevations of BMDM M1 polarization (Fig. 5, D and E) and inflammation (Fig. 5F). AICAR addition reversed the LPS-induced alterations, and compound C could abolish the efficiencies of AICAR (Fig. 5, C–F). In LPS-treated BMDMs, similar to AICAR, 10 mM L-lactate also elevated AMPKα1 phosphorylation (Fig. 5C), and compound C also abated its action on AMPKα1 phosphorylation and macrophage M1 polarization and inflammation (Fig. 5, D–F). Therefore, L-lactate addition suppressed proinflammatory M1 polarization in BMDMs through activating the AMPKα1 signal.

L-lactate suppressed proinflammatory M1 polarization in BMDMs through activating the GPR132–PKA–AMPKα1 signal

The previous report showed that L-lactate could bind to the GPR132 and promote M2 polarization of RAW264.7 macrophages and BMDMs (34). Another recent study also reported that L-lactate could facilitate M2 polarization of IL-4-treated BMDMs by monocarboxylic acid transporter 1 (MCT1) (35). To explore the involvement of GPR132 or MCT1 in macrophage AMPKα1 activation induced by L-lactate, we first detected their expressions in mouse macrophages. Relative to LFD, HFD downregulated GPR132 expression in EAT and EAT ATMs (Fig. 6, A and B). However, moderate L-lactate administration powerfully reversed the action of HFD on
GPR132 expression in EAT and EAT ATMs (Fig. 6, A and B). Unlike GPR132 expression, both HFD and moderate l-lactate administration elevated MCT1 expression in EAT and EAT ATMs (Fig. S5, A and B). Furthermore, GPR132 and MCT1 expression was examined in LPS-treated BMDMs. Similar to the action of HFD on ATM GPR132 expression, LPS treatment also downregulated BMDM GPR132 expression, and the downregulation was also abated by l-lactate addition (Fig. 6C). Interestingly, either LPS or l-lactate addition also elevated MCT1 expression in BMDMs (Fig. S5C). The results suggested that l-lactate may suppress EAT macrophage M1 polarization by GPR132, rather than by MCT1.

Next, the expression of GPR132 was detected in adipocytes and stromal vascular fraction (SVF) cells, which involve...
Immune cells and adipocyte progenitors in mouse EATs. Consistent with the high expression of GPR132 in macrophages reported in the previous study (34, 36), our result also showed that GPR132 was mainly expressed in EAT SVFs (Fig. S6A). Furthermore, SVFs were differentiated into mature adipocytes. L-lactate treatment did not affect the GPR132 expression in the mature adipocytes (Fig. S6B). However, in the noninduced control SVFs, 10 mM L-lactate treatment significantly elevated the GPR132 expression (Fig. S6C). Therefore, in EATs, macrophage GPR132, but not adipocyte GPR132, was mainly in response to L-lactate treatment.

It is known that the activation of GPR132 typically drives the downstream cAMP–PKA signal through Gs protein (37, 38), which promotes liver kinase B1 (LKB1) phosphorylation and subsequently activates the AMPK α1 signal in cancer cells and nerve cells (39, 40). Here, HFD also significantly reduced GPR132 expression and LKB1 phosphorylation in EATs, whereas moderate L-lactate administration reversed the inhibitory actions of HFD (Fig. 6D). To affirm the involvements of GPR132–PKA–AMPKα1 signaling in L-lactate–inhibited macrophage M1 polarization, GPR132 siRNA and PKA inhibitor H89 were introduced in LPS-stimulated BMDMs. LPS treatment reduced LKB1 and AMPKα1 phosphorylation in BMDMs, and L-lactate addition reversed the effects of LPS (Fig. 6, E and F). Remarkably, the GPR132 knockdown (Figs. S7 and 6E) and the PKA inhibition abated the reversion of L-lactate addition on LKB1 and AMPKα1 phosphorylation (Fig. 6, E and F). Consistently, the GPR132 knockdown and the PKA inhibition also reversed the repression of L-lactate on the expressions of proinflammatory genes and M1 markers in LPS-stimulated BMDMs (Fig. S8, A–F). Thus, L-lactate suppressed proinflammatory M1 polarization in BMDMs via the GPR132–PKA–AMPKα1 signal.

In addition, L-lactate could stimulate the secretion of TGF-β1 and TGF-β2 to induce macrophage M2 polarization (11, 41). Therefore, we investigated the expression of TGF-β1 and TGF-β2 in EATs. Relative to LFD, HFD elevated the mRNA and protein expression of TGF-β1 and reduced the protein level of TGF-β2 in EATs, but moderate L-lactate administration did not alter TGF-β1 and TGF-β2 expression in EATs from either LFD-fed or HFD-fed mice (Fig. S9, A–C).

L-lactate activated macrophage AMPKα1 signal to reduce associated adipocyte insulin resistance

As functional cells in adipose tissues, adipocytes regulate serum glucose levels through insulin signaling. The proinflammatory M1 macrophage would release various proinflammatory cytokines, such as MCP-1, TNF-α, and IL-1β, to accelerate adipose tissue inflammation and adipocyte insulin resistance (13, 14). Thus, we finally evaluated whether L-lactate improves adipocyte insulin sensitivity and glucose uptake through suppressing macrophage proinflammatory polarization. Relative to those from vehicle-treated BMDMs, the conditional media from LPS-treated BMDMs increased inflammatory gene expressions (Fig. 7, A and B) and reduced AKT phosphorylation and GLUT4 translocation (Fig. 7, C and D) in 3T3-L1 adipocytes. Dramatically, L-lactate addition reversed the effects of LPS-treated BMDM conditional media on adipocyte inflammation, insulin sensitivity, and glucose uptake.
uptake (Fig. 7, A–D), whereas compound C could abrogate the actions of L-lactate addition (Fig. 7, A–D).

Discussion

Lactate naturally has two optical isomers, including D-lactate and L-lactate, in which L-lactate is the dominant form in the metabolism of mammals (42). As an endogenous metabolic intermediate, L-lactate is largely produced during exercise training (2). Moderate exercise training is considered to be an effective nonpharmacological strategy for preventing and improving obesity-associated complications, particularly type 2 diabetes (43). During moderate exercise training, plasma L-lactate levels could transiently increase to about 4 mM and

return to physiological concentration in 1 to 3 h after exercise training (3, 8, 44). In this study, we adopt 800 mg/kg/day \( \text{L-lactate} \) to inject HFD-fed mice, and their plasma \( \text{L-lactate} \) concentration is elevated to 4 to 6 mM in 3 h after \( \text{L-lactate} \) injection. Thus, 800 mg/kg/day \( \text{L-lactate} \) injection is defined as a dose of moderate \( \text{L-lactate} \) administration, and 5 to 10 mM \( \text{L-lactate} \) is used as an appropriate concentration of cellular treatment. Moderate \( \text{L-lactate} \) administration obviously improves obesity-associated insulin resistance in HFD-fed mice. Meanwhile, in EATs, ATM contents and subpopulations are modified by moderate \( \text{L-lactate} \) administration. Further mechanistic studies reveal that \( \text{L-lactate} \) treatment activates macrophage GPR132–PKA–AMPKα1 signal to suppress proinflammatory M1 polarization, finally improving adipocyte glucose homeostasis (Fig. S10).

With regard to the effects of \( \text{L-lactate} \) on glucolipid metabolism in adipose tissues, the previous studies mainly focused on adipocytes (3, 11, 45). Carrière et al. (45) reported that \( \text{L-lactate} \) (5–50 mM) could promote adipocyte browning by activating PPARγ signaling. The injection of \( \text{L-lactate} \)
Moderate \(\ell\)-lactate administration reduces insulin resistance

Ahmed et al. (3) showed that \(\ell\)-lactate could activate GPR81 on the adipocyte membrane and elevate the lipid storage ability of adipocytes in mice. The single-time \(\ell\)-lactate injection (1250 mg/kg; i.p.) strongly enhanced insulin-induced antilipolytic effects in wildtype mice rather than GPR81-deficient mice (3). A recent study by Takahashi et al. (11) indicated that adipokine TGF-\(\beta\)2 promoted adipocyte glucose uptake and attenuated adipose tissue inflammation in HFD-fed mice. \(\ell\)-lactate treatment (10–40 mM) increased the expression of TGF-\(\beta\)2 in 3T3-L1 adipocytes, and the single-time injection of \(\ell\)-lactate (504 mg/kg; i.p.) elevated adipokine TGF-\(\beta\)2 secretion in mice (11). However, it is still unclear whether long-term moderate \(\ell\)-lactate injection could improve obesity-associated metabolic dysfunction in HFD-fed mice. Here, we adopted moderate \(\ell\)-lactate administration, a comparable dose to Ahmed et al. (3) and Takahashi et al. (11), to inject the mice for 12 weeks and found that long-term moderate \(\ell\)-lactate administration alleviated obesity-associated insulin resistance in HFD-fed mice (Fig. 1).

Noteworthily, a previous study by Choi et al. (46) showed that one-time tail vein infusion of \(\ell\)-lactate would impair insulin signal and induce insulin resistance in skeletal muscle. The inconsistent observations with our results should be due to different experimental aims and designs. Our study aimed to

Figure 7. \(\ell\)-lactate activated macrophage AMPK\(\alpha\)1 signal to reduce associated adipocyte insulin resistance. BMDMs were treated with vehicle, \(\ell\)-lactate, or AICAR, and then LPS was added. Compound C was used as an AMPK inhibitor. BMDMs conditional media were collected after 24 h of incubation in the fresh media. A and B, the mRNA levels of TNF-\(\alpha\) (A) and MCP1 (B) in 3T3-L1 adipocytes. C, immunoblots for phosphorylated AKT (Ser473) and total AKT in 3T3-L1 adipocytes. D, immunoblots for plasma membrane GLUT4 and total GLUT4 in 3T3-L1 adipocytes. Data are presented as means ± SD of six parallel samples per group, two-tailed Student’s \(t\) test; * \(p < 0.05\), ** \(p < 0.01\), and *** \(p < 0.001\). AICAR, 5-aminoimidazole-4-carboxamide-1-\(\beta\)-D-ribofuranoside; AMPK\(\alpha\)1, AMP-activated protein kinase alpha 1; BMDM, bone marrow-derived macrophage; CC, compound C; CM, conditional media; Con, control; GLUT4, glucose transporter type 4; Lac, \(\ell\)-lactate; LPS, lipopolysaccharide; MCP1, monocyte chemoattractant protein 1; PM, plasma membrane; TNF-\(\alpha\), tumor necrosis factor alpha.
explore the effect of long-term moderate l-lactate administration on obesity-associated insulin resistance in HFD-fed mice, while the previous study tried to assess the action of one-time l-lactate infusion on skeletal muscle insulin resistance in the rat under normal physiological conditions. The different experimental objectives lead to different experimental designs and results. First, the previous study employed the one-time tail vein infusion of l-lactate, which increased plasma l-lactate concentration to a fourfold level in 3.5 h. However, in our study, the mice were received a daily i.p. injection of l-lactate for 12 weeks, which repeatedly elevated the plasma l-lactate concentration to a twofold level in 0.5 to 1 h after l-lactate injection and then decreased to the basic level in 3 h (Fig. 1B). Second, in the previous study, insulin was preinfused for 2.5 h to activate insulin signal and then infused l-lactate and insulin for 3.5 h to assess the action of l-lactate infusion on insulin signal. In our study, the tested mice were only injected with l-lactate or saline. Third, in the previous study, the tested rats were fed with a chow diet before l-lactate infusion was performed. Yet, in our study, the tested HFD-fed mice got free access to water and food. It seems that the action of l-lactate on individual insulin sensitivity is elusive. Thus, its negative or positive effects on insulin sensitivity may greatly depend on the experimental animal kind and strain, the diet type, the animal physiological status, and the dose and duration of l-lactate treatment.

Besides adipocytes, adipose tissue also contains various SVF cells, such as adipose-derived stem/stromal cells, endothelial cells, and immune cells (32). Along with the development of obesity, the numbers and subpopulation ratios of multiple innate and adaptive immune cells dynamically altered in adipose tissues (47). In the immune cells, the proportions of macrophages, mast cells, neutrophils, dendritic cells, and CD8$^+$ T cells are increased, whereas the proportions of eosinophils, Treg cells, and Th2 cells are decreased, leading to adipose tissue inflammation (13, 47). Remarkably, macrophages account for the largest proportion of these immune cells and comprise up to 40% of SVF cells in obese adipose tissue (47, 48). Meanwhile, the polarization of ATMs correlates positively with the changes in adipose tissue inflammatory status. In obese adipose tissue, the recruited ATMs polarize to F4/80$^{+}$CD11c$^{+}$ proinflammatory M1 type but not F4/80$^{+}$CD206$^{+}$ anti-inflammatory M2 type (14). As the major source of adipose tissue proinflammatory cytokines, M1 ATMs secrete various chemokines and cytokines, which attract more ATM and other proinflammatory immune cell recruitment, exacerbate adipose tissue inflammation, and induce local and systemic insulin resistance (47, 48). Deletion of macrophage-specific gene CCR2 would impair ATM infiltration and proinflammatory cytokine secretion, improving adipose tissue inflammation and insulin resistance (13). In addition, the regulation of other immune cells on adipose tissue inflammation mostly needs the involvement of macrophages. For instance, eosinophil-derived IL-4 and IL-13 drive ATM M2 polarization to suppress adipose tissue inflammation (16, 48). And CD8$^+$ T cells promote ATM recruitment and M1 polarization to aggravate adipose tissue inflammation (48, 49).

Thus, ATMs play a central role in regulating obesity-associated adipose tissue inflammation and insulin resistance. Here, our study focused on ATMs and their subpopulations and found that moderate l-lactate treatment suppressed ATM infiltration and M1 polarization (Figs. 3 and 4).

In obese individuals, the activation of AMPK$\alpha$1 inhibits several classic inflammatory signals in ATMs, such as NF-kB and F06BB signal and NOD-, LRR-, and pyrin domain–containing protein 3 inflammasome signal (24–26). The secretion of multiple inflammatory cytokines from ATMs, such as MCP1, TNF-$\alpha$, and IL-1$\beta$, was also inhibited after AMPK$\alpha$1 phosphorylation (14, 50, 51). Along with the declines in inflammatory signals and cytokines, AMPK$\alpha$1 activation reduced the expressions of M1 markers, such as CD11c and NOS2, and suppressed proinflammatory polarization in ATMs (23, 24). Therefore, the AMPK$\alpha$1 signal plays a critical role in ATM polarization and associated insulin resistance during diet-induced obesity. Here, our study focused on the AMPK$\alpha$1 signal and found that l-lactate treatment activated the AMPK$\alpha$1 signal to suppress macrophage M1 polarization (Fig. 5), which improved associated adipocyte insulin resistance (Fig. 7).

In macrophages, l-lactate could be transported into the cell by MCTs as an energy substrate or bonded to surface receptor GPR132 as a signal molecule. Previous reports about muscle regeneration and cancer indicate that l-lactate could affect macrophage polarization by cell surface receptor MCT1 and GPR132. On the one hand, l-lactate facilitates M2 polarization in IL-4-treated BMDMs by binding to MCT1 and regulating muscle regeneration (35). On the other hand, cancer cell–derived l-lactate could activate GPR132, which is highly expressed in macrophages, and result in the M0 to M2 phenotype transformation in BMDMs or RAW264.7 macrophages (34). However, it is unclear whether MCT1 or GPR132 mediated the suppression of l-lactate on ATM M1 polarization. In the context of obesity-associated inflammation, our observations suggested that l-lactate might preferentially suppress M1 polarization in macrophages through GPR132, rather than MCT1 (Figs. 6 and S5). The activation of G protein–coupled receptors would trigger the downstream cAMP–PKA signal and subsequently activate LKB1 and AMPK$\alpha$1 (39, 40, 52). Correspondingly, our study also found that the activation of GPR132 would increase the PKA–LKB1–AMPK$\alpha$1 signal and suppress macrophage M1 polarization (Figs. 6 and S8). In addition, since the expression of MCT1 in ATMs and the proportion of M2 macrophage was increased in response to moderate l-lactate administration in HFD-fed mice (Figs. 3 and S5), l-lactate may also promote ATM M2 polarization via MCT1, a hypothesis merits further investigation.

Metabolic disorders are often accompanied by a persistent elevation in l-lactate levels. In obese individuals, blood l-lactate level is slightly increased along with the development of obesity and insulin resistance (53). However, moderate exercise training, accompanied by the transient increment of blood l-lactate concentration, can improve the common metabolic disorders (2, 7). Thus, it is of practical significance.
Moderate l-lactate administration reduces insulin resistance

to elucidate the paradoxical correlation between the elevation of l-lactate level and the metabolic health of organisms. In this study, moderate l-lactate administration leads to the transient increment of blood l-lactate level, similar to moderate exercise training, and recapitulates the improvements of moderate exercise training on obesity-associated insulin resistance. Although we did not well explain the aforementioned paradoxical correlation in this study, our results reveal that moderate l-lactate administration suppresses ATM M1 polarization to ameliorate insulin resistance in HFD-fed mice, suggesting a potential therapeutic and interventional approach to obesity-associated type 2 diabetes.

Experimental procedures

Animals

All male C57BL/6 mice were purchased from Vital River Laboratory Animal Technology Co Ltd at their 4 weeks old. The mice were fed on an LFD (Research Diets; D12450B containing 3.85 kcal/g and 10% fat) and maintained in a pathogen-free barrier facility with a 12 h light/12 h dark cycle. After 2 weeks of dietary and environmental adaptation, the mice were used in the following experiments. All animal experimental procedures were approved by the Ethics Committee on Animals of the Hefei University of Technology and were conducted under the guidance of international ethical standards.

Experimental design and l-lactate administration

To obtain the dose of moderate l-lactate administration, we first designed the experiment of gradient sodium l-lactate (Sigma–Aldrich) injection. At 6 weeks old, the mice were fed on an HFD (Research Diets; D12451 containing 4.73 kcal/g and 45% fat) and received l-lactate injection (i.p.) at the dose of 200, 400, 800, and 1600 mg/kg/time (twice per day), respectively. After 7 days, we weighed the mice and calculated their weight changes. The blood was collected from mouse tails, and the real-time concentrations of plasma l-lactate were detected using l-lactate assay kit (Sigma–Aldrich).

When the dose of moderate l-lactate administration was affirmed at 800 mg/kg/day, another independent study was designed to assess the effect of moderate l-lactate administration on diet-induced obesity and insulin resistance in mice. At 6 weeks old, the mice were randomly divided into four groups: (1) LS group (n = 8), fed on LFD and received saline injection (twice per day; i.p.); (2) LL group (n = 8), fed on LFD and received l-lactate injection (400 mg/kg/time; twice per day; i.p.); (3) HS group (n = 8), fed on HFD and received saline injection (twice per day; i.p.); and (4) HL group (n = 8), fed on HFD and received l-lactate injection (400 mg/kg/time; twice per day; i.p.). And then, the mouse weight and food intake were monitored each week. After 12 weeks, mouse lean and fat masses were first determined using body composition analyzer (Bruker). Glucose tolerance tests, insulin tolerance tests, and body temperature detection were conducted as the previous description (29, 54). Subsequently, mice were fed in the combined indirect calorimetry system (TSE Systems GmbH) for 2 days. VO2 (oxygen consumption), VCO2 (CO2 production), and respiratory exchange ratio were monitored in the next 24 h. Finally, the mice were sacrificed by exposure to CO2. Their sera and tissues were harvested and stored at ~80 °C. The serum pH value was detected by the blood-gas analyzer (Beckman Coulter). And the serum lipid level was detected by the biochemical analyzer (Beckman Coulter).

H&E staining

Tissues were fixed, dehydrated, embedded, and sliced at a thickness of 5 μm. The sections were subsequently deparaffinized, rehydrated, and stained with hematoxylin and eosin. Five random fields from each section were photographed, and adipocyte average diameters were measured by Image-Pro Plus, version 6.0 (Media Cybernetics).

Total RNA isolation and quantitative real-time PCR

Total RNA was isolated from the tissues or cells using RNAiso Plus reagent (Takara) and was reverse transcribed to complementary DNA by reverse transcription kit (Takara) according to the manufacturer’s protocol. Quantitative real-time PCR was conducted with SYBR Premix Ex Taq II (Takara) on a real-time fluorescent quantitative PCR analyzer (Bio-Rad). All primer sequences are presented in Table S1.

Protein extraction and Western blot analysis

The tissues and cells were lysed in radioimmunoprecipitation assay lysis buffer with PMSF (Sangon) and phosphatase inhibitor complex (Sangon). The protein concentration was detected with the bicinchoninic acid assay kit (Sangon). Moreover, the membrane protein extraction kit (Sangon) was used to obtain plasma membrane protein. All protein samples were loaded on SDS-polyacrylamide gel electrophoresis and were tested by immunoblot as described previously (29). Immunoblot data were quantified by Image Quant TL 7.0 software (GE Healthcare) and were expressed as the ratio of the target protein to the corresponding reference protein. In mouse studies, eight samples per animal group were tested and quantified. In cell studies, four or six samples per cellular group were tested and quantified. Antibodies are exhibited in Table S2.

Flow cytometry and cell sorting of ATMs

SVFs were isolated from EATs as described (55). And then, the SVFs were stained with the antibody cocktail containing F4/80-APC, CD11c-PE, and CD206-FITC (Table S2). The M1 and M2 macrophages were identified, and the total macrophages were sorted by flow cytometer MoFlo XDP (Beckman Coulter). Data were analyzed using Summit 5.2 (Beckman Coulter). Flow cytometry antibodies are listed in Table S2.

BMDM culture and treatment

Bone marrows were isolated from the femurs of C57BL/6 mice. The cells were cultured in Dulbecco’s modified Eagle’s medium (DMEM; Gibco) containing 20% fetal bovine serum.
(Gibco) and 30% L929 conditional medium for 7 days to differentiate into BMDMs as the previous description (56). To examine the action of l-lactate treatment on macrophage polarization in vitro, BMDMs were treated with l-lactate (5 mM or 10 mM) for 24 h. And then, LPS (Sigma–Aldrich; 100 ng/ml) was used to promote M1 polarization of BMDMs as previously reported (29, 33).

To explore the involvement of the PKA–AMPK/α1 signal, BMDMs were first treated with AMPK inhibitor compound C (Sigma–Aldrich; 1 μM) or PKA inhibitor H89 (Sigma–Aldrich; 30 μM) for 1 h. Subsequently, AMPK agonist AICAR (Sigma–Aldrich; 0.5 mM) or l-lactate (10 mM) was added. After 24 h, BMDMs were stimulated by LPS (100 ng/ml) and finally harvested as previously reported (29, 33).

**BMDM siRNA transfection**

The siRNAs against GPR132 and the scrambled siRNA as control were purchased from Sangon Biotech. The siRNA sequences against GPR132 were 5′-CCACAGAGCUUUCAAA CACAU TTdTdT-3′ (sense) and 5′-AUGUGUUUGAAA GCUCUGUGGT TTdT TdT-3′ (antisense). The negative control siRNA sequences were 5′-UUCUCCGAACGUGACGU TTdT TdT-3′ (sense) and 5′-ACUGACACGUGUCGGAGA TTdT TdT-3′ (antisense). The siRNAs were transfected into BMDMs using Lipofectamine 3000 (Invitrogen) following the manufacturer’s protocol. After 12 h, 10 mM l-lactate was added to treat BMDMs for 24 h. Then, BMDMs were stimulated by LPS (100 ng/ml) and finally harvested as previously reported (29, 33).

**BMDM conditioned media collection and 3T3-L1 adipocyte treatment**

According to the method of Ceppo et al. (57), we prepared a series of BMDM conditioned media. Briefly, BMDMs were treated with vehicle, l-lactate (10 mM), and AICAR (0.5 mM), respectively. And then, the cells were stimulated with LPS (100 ng/ml) for 3 h and incubated in the fresh media for 24 h. Finally, the BMDM conditioned media were collected.

3T3-L1 preadipocytes were purchased from the Cell Culture Center of Peking Union Medical College. The cells were cultured in DMEM (Gibco) containing 10% fetal bovine serum (Gibco) and differentiated into mature adipocytes as described previously (29). The adipocytes were cultured in BMDM conditioned media for 24 h and followed by the stimulation of insulin (1 nM) for 7 min.

**Primary adipocyte induction**

The isolated SVF cells were cultured in DMEM (Gibco) containing 10% fetal bovine serum (Gibco). For adipogenesis, the confluent cells were cultured in the induction medium (DMEM supplemented with 850 nM insulin, 0.5 mM isobutylmethylxanthine, 1 μM dexamethasone, and 5 μM rosiglitazone) for 2 days. Then, the cells were maintained in DMEM supplemented with insulin and rosiglitazone for another 6 days to induce primary adipocytes.

**Statistical analysis**

All data were given as mean ± SD. In mouse assays, one-way ANOVA with Mann–Whitney tests was used. In cell assays, two-tailed Student’s t-tests were used. GraphPad Prism 9 (GraphPad Software, Inc) was used as statistical software, and p < 0.05 was considered statistically significant.

**Data availability**

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.
