Abstract

In this paper, we address the problem of Multiple Transmitter Localization (MTL). MTL is to determine the locations of potential multiple transmitters in a field, based on readings from a distributed set of sensors. In contrast to the widely studied single transmitter localization problem, the MTL problem has only been studied recently in a few works. MTL is of great significance in many applications wherein intruders may be present. E.g., in shared spectrum systems, detection of unauthorized transmitters and estimating their power are imperative to efficient utilization of the shared spectrum.

In this paper, we present DeepMTL, a novel deep-learning approach to address the MTL problem. In particular, we frame MTL as a sequence of two steps, each of which is a computer vision problem: image-to-image translation and object detection. The first step of image-to-image translation essentially maps an input image representing sensor readings to an image representing the distribution of transmitter locations, and the second object detection step derives precise locations of transmitters from the image of transmitter distributions. For the first step, we design our learning model \textit{sen2peak}, while for the second step, we customize a state-of-the-art object detection model \textit{YOLOv3-cust}. Using DeepMTL as a building block, we also develop techniques to estimate transmit power of the localized transmitters. We demonstrate the effectiveness of our approach via extensive large-scale simulations, and show that our approach outperforms the previous approaches significantly (by 50\% or more) in accuracy performance metrics, and incurs an order of magnitude less latency compared to other prior works. We also evaluate our techniques over a small-scale area with real testbed data.

1. Introduction

The RF spectrum is a limited natural resource in great demand due to the unabated increase in mobile (and hence, wireless) data consumption\[1\]. In 2020, the U.S. FCC moves to free up 100 MHz of previously military occupied mid-band spectrum in the 3.45-3.55 GHz band for paving the way for 5G development. Also, the research and industry communities have been addressing this capacity crunch via the development of *shared spectrum*. Spectrum sharing is the simultaneous usage of a specific frequency band in a specific geographical area and time by a number of independent entities where harmful electromagnetic interference is mitigated through agreement (i.e., policy, protocol) [2]. Spectrum sharing techniques are also normally used in 5G networks to enhance spectrum efficiency [3]. However, protection of spectrum from unauthorized users is important in maximizing spectrum utilization.

The increasing affordability of the software-defined radio (SDR) technologies makes the shared spectrum particularly prone to unauthorized usage or security attacks. With easy access to SDR devices (e.g. HackRF, USRP), it is easy for selfish users to transmit data on a shared spectrum without any authorization and potentially causing harmful interference to the incumbent users. Such illegal spectrum usage could also happen as a result of infiltration of computer viruses or malware on SDR devices. [3] depicts 3 cases of spectrum attack. As the fundamental objective behind such shared spectrum paradigms is to maximize spectrum utilization, the viability of such systems depends on the ability to effectively guard the shared spectrum against unauthorized usage. The current mechanisms however to locate such unauthorized users (intruders) are human-intensive and time-consuming, involving the FCC enforcement bureau which detects violations via complaints and manual investigation [4]. Motivated by the above, we seek an effective technique that is able to accurately localize multiple simultaneous intruders (transmitters). Below, we describe the multiple transmitter localization problem.

**Multiple Transmitter Localization (MTL).** The transmitter localization problem has been well studied, but most of the focus has been on localizing a single intruder at a time. However, it is important to localize multiple transmitters simultaneously to effectively guard a shared spectrum system. E.g., a malware or virus-based attachment could simultaneously cause many devices to violate spectrum allocation rules; spectrum jamming attacks would typically involve multiple transmitters. More importantly, a technique limited by the localization of a single intruder could then be easily circumvented by an offender by using multiple devices. The key challenge in solving the multiple transmitter localization (MTL) problem comes from the fact that the deployed sensor would receive only a sum of the signals from multiple transmitters, and separating the signals may be impossible.

**Prior Works.** The MTL problem has been recently addressed in a few prior works, among which SPLIT [4], MAP* [5], and DeepTxFinder [6] are the most prominent. SPLIT essentially decomposes the MTL problem to multiple single-transmitter localization problems based on the sensors with the highest power readings in
a neighborhood. However, their technique implicitly assumes a propagation model, and thus, may not work effectively in areas with complex propagation characteristics, and it is not effective in the case of transmitters being located close by (a key challenging scenario for MTL problem). Our recent work \textit{MAP}\textsuperscript{*} solves the MTL problem using a hypothesis-driven Bayesian approach; in particular, it uses prior training in the form of distributions of sensor readings for various transmitter locations, and uses the training data to determine the most likely configuration (i.e., transmitters' locations and powers) for a given vector of sensor readings. However, to circumvent the high computational cost of a pure Bayesian approach, \textit{MAP}\textsuperscript{*} uses a divide and conquer heuristic which results in somewhat high number of misses and false alarms while still incurring high latency. \textit{DeepTxFinder} uses a CNN-based learning model approach; however, they use a separate CNN model for a specific number of transmitters and thus may incur high training cost while also limiting the number of transmitters that can be localized. In our evaluations, we compare our work with each of the above approaches.

\textbf{DeepMTL: Our Two-Step Approach.} As in prior works \cite{4, 7}, we assume a crowdsourced sensing architecture (See Fig. 1) wherein relatively low-cost spectrum sensors are available for gathering signal strength in the form of received power. We use a convolutional NNs (CNNs) based approach to solve the MTL problem. In particular, we frame MTL as a sequence of two steps: image-to-image translation and object detection, each of which is solved using a trained CNN model. The first step of image-to-image translation maps an input image representing sensor readings to an image representing the distribution of transmitter locations, and the second object detection step derives precise locations of transmitters from the image of transmitter distributions. We name our MTL approach as \textit{DeepMTL}.

\textbf{Motivation.} Our overall approach and its various aspects are motivated by the following considerations. \textbf{First}, we use a learning-based strategy to preclude assuming a propagation model \cite{4} or conducting surveys of sensors reading dis-
tributions. Assumption of propagation model suffers from the fact that even sophisticated propagation models yield unsatisfactory accuracy and thus lead to degraded performance. Moreover, even though a learning-based approach incurs a one-time high training cost, it generally incurs minimal latency during inference, which is an important consideration for our MTL problem. The intruder detection should incur minimal latency to be effective. Second, the geographical nature of the MTL problem suggests that convolutional neural networks (CNNs) are well-suited for efficient learning of the desired function. In particular, the features of the MTL problem can be represented in a 2D array corresponding to their geographic locations, which can be fed as an input to an appropriate CNN model which can leverage the spatial correlation among the input features to facilitate efficient learning. Lastly, we use a two-step architecture to facilitate efficient training by essentially providing an additional intermediate target. In particular, we are able to map each step to well-studied standard computer vision problems, allowing us to build upon known techniques.

Overall Contributions. The goal of our work is to develop an efficient technique for accurate localization of simultaneously present multiple transmitters/intruders. We also extend our technique to address various extensions such as power estimation and the presence of authorized users. Overall, we make the following contributions.

1. For the MTL problem, we develop a novel two-step CNN-based approach called DeepMTL approach. For the first step of image-to-image translation, we develop a CNN model that translates an image representing the sensor readings into a target image that encodes distributions of transmitter locations (Section 3). For the second step of mapping distributions to precision locations via object detection, we customize the well-known object detection platform YOLOv3 (Section 4).

2. For localization of transmitters in presence of authorized users, we augment the DeepMTL model by adding a pre-processing step based on a CNN-model that first reduces the sensor readings by the power received from the authorized users (Section 5).

3. To estimate transmit power of the intruders, we augment our DeepMTL model with a power-estimation CNN-model which iteratively estimates powers of transmitters in sub-areas (Section 6).

4. We evaluate our techniques via large-scale simulations as well as a small-scale testbed data and demonstrate their effectiveness and superior performance compared to the prior works (Section 7).

A preliminary version of this paper appeared at IEEE WoWMoM 2021.

2. Background, MTL Problem and Our Approach

In this section, we describe the background of the shared spectrum systems, formulate the MTL problem, then describe our methodology.
Shared Spectrum System. In a shared spectrum paradigm, the spectrum is shared among licensed users (primary users, PUs) and unlicensed users (secondary users, SUs) in such a way that the transmission from secondaries does not interfere with that of the primaries (or secondaries from a higher-tier, in case of a multi-tier shared spectrum system). In some shared spectrum systems, the location and transmit power of the primary users may be unavailable, as is the case with military or navy radars in the CBRS band. Such sharing of spectrum is generally orchestrated by a centralized entity called spectrum manager, such as a spectrum database in TV white space [9] or a central spectrum access system in the CBRS 3.5GHz shared band [10]. The spectrum manager allocates spectrum to requesting secondaries (i.e., permission to transmit up to a certain transmit power at their location) based on their location, spectrum demand, configurations of the primaries, other active secondaries, prevailing channel conditions, etc. Users that transmit without explicit permission are referred to as unauthorized users or intruders; the MTL problem is to essentially localize such intruders.

MTL Problem. Consider a geographic area with a shared spectrum. Without loss of generality, we assume a single channel throughout this paper (multiple channels are handled independently). For localization of intruders, we assume available crowdsourced sensors that can observe received signal in the channel of interest, and compute (total) received signal strength indicator (RSSI). RSSI can be measured using low-cost sensors and has been shown to achieve good accuracy for single-transmitter localization [11]. At any instant, there may be a set of intruders present in the area with each intruder at a certain location transmitting with a certain power which may be different for different intruders. The MTL problem is to determine the set of intruders with their locations at each instant of time, based on the set of sensor observations at that instant. For the main MTL problem, we assume that there are no primary or authorized users, and thus, assume that the sensor readings represent aggregate received power from the transmitters we wish to localize. However, in Section 5, we investigate the more general MTL problem where the background primary and/or secondary users may also be present.

Our Approach. In our context, each sensor communicates its observation to a centralized spectrum manager which then runs localization algorithms to localize any potential (multiple) transmitters. We design and implement a novel two-step localization algorithm named DeepMTL, as illustrated in Fig. 2, based on CNN models. The first step (Section 3) is a four-layer image-to-image translation CNN model that is trained to translate an input image representing sensor readings to an image of transmitters’ locations distributions. Each distribution of a transmitter can be visualized as a mountain with a peak, so we name this

\[1\] If we assume the channel propagation characteristics to be similar for different channel, then we don’t need to train different models for different channels. Our localization techniques would still work for scenarios wherein the intruders may change their transmit channels dynamically.
Figure 2: The overall two-step CNN architecture of the DeepMTL model. The first step is the \textit{sen2peak}, whose higher idea is to translate the input image of sensor readings to the image of peaks where each peak implies a transmitter. The \textit{sen2peak} architecture is illustrated in Fig. 4. The second step is \textit{YOLOv3-cust}, a customized version of YOLOv3, to perform object/peak detection in the output image of the first step. This step returns the precise location coordinates of TX. The \textit{YOLOv3-cust} architecture is illustrated in Fig. 5. A zoom-in of the peak detection result of the second step is in Fig. 6.

3. DeepMTL Step 1: Sensor Readings to TX Location Distributions

In this section, we present the first step of our overall approach to the MTL problem, i.e., the image-to-image translation step which translates/transforms the sensor reading to distributions of TX locations. Here, we first create a grayscale image to represent the input sensor readings; this image encodes both the sensors’ RSSI readings and the sensors’ physical location. We then train and use a convolutional neural network (CNN) model to transform this input image to an output image which represents the distribution of TX locations. Pixels in the output image that have higher values will have a higher chance of having a TX being present at that location.

\textbf{Input/Output Image Sizes and Tiling Approach for Large Areas.} We need to represent data by images of certain sizes. Typically, an image should be a size of a few hundred pixels by a few hundred pixels, since a thousand pixels by thousand pixels images will consume too much GPU memory. For example, a size of $224 \times 224$ is used by ResNet [13]. In this paper, we pick $100 \times 100$ as the size for both our input and output images in the first image-to-image translation step. Given an area that we want to monitor and a $100 \times 100$ size image, we will know how large an area a pixel will represent and we call it a pixel subarea. A large pixel subarea could certainly lead to high localization errors, due to very coarse granularity. We can address this by using a “tiling” technique, wherein we divide the given area into tiles, represent each tile by $100 \times 100$ size image and
use our localization techniques, and do some post-processing to handle cross-tiling issues (e.g., [6] uses overlapping tiles and employs a voting scheme inside the overlapping tile area).

3.1. Input Image Representing Sensors’ Readings

We localize transmitters based on observations from a set of sensors, i.e. solve the MTL problem assuming only intruders. The input of the localization method is sensor observations. Here, an observation at an individual sensor is the received power over a time window of a certain duration, in the frequency channel of interest (we assume only one channel). RSSI (in decibels) is computed from the FFT operation of the I/Q samples collected in a time window. More specifically, in our evaluations, we use a Python API [14] that computes the power spectral density from a sequence of signal data (I/Q samples), and then, we choose the RSSI at the frequency of interest.

Different than [5, 4], we represent the information of the sensors, both locations and RSSI observation readings, in a 2D-image-like input. A 2D image is able to encode the location as well as the readings of the distributed sensors. Strictly speaking, an image’s pixel value needs to be an integer between 0 and 255. But in our case, we want real number values to avoid information loss. So actually we use a 2D matrix $X$ consisting of real number values. We still call the first step image-to-image translation instead of matrix-to-matrix translation for naming convention. In $X$, the entry $X_{i,j}$ denotes the observation of the sensor at the grid cell whose index is $(i,j)$. For example, $X_{10,20} = -50$ means there is a sensor at coordinate $(10,20)$ and its sensor reading is $-50$ dB. If there is no sensor at location $(i,j)$, we assign the noise floor $N$ (i.e. -80 dB) value to $X_{i,j}$. Fig. 3(b) shows how a matrix is used to represent the input information that contains both the RSSI and the spatial location of the distributed sensors in a toy example of an area that exists 14 sensors in Fig. 3(a). Before we pass this observation matrix as input to our CNN model, we do a normalization step; we first subtract the $N$ from each value and then divide it by $-N/2$. This ensures
that the value $X_{i,j}$ is zero at locations without sensors, and for locations with sensors, the value $X_{i,j}$ is a positive real number usually no larger than two. The input observation matrix $X$ can be looked upon as a *gray-scale image* which is in contrast to a usual color image that has three sheets.

### 3.2. Output Image Representing TX locations’ Distributions

We now focus on designing the output image to represent the distribution of TX locations; the output image is essentially the “label” assigned to each input image that guides the training of the CNN model. Fig. 3 (c) illustrates the output image of the image-to-image translation step for Fig. 3 (a) that contains 3 transmitters.

A straightforward representation that represents the TXs with locations is to just use an array of $(x,y)$ elements where each $(x,y)$ element is the location of a transmitter, as in [6]. However, this simple representation is less conducive to efficient model learning, as the representation moves away from spatial representation (by representing locations as positions in the image) to direct representation of locations by coordinate values. E.g., in [6]’s CNN-based approach to MTL problem, the authors assume a maximum number $N$ of transmitters and train as many as $N + 2$ different CNN models and thus, limiting the overall solution to the pre-defined maximum number of transmitters. Instead, in our approach, we facilitate the learning of the overall model, by solving the MTL problem in two steps, and in this step of translating sensors’ reading to transmitter locations’ distributions, we represent the output also as an image. This approach allows us to use a spatial learning model (e.g. CNN) for the second step too, and preclude use of regression or fully-connected layers in the first step.

Inspired by recent work on wireless localization problem [15] which represents the input and output as images, we choose to represent our output of the first step as an image as well. Same as the first step’s input, however, we are actually using a 2D matrix with real number values. But for naming convention, we are calling it an image. So, the output is also a grayscale image with one sheet. In the output image, we use 25 ($5 \times 5$) pixel values to represent the presence of a transmitter. It is desirable to use an odd side length square (i.e. $3 \times 3$, $5 \times 5$, $7 \times 7$) for symmetry. For a $100 \times 100$ size input we use, while $3 \times 3$ gives too little information for a transmitter and $7 \times 7$ generates too many overlaps for close-by transmitters, $5 \times 5$ is the sweet spot. Other pixels far away from any transmitter are zero-valued. Among multiple potential ways to represent a transmitter presence by a number of pixels, we found that using a 2D Gaussian distribution around the pixel of TX location, as shown in Fig. 3 (c), yields the best model performance. Thus, a geographic area with multiple transmitters present is represented by a grayscale image with multiple Gaussian distributions, with each Gaussian distribution’s peak inside the pixel corresponding to transmitter’s location. Based on preliminary performance tests, we picked the amplitude of the 2D Gaussian peak to 10, the standard deviation to 0.9, and located the center of the distribution at the location of each transmitter. Note that the
Figure 4: Architecture of the first step CNN, a four layer image-to-image translation model (sen2peak). The figure displays how the data volume flows through the various convolutional layers. C stands for Conv2d, and for each Conv2d layer, the five values shown are [number of input sheets, number of output sheets, kernel-size, stride, padding]. G stands for group normalization, and, for each group normalization, the two values shown are [number-of-groups, number-of-sheets]. See §3 for details.

location of the TX is in continuous domain and usually not at the center of the grid cell.

3.3. Image-to-Image Translation: sen2peak CNN Model

At a higher level, we use a deep and spatial neural network, in particular a CNN, to learn the approximation function that maps the input image (of sensor readings) to the output image (of Gaussian distributions for TX locations). We refer to this as the image-to-image translation model. Our approach is inspired by the recent work [15] that frames a different wireless localization problem as an image-to-image translation problem. We incorporate the idea into our multiple transmitter localization problem and utilize recent advances in the computer vision area. Encoder-decoder based CNN models like U-Net [16] with down-sampling and up-sampling convolutional layers have been successful in effectively learning image-to-image translation functions. However, in our setting, we observe that the usage of down-sampling layers (such as max-pooling) degrades the performance of the model, especially in the case when transmitters may be close to each other wherein the model is unable to distinguish the nearby transmitters and generate a single large distribution in the output image. To circumvent this, we avoid using any down-sampling layers in our model and redesign the image-to-image translation model as described below.

**sen2peak CNN Model.** We refer to our image-to-image translation CNN model as sen2peak, as it translates sensors’ readings to “peaks” with Gaussian distributions corresponding to transmitter locations. It has four convolutional layers, as shown in Fig. 4(a). We use an input size of 100 × 100. The number of convolutional filters are varying for different layers, with up to 32 in one of the layers. We tried doubling the filter numbers at each layer, but it doesn’t lead

---

2We observe that a four-layer lightweight and symmetric sen2peak model produces good results and adding more layers gives marginal improvement.
to significant improvement (it does yield a lower error, but the output image doesn’t improve significantly to impact the second step of our architecture). We use a kernel size of $5 \times 5$, a stride of 1, and a padding of 2. This ensures that the dimensions don’t decrease and all the pixels are treated uniformly, including the ones at the edge of the image. With the above four convolutional layers, the receptive field of each neuron in the output layer is $17 \times 17$. Normalization layers can improve the learning process. We chose group normalization and put it after the first three convolutional layers. We compared group and batch normalization methods in our context, and observed better performance with the group normalization. For the activation layers, we select rectified linear unit (ReLU) and put it after the group normalization layers.

The Loss Function. Our inputs ($X$) and output ($Y$) are images. We use L2 loss function which computes the mean squared error aggregated over individual pixels. More formally, our loss function is defined as:

$$
\frac{1}{N} \sum_{i} \| \text{sen2peak}(X_i) - Y_i \|^2
$$

where $N$ is the number of samples used in computing the loss, $\| \cdot \|^2$ is L2 loss function, $X_i$ and $Y_i$ are the $i_{th}$ sample’s input and output images respectively, and $\text{sen2peak}(X_i)$ is the predicted output image corresponding to the input $X_i$. During training, we use Adam as the optimizer that minimizes the loss function. We set the learning rate to 0.001 and the number of epochs to 20 and the model converges well.

4. DeepMTL Step 2: TX Locations’ Distributions to Precise Locations

In this section, we present the second step of our overall localization approach. We refer to this step as the peak detection step, as the goal is to detect the peaks within the Gaussian distributions in the input image (which is also the output image of the first step). The first step outputs an image that has multiple distributions (presumably, Gaussian), whose peaks need to be interpreted as precise locations of the transmitters/intruders. As, our end goal is to determine the precise locations of the present transmitters, we develop techniques to detect peaks within the output image of the first step. We propose two different strategies for the peak-detection task. The first strategy is a straightforward peak detection algorithm based on finding local maximal values, while the second strategy is based on framing the problem as an object detection task; for the second strategy, we utilize a widely used state-of-the-art computer vision model called YOLOv3.

Simple Peak Detection Method. The simple and straightforward peak detection method is to designate pixels with locally maximal values as peaks, subject to certain thresholds. More formally, we use a threshold $x$ for a peak value, and also use a parameter $r$ to define a $r$-radius neighborhood of a pixel.
Figure 5: Our YOLOv3-cust in the second step of the DeepMTL. The two major customization are: (i) Use only the YOLO layer 3 that detects small size objects (the output of YOLOv3-cust is the bounding box predicted by YOLO layer 3 and we use the center of the bounding box as the transmitter location), and (ii) change the rectangle anchors to square anchors.

Then, any pixel whose value is more than $x$ and is the maximum among all pixels with a $r$-radius neighborhood, is designated as a peak (transmitter location). We use $x = 2$ and $r = 3$, in our evaluations. Note that each pixel represents a subarea; thus, a pixel designated as pixel only implies the transmitter location at the center of the corresponding subarea. To localize the transmission more precisely with the pixel’s subarea, we use a scheme that localizes the transmitter within the subarea by computing a weighted average of the peak pixel’s coordinate and the peak’s neighbor pixels’ coordinates. The weight of a pixel is the predicted pixel value itself from the first step $\text{sen2peak}$. We refer to the above simple approach for the second-step of DeepMTL as $\text{simplePeak}$.

4.1. Object-Detection Based Precise Localization: YOLOv3-cust

The simple hand-crafted method described in the previous subsection performs reasonably well in most cases in our simulations. However, its key drawback is that it needs appropriate threshold values that may vary from case to case; such thresholds can be difficult to determine, especially since the input images (with distributions) are not expected to be perfect as they are themselves output of a learning model. Inaccurate threshold values can lead to false alarms and misses. Also, the previous method is not sufficiently accurate at the sub-pixel level, where each pixel may represent a large area such as 10m by 10m or even 100m by 100m. Thus, we propose a CNN-based learning method that overcomes the above shortcomings. CNN has been widely used for object detection in different areas [21, 22].

We frame this problem as an object detection task where the objective is to detect and localize known objects in a given image. We observe that our second-step peak detection problem is essentially an object detection problem where the “object” to detect is a “peak”. Thus, we turn the MTL problem of localizing multiple transmitters into detecting peaks in the images output by $\text{sen2peak}$ model. For object/peak detection, we design YOLOv3-cust, our
customized version of YOLOv3 [12]. Fig. 6 is a zoom-in of localizing two close by transmitters (peaks) in Fig. 2(b).

Peak Detection Using YOLOv3-cust. Object detectors are usually comprised of two parts: (i) a backbone which is usually pre-trained on ImageNet, and (ii) a front part (head), which is used to predict bounding boxes of objects, probability of an object present, and the object class. For the front part, object detectors are usually classified into two categories, i.e., one-stage detectors such as the YOLO [23] series, and two-stage detectors such as the R-CNN [24] series. We choose the one-stage YOLO series because of its computational efficiency, low latency, high popularity and available ways to customize it for our specific context. We refer to the customized version as YOLOv3-cust, see Fig. 5. Implementing a 106-layer deep neural network with a complex design from scratch is out of scope of our work. Thus, we use a publicly available source repository [25] and made customization on top of it. We refer to the architecture that uses sen2peak and YOLOv3-cust in sequence as DeepMTL, our key product. In addition, we also use sen2peak in combination with the uncustomized original YOLOv3, and refer to it as DeepMTL-yolo (still change the class number to 1).

Customization of YOLOv3. Overall, we incorporated four customization to YOLOv3, of which two are significant and the other two are relatively minor. See Table 1. YOLOv3 is designed to be a general object detector that can detect objects of various sizes, shapes, and classes within input images of various sizes. However, in our context, the input images are of a fixed size, with only a single class of objects which are relatively small and semi-circular. Based on the above observations, we make changes to the original YOLOv3 that both decrease the model complexity and improve its performance.

Customization Details. The first and second changes presented in Table 1 are major changes and we elaborate them in the following paragraphs. Making prediction at three different scales is one of the highlights of YOLOv3 and an improvement comparing to the previous version YOLOv2 which was prone to missing at detecting small objects. As shown in Fig. 5, the coarse-grain 13 × 13 YOLO layer-1 is designed for detecting large size objects, the 26 × 26 YOLO layer-2 is designed for detecting middle-sized objects, and the fine-grained 52 × 52 YOLO layer-3 is designed for detecting small-sized objects. Since the peaks in our translated images are always small objects, we only use the last 52 × 52 YOLO detection layer (and skip the first two YOLO layers). As shown in Fig. 6 by “skipping” the two YOLO layers means that we do not use them in computing the overall loss function and their outputs are not used in predicting
Table 1: Differences between the original YOLOv3 and our YOLOv3-cust.

| YOLOv3                              | YOLOv3-cust                                      |

| object class                        | peak class                                      |

The bounding boxes. In our YOLOv3-cust, the only YOLO layer predicts 8112 bounding boxes, since it has a dimension of 52 × 52 and each cell results in prediction of 3 bounding boxes; this is in contrast to the original YOLOv3, which predicts 10647 bounding boxes (3 × (13 × 13 + 26 × 26 + 52 × 52) = 10647).

The anchor box is one of the most important hyperparameters of YOLOv3 that can be tuned to improve its performance on a given dataset. The original YOLO’s anchor boxes are 10 × 13, 16 × 30, and 33 × 23 (for the input image of size 416 × 416 pixels), which are essentially bounding boxes of a rectangular shape. These original YOLOv3 anchors were designed for the Microsoft COCO [26] data set, and were chosen since they best describe the dimensions of the real world objects in the MS COCO data set. In our context, since the peaks are generally squares—we use the anchor boxes to be 15 × 15, 25 × 25, and 35 × 35.

Input Image for YOLOv3-cust. Note that the size of the first step (sen2peak) output image is 100 × 100, whereas the input image of YOLOv3-cust is required to be a three-sheet (RGB) image with each sheet being size of 416 × 416. To fit the YOLOv3-cust, we first duplicate two copies of 100 × 100 and stack all three together. And then resize the 100 × 100 image to 416 × 416 by the PyTorch default “nearest neighbor” interpolation. See Fig. [7] Only in this way, can we feed this data into the YOLOv3-cust model. An input image size of 100 × 100 for sen2peak being different than an input image size of 416 × 416 for YOLOv3-cust is not an issue. For a general object detector like YOLO, it can take in input images of any sizes because resizing by interpolation is an easy and default step.

Output of YOLOv3-cust. YOLO treats object detection as a regression problem. The regression target (or “label”) for an object is a 5-value tuple (x, y, length, width, class). In our case, there is only one class. x and y are real number location coordinates of the center of the bounding box, which we use as the location of the transmitter. Width and height determine the size and

---

3The computer vision community uses the word channel for what we refer to as sheet here. We use the word sheet to avoid confusion with the usage of wireless channel.
shape of the object—which we consistently set to be 5 each to signify a \(5 \times 5\) square. Note that the center of the bounding box is in the continuous domain. Thus, we are able to get sub-pixel level location of the transmitters.

5. Localization in the Presence of Authorized Users

Till now, we have assumed that the only transmitters present in the area are the intruders which need to be localized. In this section, we solve the more general MTL problem, where there may be a set of authorized users in the background. This is referred to as the multiple transmitter localization - shared spectrum (MTL-SS) problem [5].

In particular, in a shared spectrum paradigm, there are primary users and an evolving set of active secondary users transmitting in the background. Different than the intruders whose locations are unknown, the authorized users’ locations are known and we wish to utilize this known information to better localize the unknown intruders. The key challenges come from the fact that the set of authorized users is not static and changes over time as allocation requests are granted and/or active secondary users become inactive over time. A straightforward way to handle background authorized users is to localize every transmitter, and then remove the authorized users. However, any localization approach is susceptible to performance degradation with the increase in the number of transmitters to be localized. Thus, the straightforward approach of localizing every transmitter likely to be error-prone. Therefore, we attempt to develop a new approach that uses DeepMTL as a building block that uses the information of the location of the authorized uses in a way other than removing them after localizing all. The new approach tries to subtract the received signal strength at the sensors by a value received from the authorized users. This subtraction is done by a novel CNN model; we refer to it as SubtractNet. Then we feed the image with subtracted powers to the DeepMTL and get the locations of the intruders. See Fig. 8 (c)–(d)–(f). We describe SubtractNet in the following paragraphs.

**SubtractNet Input Image.** The sensor reading has two sources, one is the intruders and the other is the authorized users. We aim to subtract the power of the authorized users and remain the power from the intruders. So the input of the SubtractNet will contain two kinds of information: the authorized users’ information (Fig. 8(a)), including both the location and the transmitter...
Figure 8: Overall architecture of second approach to localize 3 intruders in the presence of 5 authorized users. The input of the SubtractNet is (c), which is stacking authorized user matrix (a) and the sensor reading matrix (b). (d) is the output of SubtractNet, where the transmission power of the authorized users is subtracted from the area. The details of the SubtractNet model is in (e). (f) is the output after feeding (d) into DeepMTL.

power, and the sensor reading matrix (Fig. 8(b)) that encode the power from all transmitters. To incorporate the two kinds of information, we first encode the authorized user information into a matrix that has the same dimension as the sensor reading matrix. Then stack the two matrices together. The combined stacked image is nothing but a two-sheet image, which can be interpreted as Red and Green sheets. The sensor reading matrix is the Red sheet and the authorized user matrix is the Green sheet. There is no Blue sheet. To represent the authorized transmitter in the green sheet, we use a Gaussian peak similar to what we did in the sen2peak for representing transmitters (Section 3). The difference is that in sen2peak, all the peaks have a uniform height, whereas in SubtractNet, the height of the peak is the power of the authorized transmitter. So the higher the power of the authorized transmitter, the higher the peak in the Green sheet. Another difference is that the authorized transmitters are approximated at discrete locations instead of the continuous locations used for transmitters in sen2peak.

SubtractNet Output Image. The output is the image merely representing the sensor readings due to only the intruders. Note that the size of the output image $1 \times 100 \times 100$ is different than the input image $2 \times 100 \times 100$. Since the output of SubtractNet needs to feed into DeepMTL which requires a grayscale image as input. SubtractNet handles this difference, and it can be observed in the leftmost module and rightmost module of the SubtractNet in Fig. 8(e).

SubtractNet CNN Architecture. We refer to the model that subtracts the power from the authorized users as the SubtractNet. It has a similar design
6. Estimating the Transmit Power of Transmitters

In this section, we extend our techniques to estimate transmit power of the intruders; we refer to the overall problem as Multiple Transmitter Power Estimation (MTPE). Estimation of the transmit power of transmitters can be very useful in the shared spectrum systems. In particular, estimated transmit powers of the primary users (if unknown, as in the case of military users or legacy systems) can be used to set a “protective” region around them—inside which secondary users can be disallowed [27]. Estimating transmit power of secondary users can also be useful. E.g., if the violation in a shared spectrum system is based on a certain minimum threshold, then it is important to estimate the transmit power to determine a violation. Also, the estimated transmit power of secondary users can also be used to “circumvent” their intrusion—i.e., for the primary users to appropriately increase their transmit power to overcome the harmful interference from the secondary users. In general, estimating the transmission power is beneficial to various operations such as node localization, event classification, jammer detection [28].

There are several works that estimates the transmission power of a single transmitter, often jointly with its location [28, 27, 29]. Our previous work [5] can estimate the power of multiple transmitters. The similarity among all five of these methods is that they are estimating the power and location jointly. In this paper, we propose a new method that leverages the capabilities of DeepMTL by using it as a building block. We first localize the transmitters by DeepMTL. Then given the localized locations, estimate the transmitters’ transmission power by a newly designed CNN model PredPower. Although PredPower is designed to only estimate the power of a single transmitter, we use it together with a machine learning-based error correction method that can mitigate the errors while applying PredPower to the multiple transmitter power estimation scenario.

In this section, we develop a technique to also predict the transmission powers of the intruders. Here, for simplicity, we assume no background authorized users, though, the techniques in this section also work in the presence of authorized users. All previous work [5, 28, 27, 29] on estimating the transmission power are done by estimating the power jointly with its location. In this paper, we can leverage our accurate and robust localization solver that tolerates varying transmission power for different transmitters (the varying transmission power needs to be in a range). We propose an efficient approach and its overall methodology at a high-level is as follows. And then in the next subsection we describe our PredPower model.
1. We use DeepMTL to localize the multiple transmitters in a field.

2. We develop a CNN model PredPower to predict power of a single isolated (far away from other intruders) intruder.

3. For other (non-isolated) intruders, we still use PredPower to predict their powers but employ a post-processing “correction” technique to account for nearby intruders.

6.1. PredPower: Predicting Power of a Single Isolated TX

**PredPower Input Image.** Let’s consider an “isolated” transmitter $T$. To predict $T$’s power, we start with creating a smaller-size image by cropping the original sensor readings image with the area of a certain size around $T$. In our evaluations, the transmitters have a transmit radius of around 20 pixels. For this setting, we used an cropped area of $21 \times 21$ around the isolated transmitter $T$ to predict its power, with $T$ is at the center of this area; also, in this setting, we define a transmitter to be *isolated* if there is no other transmitter within a 20-pixel distance. Note that the above cropping process requires the location of the transmitter to be known, and hence, we undertake the above power-estimation process after the localization of the transmitters using the DeepMTL model. We crop images from the same dataset where DeepMTL is trained on.

**PredPower Output Power.** The output of the PredPower is a single pixel whose value is the predicted power of the transmitter located at the center of the cropped image. Before coming into this single pixel output design, we tried using the height or radius of the peak from the output of sen2peak to indicate the power. But we figure out that the height or radius of the peak is hard to accurately predict and therefore is not an accurate indicator of the power. So we reduced the output complexity and designed the output as a simple single pixel whose value directly represents the power of the transmitter. By simplifying both the input side and output side, we can design and implement a novel CNN model that can accurately predict the power of a single transmitter, as described in the following paragraph.

**PredPower CNN Architecture.** We refer to our CNN model that estimates the power of a single transmitter as PredPower. See Fig. 9. It has a similar design to sen2peak as well, where it has no max-pooling layers and no fully connected layers. We don’t use the fully connected layers and design a fully-convolutional network since the usage of fully connected layers will destroy the spatial relationships. PredPower has five CNN layers and each CNN layer has a kernel size $5 \times 5$, striding 1 and padding 0. With this setting, a pixel in the output layer

---

4I.e., sensors beyond a distance of 20 pixels away from a transmitter $x$ receive only negligible power from $x$.

5Ideally, transmitters with a transmit radius of 20 pixels should entail defining isolated transmitters as ones that have no other transmitters within a 40-pixel distance, and then use a 41 x 41 area around the isolated transmitter. However, in our evaluations, our chosen values yielded a more efficient technique with sufficient accuracy.
Figure 9: Architecture of the PredPower, a five-layer CNN model that takes in a cropped image from the original input image and outputs the predicted power of one transmitter. The figure displays how the data volume flows through the various convolutional layers. C stands for Conv2d, a 2D convolutional layer, and for each Conv2d layer, the five values shown are [number of input sheet, number of output sheet, kernel-size, stride, padding]. B stands for batch normalization 2d, and for each batch normalization, the value shown is [number-of-features].

has a receptive field of $21 \times 21$, which is exactly the size of the input cropped image. Also note that the pixel is exactly at the location where the transmitter is assumed to be located (recall that the transmitter is at the center of the cropped image). We tried both batch normalization and group normalization and found that batch normalization is better than group normalization, which is the opposite to the sen2peak scenario. ReLU is used as the activation function.

Loss Function. The output of the last convolutional layer is technically a 3D cube, although $1 \times 1 \times 1$. So we flatten it in the end to get one scalar value. Let the cropped input image be $X^c$ and the target be $y$. We use L2 loss function, which is formally defined as:

$$\frac{1}{N} \sum_{i}^{N} (\text{PredPower}(X^c_i) - y_i)^2,$$

where $N$ is the number of training samples. $X^c_i$ is the cropped input image for the $i^{th}$ sample and $y_i$ is the ground truth power for the $i^{th}$ sample. $\text{PredPower}(X^c_i)$ is the predicted power. We use Adam as the optimizer, and set the learning rate to 0.001 and the number of epochs to 20 which is sufficient for the model convergence.

6.2. Estimating Powers of Multiple Transmitters

Our end goal is to estimate the power of multiple transmitters at the same time. When the multiple transmitters are far away and isolated from each other, the problem reduces to single transmitter power estimation, which PredPower handles well. The hard part is to localize multiple transmitters that are close by. In this case, a sensor will receive an aggregated power from multiple transmitters. We assume that blind source power separation is not viable.

Overall High-Level Approach. For each localized intruder by using DeepMTL (whether isolated or not), we crop the $21 \times 21$ size area around it and feed it to PredPower, and estimate its power. If it is actually isolated, then the predicted
power is final. If it is not isolated, then we apply a post-processing correction phase to account for the overestimation of the powers, as described below.

Correction Method for Close-by Transmitters. Let’s first consider the case where there are two close-by transmitters $T_0$ and $T_1$. We use PredPower to estimate the power of two transmitters and get $p'_0$ and $p'_1$ respectively. Let’s say the ground truth are $p_0$ and $p_1$ respectively. The estimated power will most likely be higher than the ground true power, i.e., $p'_0 > p_0$ and $p'_1 > p_1$. Because PredPower can only “see” one transmitter, and it will view two transmitters in the areas as a combined single one. Let’s focus on $T_0$ and assume $\delta_0 = p'_0 - p_0$.

The intuition is that $\delta_0$ has some underlying patterns that we are able to recognize. We model $\delta_0$ as a function of some features related to $T_0$ and $T_1$. We model $\delta_0$ as follows,

$$\delta_0 = \theta_0 \cdot p'_0 + \theta_{(1,1)} \cdot d_{01} + \theta_{(1,2)} \cdot p'_1 + \theta_{(1,3)} \cdot \frac{p'_1}{d_{01}}$$  \hspace{1cm} (3)

where $d_{01}$ is the distance between $T_0$ and $T_1$, and the four $\theta$s are the coefficients for the four terms respectively. The first term is related to $T_0$ itself, and the other three terms are related to $T_1$. We observe that the smaller the $d_{01}$, the larger the value of $\delta_0$. And the bigger the $p'_1$, the larger the value of $\delta_0$. So $d_{01}$ has a negative correlation with $\delta_0$ while $p'_1$ has a positive correlation. $\frac{p'_1}{d_{01}}$ is a combination of two terms to increase the number of features. We also tried a few other features, but we decided to use only these three features for a close by transmitter as a balance of model accuracy and model complexity.

Equation 3 is for the case of one close by transmitter, we then extend the equation to handle multiple close by transmitters in the following equation 4,

$$\delta_0 = \theta_0 \cdot p'_0 + \sum_{i=1}^{N} (\theta_{(i,1)} \cdot d_{0i} + \theta_{(i,2)} \cdot p'_i + \theta_{(i,3)} \cdot \frac{p'_i}{d_{0i}})$$  \hspace{1cm} (4)

where $N$ is the number of close by transmitters for $T_0$, the transmitter of interest. For the $i$th close by transmitter, we introduce three terms, and assign three coefficients $\theta_{(i,1)}, \theta_{(i,2)}, \theta_{(i,3)}$ to the three terms respectively. So for $N$ close by transmitters, there are $1 + 3N$ number of terms in the equation.

After modeling $\delta_0$, in equation 5, we “correct” $p'_0$ by subtracting $\delta_0$ from $p'_0$ to get more accurate estimation of the power of transmitter $T_0$.

$$p_{0\text{correct}} = p'_0 - \delta_0$$  \hspace{1cm} (5)

Estimating the parameter $\theta$. Equation 4 is essentially a linear model and we can train it by using either linear, ridge, or LASSO regression models. We perform experiments using ridge regression. In reality, we set a distance threshold for a neighbor transmitter to be classified as a close by transmitter. Transmitters will have a different number of close-by transmitters and $N$ is the maximum number of close-by transmitters we see in the dataset. For a transmitter with a small number of close-by transmitters, let’s say $n$, only the first $1 + 3n$ terms will have a positive value. And for the rest $3(N - n)$ terms, we set the value to zero.
7. Evaluation

To evaluate the performance of our proposed techniques, we conduct large-scale simulations over two settings based on two different propagation models. In particular, we consider the log-distance-based propagation model and the Longley-Rice model obtained from SPLAT! [31]. We evaluate various algorithms, using multiple performance metrics as described below.

Performance Metrics. We use the following metrics 1, 2, and 3 to evaluate the localization methods and use the 4th metric to evaluate the power estimation methods.

1. Localization Error (L_{err})
2. Miss rate (M_r)
3. False Alarm rate (F_r)
4. Power Error (P_{err})

Given a multi-transmitter localization solution, we first compute the L_{err} as the minimum-cost matching in the bi-partite graph over the ground truth and the solution’s locations, where the cost of each edge in the graph is the Euclidean distance between the matched ground truth node location and the solution’s node location. We use a simple greedy algorithm to compute the min-cost matching. The unmatched nodes are regarded as false alarms or misses. We put an upper threshold on the cost of an eligible match. E.g., if there are 4 intruders in reality, but the algorithm predicts 6 intruders then it is said to incur 0 misses and 2 false alarms, so the M_r is 0 and the F_r is 2/6. If it predicts 3 intruders then it incurs 1 miss and 0 false alarms, so the M_r is 1/4 and the F_r is 0. In the plots, we stack the miss rate and false alarm rate to reflect the overall performance.

Algorithms Compared. We implement and compare six algorithms in two stages. In stage one, we compare three versions of our techniques, viz., DeepMTL, DeepMTL-yolo, and DeepMTL-peak. Recall that DeepMTL, DeepMTL-yolo, and DeepMTL-peak use sen2peak in the first step, and YOLOv3-cust, original YOLOv3, and simplePeak respectively in the second step. In the first stage of our evaluations, we will show that DeepMTL outperforms DeepMTL-yolo and DeepMTL-peak in almost all performance metrics. Thus, in the second stage, we only compare DeepMTL with schemes from three prior works, viz., SPLOT [4], DeepTxFinder [4], and MAP*[5] and show that DeepMTL outperforms the prior works.

Training and Testing Dataset. We consider an area of 1km x 1km, and use grid cells (pixels) of 10m x 10m, so the grid is 100 x 100. The transmitters may be deployed anywhere within a cell (i.e., their location is in the continuous domain), while the sensors are deployed at the centers of the grid cells (i.e. their

---

6Source code at: https://github.com/caitaozhan/deeplearning-localization
location is in the discrete domain). For each instance (training or test sample), the said number of sensors and transmitters are deployed in the field randomly. For each of the two settings (propagation models described below), we create a 100,000 sample training dataset to train our models and create another 20,000 sample testing dataset to evaluate the trained model.

We will evaluate the performance of various techniques for varying number of transmitters/intruders and sensor density. When we vary a specific parameter, the other parameter is set to its default value; the number of transmitters varies from 1 to 10 and the default value is 5; the sensor density varies from 1% to 10% and the default value is 6% (600 sensors in a 100 × 100 grid). The two default numbers 5 and 6% are chosen because they are in the middle of their ranges. When not mentioned, the default values are used. The transmitter power varies from 0 to 5 dBm and is randomly picked. To minimize overfitting, the training dataset and testing dataset have sensors placed at completely different locations.

We train the **DeepMTL** model using the 100,000 sample dataset. To train **DeepTxFinder** [6], we partition the 100,000 sample training dataset into 10 datasets based on the number of transmitters in the samples which varies from 1 to 10. These 10 datasets are used to train the 10 “localization” CNN models in **DeepTxFinder**, and the full dataset of 100,000 samples is used to train the **DeepTxFinder** model that determines the number of transmitters. For the MAP* scheme [5], we assume the availability of all required probability distributions. We note that using a simple cost model (number of samples need to be gathered), the overall training cost for MAP* is an order of magnitude higher than **DeepMTL** and **DeepTxFinder**. Lastly, **SPLOT** [4] doesn’t require any training.

**Two Propagation Models and Settings.** The sensor readings (i.e. the dataset) are simulated based on a propagation model. To demonstrate the generality of our techniques, we consider two propagation models as described below.

**Log-Distance Propagation Model and Setting.** Log-Distance propagation model is a generic model that extends Friis Free space model which is used to predict the path loss for a wide range of environments. As per this model, the path loss (in dB) between two points \(x\) and \(y\) at a distance \(d\) is given by: \(PL_d = 10\alpha \log\,d + X\), where \(\alpha\) (we use 3.5) is the path-loss exponent and \(X\) represents the shadowing effect of the propagation channel which can be represented by a zero-mean Gaussian distribution with a certain (we use 1) standard deviation. Power received (in dBm) at point \(y\) due to a transmitter at point \(x\) with a transmit power of \(P_x\) is thus: \(P_x - PL_d\). Power received at point \(y\) due to multiple sources is assumed to be just an aggregate of the powers (in linear) received from each of the sources.

**SPLAT! Model and Setting.** This is a complex model of wireless propagation based on many parameters including locations, terrain data, obstructions, soil conditions, etc. We use SPLAT! [31] to generate path-loss values. SPLAT! is an open-source software implementing the Longley-Rice [32] Irregular Terrain With Obstruction Model (ITWOM) model. We consider a random area in Long Island, New York of 1km × 1km large and use the 600 MHz band to generate
7.1. DeepMTL vs. DeepMTL-yolo vs. DeepMTL-peak

In this subsection, we compare the three variants of our technique, viz., DeepMTL, DeepMTL-yolo, and DeepMTL-peak. For simplicity, we only show plots for the log-distance propagation model setting in this subsection (we observed similar performance trends for the Longley-Rice propagation model too).

**Performance Results.** In Fig. 10, we plot the cumulative density function (CDF) of the localization error, for the simple case of a single transmitter. We observe that DeepMTL outperforms the other variants, as it yields a higher cumulative probability for a lower range of errors. In addition, we evaluate the three variants for varying number of transmitters (Fig. 11) and sensor density (Fig. 12), and evaluate the localization error as well as the false alarm and miss rates. We observe that DeepMTL consistently outperforms the other two variants across all plots and performance metrics. As expected, the performance of all algorithms
degrades with an increase in the number of transmitters (in terms of false alarms and miss rates) or with a decrease in sensor density. In general, the localization error of DeepMTL is around 15-30% lower than the other variants. Impressively, the total cardinality error (i.e., false alarms plus miss rates) is fewer than 1% for the DeepMTL technique, when the sensor density is 6% or above.

When the sensor density is as low as 1%, the performance of all methods significantly decreases. Because when the sensor density is 1% or lower, the input image will be very sparse and contain only a few pixels. DeepMTL’s first part sen2peak has a receptive field of $17 \times 17$. This area will contain an average of less than 3 sensors when the sensor density is 1% ($17 \times 17 \times 0.01 = 2.89$). This number is considered too low and note that 2.89 sensors are not enough for the trilateration localization method, which needs 3 sensors. Our CNN models need to function well with enough pixels that contain useful information. So we suggest the sensor density to be at least 2% to achieve reasonable results.

| Intr. | DeepMTL-peak | DeepMTL-yolo | DeepMTL | MAP’ | SPLOT | DeepTxFinder |
|-------|---------------|---------------|---------|------|--------|--------------|
| 1     | 0.0013        | 0.0180        | 0.0180  | 8.78 | 1.53   | 0.0015       |
| 3     | 0.0014        | 0.0183        | 0.0186  | 15.1 | 1.79   | 0.0016       |
| 5     | 0.0016        | 0.0192        | 0.0189  | 19.3 | 2.06   | 0.0017       |
| 7     | 0.0018        | 0.0196        | 0.0194  | 24.1 | 2.32   | 0.0019       |
| 10    | 0.0023        | 0.0205        | 0.0206  | 28.5 | 2.72   | 0.0022       |

Running Time Comparison. For the running time comparison of the variants, see Table 2. Our hardware is an Intel i7-8700 CPU and an Nvidia RTX 2070 GPU. We observe that, as expected, DeepMTL and DeepMTL-yolo which use a sophisticated object-detection platform do incur higher latency (around 20 milliseconds) than DeepMTL-peak (around 2 milliseconds). As our key performance
Localizing Transmitters Close By. Localizing two or more transmitters close by is a hard part of the MTL problem. Fig. 6 (c) and (d) gives an example of when an advanced object detection algorithm will work while a simple local maximal peak detection might not. Fig. 6 (c) and (d) shows DeepMTL can successfully localize two transmitters as close as 3 pixels apart. When a pixel represents a $10 \times 10$ m area, then it is 30 meters apart. If a pixel represents a smaller area, such as $1 \times 1$ m, it has the potential to localize two transmitters as close as 3 meters apart.

Two YOLO Thresholds. YOLO has two important thresholds to tune that can directly control the miss rate and false alarm rate. One is the confidence threshold ($conf$) and the other is the non-maximum suppression threshold ($nms$). An object will be recognized as a peak only if its confidence level is larger than $conf$. If two recognized peaks’ bounding boxes overlap is high, and their intersection of union is higher than $nms$, then the two peaks will be considered as one peak, i.e. only the peak with higher $conf$ keeps. We pick $conf = 0.8$ and $nms = 0.5$ for DeepMTL. A higher $conf$ will bring less false alarm rate but a higher miss rate. A higher $nms$ will bring less miss rate but a higher false alarm rate.

7.2. DeepMTL vs. Prior Works

In this subsection, we compare DeepMTL with SPlot, $MAP^*$, DeepTxFinder in both log-distance (Fig. 13, 14, 15) and SPLAT (Fig. 16, 17, 18) propagation models and thus, datasets. We observe similar performance trends for both datasets, i.e., DeepMTL significantly outperforms the other approaches by a large margin (in many cases, by more than 50% in localization errors, false alarms, and miss rates). For all techniques, as expected, the performance is generally worse in the SPLAT dataset compared to the log-distance dataset.

Varying Number of Transmitters. Fig. 13 and Fig. 16 show the localization error with varying number of transmitters, in the two datasets. We see that DeepMTL has a mean localization error of only 2 to 2.5 meters (roughly, 1/4-th of the side
length of a pixel/grid cell) in the log-distance dataset and about 5 to 6 meters in the SPLAT dataset. In comparison, the localization errors of MAP*, SPLIT, DeepTxFinder are two to three times, eight to nine times, and few tens of times respectively more than that of DeepMTL. Fig. 14 and Fig. 17 show the miss and false alarm rates with varying number of transmitters in the two datasets. We observe that DeepMTL’s summation of miss and false alarm rate is only 1% even at 10 transmitters in the log-distance dataset, and about 4% for the case of SPLAT! dataset. In comparison, the summation of miss and false alarm rates for other schemes is at least 6% and 10% respectively for the two datasets, when there are 10 transmitters.

Varying Sensor Density. Fig. 15 and Fig. 18 plot the performance of various algorithms for varying sensor density in the two datasets. For very low sensor density of 1%, all algorithms perform badly (in comparison with higher sensor densities), but DeepMTL still performs the best except that MAP* performs best at 1% in terms of false alarm rate and miss rate. For higher sensor densities, we
observe a similar performance trend as above—i.e., DeepMTL easily outperforms the other schemes by a large margin. For the SPLAT! dataset at the 6% sensor density, the summation of false alarm rate and miss rate is 2%, higher than the 1% summation for the log-distance dataset.

Running Times. The run time of DeepMTL (in tens of milliseconds) is orders of magnitude faster than MAP* and SPLOT (both in seconds). See Table 2. The DeepMTL run time is an order of magnitude slower than DeepTxFinder (in a few milliseconds), due to the deep YOLOv3-cust taking up over 90% of the run time.

Summary and Analysis. In summary, our approach significantly outperforms the other approaches in all the accuracy performance metrics, as well as in terms of latency. In particular, our approach also significantly outperforms the other CNN-based approach DeepTxFinder. The main reason for DeepTxFinder’s inferior performance is its inability to accurately predict the number of TXs—which forms a fundamental component of their technique. In contrast, DeepMTL can circumvent explicit pre-prediction of number of transmitters by using a well-developed object-detection technique which works well for multiple objects especially in our context of simple objects.
Figure 18: (a) Localization error, and (b) miss and false alarm rates, of DeepMTL, MAP∗, SPLIT, and DeepTxFinder for varying sensor densities in the SPLAT! Dataset.

Figure 19: Localization error for varying number of transmitters when the first and second step of DeepMTL are trained on different training dataset.

7.3. Transfer Learning

We demonstrate transfer learning (generalizability) by showing that the second step in DeepMTL doesn’t need to be retrained for different channel models and terrains. In the previous experiments, the two steps of DeepMTL are both trained in the same setting, either log-distance or SPLAT!. We do the following two combinations to show that the second step doesn’t need to retrain:

1. The first step is trained in the log-distance setting and the second step is trained in the SPLAT! setting. Tested on the log-distance data.

2. The first step is trained in the SPLAT! setting and the second step is trained in the log-distance setting. Tested on the SPLAT! data.

In both combinations, the second step YOLOv3-cust is trained on a different dataset compared to the first step sen2peak. Fig. 19a shows the localization
error increases one-third in combination 1 compared to the case where both the first and second steps are trained on log-distance dataset. Fig. 19b shows the localization error increases only five percent in combination 2 comparing the case where both the first and second steps are trained on SPLAT! dataset. The miss rate and false alarm rate for both combinations also increase minimally, i.e. the summation of miss rate and false alarm rate only increases around 1% in absolute value. See Fig. 20. This implies that the second step of DeepMTL, YOLOv3-cust, is general and doesn’t need to retrain for different channel models and terrains. This is because the first step sen2peak is translating sensor readings images from different geographical areas to the same Gaussian peaks. The first step sen2peak still needs to be retrained for different situations to translate the sensor readings to the peaks.

7.4. **Localize Intruders in the Presence of Authorized Users**

The previous experiment setting is based on the assumption that all transmitters we are localizing are intruders. Different than the previous setting, here, we put five authorized users and they are spread out in the field, so those five won’t interfere with each other. This is the more general version of the MTL problem, where there are some authorized users in the background. Fig. 21 shows the localization error of two approaches localizing intruders in the presence of five authorized users with a varying number of intruders. It is observed that the first approach, localize then remove authorized users, has a ten to twenty percent smaller localization error compared to the second approach, subtract authorized user power then localize. This is due to the inaccuracy of power subtraction from the SubtractNet. Fig. 22 shows the miss and false alarm of two approaches localizing intruders in the presence of five authorized users with a varying number of intruders. It is observed that the second approach, subtract authorized TX power then localize, is having a high false alarm when the number of intruders is 3 or less. So for SubtractNet, subtracting the power of 5 background authorized users from 6 transmitters (5 out of 6 transmitters
are authorized users, 1 intruder) is relatively more difficult than subtracting the power of 5 authorized users from 9 users (5 out of 9 transmitters are authorized users, 4 intruders). Also statistically, getting 1 false alarm when there are 1 intruder and 5 authorized users is 100% false alarm rate, while getting 1 false alarm when there are 2 intruders and 5 authorized users is only 50% false alarm rate (the denominator is the number of intruders). Therefore, the false alarm rate for 1 and 2 number of intruders looks to differ a lot but in reality, the false alarm cases don’t differ a lot). When the number of intruders is 3 or 4, the two approaches are comparable. But when the number of intruders is larger than 4, the second approach is having a lower miss and false alarm rate. In summary, the two approaches both have their strengths. The main advantage for the second approach is that the sum of miss rate and false alarm rate is lower when the number of intruders is large.

7.5. Power Estimation Evaluation

In this subsection, we evaluate the transmitter power estimation performance. In all experiments, the power range is 5 dB. The power error is presented in absolute value. A power error of 0.5 dB implies a relative power error
of 10%. First, we compare the single transmitter power estimation between MAP$^\ast$ and PredPower, and then compare the multiple transmitter power estimation between MAP$^\ast$, PredPower with error correction, and PredPower with error correction.

Figure 23(a) shows the performance of single transmitter power estimation in the log-distance propagation model scenario with varying sensor density. In this case, MAP$^\ast$ has a 10 to 20 percent smaller power estimation error. Figure 23(b) shows the performance of single transmitter power estimation in the SPLAT! model with varying sensor density. In this case, PredPower is significantly lower in power error. So in average, PredPower outperforms MAP$^\ast$ in single transmitter power estimation. We can also conclude that for PredPower, a higher sensor density will decrease the power estimation error. While a 2% of sensor density will lead to a higher error, a sensor density of 6% is enough to give relatively good results.

For multiple transmitter power estimation, we compare three methods in two propagation models and show that PredPower with error correction has the best performance among the three methods. PredPower without error correction is expected to perform the worst and it suggests that the post-processing error correction stage for PredPower is important and works well. Figure 24 shows the power estimation error of three methods with a varying number of transmitters while the sensor density is 6%. In this figure, MAP$^\ast$ is the best only when the number of transmitters is one (which is consistent with Fig 23(a)). Also the number of transmitters is one is the only case when PredPower with correction and without correction has the same performance. This is also expected because there is no need to error correction when there is only one transmitter in the area. In all other cases, we see that PredPower with error correction is the best, PredPower without error correction is the worst, and MAP$^\ast$ is in the middle. In Figure 25, which shows experiment results running in the SPLAT! propagation model, we see a similar pattern compared to Figure 24. The difference is that PredPower with error correction is always the best and the power error is larger
Figure 24: The transmitter power estimation error of MAP*, PredPower with and without correction in Log-distance model for varying number of intruders.

Figure 25: The transmitter power estimation error of MAP*, PredPower with and without correction in Longley-Rice Irregular Terrain with Obstruction Model (SPLAT!) for varying number of intruders.

than the log-distance model scenario. For example in Figure 24, the power estimation error for PredPower with error correction goes up to 0.6 dB, whereas in Figure 25, the error goes up to 1 dB.

7.6. Evaluation over Testbed Data

In this subsection, we show that our DeepMTL performs well in real-world collected data. In [5], we conducted a testbed in a parking area of dimension $32m \times 32m$. Each grid cell has a size of $3.2m \times 3.2m$, thus giving us a total of 100 grid cells. We place a total of 18 sensors on the ground. The sensors consist of Odroid-C2 (a single-board computer) connected to an RTL-SDR dongle and the RTL-SDR uses dipole antennas. The transmitters are USRP or HackRF connecting to a laptop. We collect raw Inphase-Quadrature (I/Q) samples from the RTL-SDR at the 915 MHz ISM band. We perform FFT on the I/Q samples.

---

7 We have made this dataset publicly available at: https://github.com/Wings-Lab/IPSN-2020-data
with a bin size of 256 samples to get the signal power values, and then utilize the mean and standard deviation of the power at frequency 915 MHz reported from each of the sensors. However, this data collected from a testbed cannot directly be used in DeepMTL because the grid size of the area is 10 × 10, not 100 × 100. So we do the following two steps to make this testbed data usable for DeepMTL.

1. Step 1. Increase the granularity from 10 × 10 to 20 × 20. We call this 20 × 20 grid a tile. A cell in the original grid will be split into four equally smaller cells in the new grid. Only the lower-left cell among the four cells will represent the cell in the original grid.

2. Step 2. Duplicate the tile 25 times (5 rows, 5 columns) to generate a 100 × 100 grid, which represents an area of 160m × 160m.

This new 100 × 100 size image dataset will have a sensor density of 4.5% (18 sensors in a tile, 450 sensors in the 100 × 100 grid). The transmitters, however, cannot be placed at every possible location. For every tile generated in the first step above, the transmitters will not be located at the edges. Because there will be no RSSI data for the sensors at the edge of neighbor tiles. We choose the edge to be length 4. When a transmitter is inside a tile, only the sensors inside the same tile are going to receive any signals from that transmitter and all sensors in the other tiles will get noise floor. Also, the increase in granularity in step 1 results in every 3 out of 4 cells not being able to place a transmitter, because there will be no data for these 3 cells. So for each tile, the legit cell locations for a transmitter is \((20 - 4 \times 2)^2 \div 4 = 36\). Given 25 tiles, the total legit cell locations for a transmitter in the 100 × 100 grid is \(36 \times 25 = 900\). When a transmitter is inside a cell, we collect 30 samples, 20 of them go into the training dataset while the other goes into the testing dataset. So the training dataset consists of 18000 samples while the testing dataset consists of 9000 samples. When we have the data for a single transmitter, we can simulate the data for multiple transmitters. Thus, we can generate a 100 × 100 input data that can be used by DeepMTL from a much smaller size data.

The performance of DeepMTL on this real world based data is shown in Fig. 26. Compared to DeepTxFinder, DeepMTL is significantly better in all localization error and false alarm rate and miss rate, which aligns to the results in the previous subsections based on data generated from either log-distance model or SPLAT!. The localization error of DeepMTL in Fig. 26 (a) is around 2 meters. The error increases mildly with the increase in the number of transmitters. Compared to the SPLAT! data results (Fig. 16), though the error is different, they both achieve sub-pixel level accuracy (a pixel represents a different area size). The sum of false alarm rate and miss rate is 3% when the number of transmitters is 5 and is slightly more than 6% when the number of transmitters is 10. The results are a little bit worse than the numbers in SPLAT! data (Fig. 17), where the sum is 2% for 5 transmitters and 4% for 10 transmitters.
8. Related Work

**Spectrum sensing** is usually being realized by some distributed crowdsourced low-cost sensors. Electrosense [33] and its follow up work Skysense [34] are typical work of spectrum sensing. In this crowdsourced sensing paradigm [7], sensors collect I/Q samples (in-phase and quadrature components of raw signals) and compute PSD (power spectral density), which is RSSI. Crowdsourced low-cost sensors do not have the capability to collect TOA (time of arrival) or AOA (angle of arrival) data because they require more expensive hardware. Spectrum sensing platforms serve as the foundation of spectrum applications, and transmitter localization is one of the main applications. Other applications include signal classification [35], spectrum anomaly detection [36], sensor selection [37, 38], etc.

**Transmitter localization.** Localization of an intruder in a field using sensor observations has been widely studied, but most of the works have focused on localization of a single intruder [39, 40]. In general, to localize multiple intruders, the main challenge comes from the need to “separate” powers at the sensors [11], i.e., to divide the total received power into power received from individual intruders. Blind source separation is a very challenging problem; only very limited settings allow for known techniques using sophisticated receivers [42, 36]. We note that (indoor) localization of a device [11] based on signals received from multiple reference points (e.g., WiFi access points) is a quite different problem (see [43] for a recent survey), as the signals from reference points remain separate, and localization or tracking of multiple devices can be done independently. Recent works on multi-target localization/tracking such as [44] are different in the way that targets are passive, instead of active transmitters in the MTL problem. Among other related works, [45] addresses the challenge of handling time-skewed sensors observations in the MTL problem.

**Deep learning for localization.** Quite a few recent works have harnessed the power of deep learning in the general topic of localization. E.g., DeepFi
in [46] designs a restricted Boltzmann machine that localizes a single target using WiFi CSI amplitude data. DLoc in [15] uses WiFi CSI data as well. Its novelty is to transform CSI data into an image and then uses an image-to-image translation method to localize a single target. MonoDCell in [47] designs an LSTM that localizes a single target in indoor environment using cellular RSSI data. DeepTxFinder in [6] uses CNN to address the same MTL problem using RSSI data in this paper. Localization techniques mainly fall into two categories: fingerprinting-based and geometry mapping. Geometry mapping mainly has two subcategories: ranging-based (via RSSI, time of arrival, time difference of arrival) and direction-based (via angle of arrival). Fingerprinting-based methods can use all signal physical measurements including but not limited to amplitude, RSSI, time of arrival, time difference of arrival, and angle of arrival. Whenever deep learning is used for localization, it can be considered as a fingerprinting-based method, since it requires a training phase to survey the area of interest and a test phase to search for the most likely location.

Transmitter Power Estimation. There are several work that estimate the transmission power of a single transmitter. [28] studies the “blind” estimation of transmission power based on received-power measurements at multiple cooperative sensor nodes using maximum likelihood estimation. Blind means there is no prior knowledge of the location of the transmitter or transmit power. [27] propose an iterative technique that jointly estimate the location and power of a single primary transmitter. In [29], the primary transmitter location and power is jointly estimated by a constrained optimization method without the prior information of the transmission power. [5] uses the maximum likelihood estimation method to estimate the power of an isolated single transmitter and adopts an online learning method to estimate the power of multiple close-by transmitters simultaneously.

9. Conclusion

In this paper, we have designed and developed some novel deep-learning based scheme (DeepMTL) for the multiple transmitter localization (MTL) problem. We extended this problem to localizing the intruders in the presence of authorized users and developed a novel technique to solve it. We also developed a novel technique that can solve the multiple transmitter power estimation (MTPE) problem. Solving the general MTL and MTPE are both achieved by utilizing our robust DeepMTL as a building block. We evaluated all our methods extensively through data simulated from two propagation models as well as a small-scale data collected from a real world testbed. Our developed technique outperforms prior approaches by a significant margin in all performance metrics.
