The transition from a specified germ cell to a population of pluripotent cells occurs rapidly following fertilization. During this developmental transition, the zygotic genome is largely transcriptionally quiescent and undergoes significant chromatin remodeling. In Drosophila, the DNA-binding protein Zelda (also known as Vielfaltig) is required for this transition and for transcriptional activation of the zygotic genome. Open chromatin is associated with Zelda-bound loci, as well as more generally with regions of active transcription. Nonetheless, the extent to which Zelda influences chromatin accessibility across the genome is largely unknown. Here we used formaldehyde-assisted isolation of regulatory elements to determine the role of Zelda in regulating regions of open chromatin in the early embryo. We demonstrate that Zelda is essential for hundreds of regions of open chromatin. This Zelda-mediated chromatin accessibility facilitates transcription-factor recruitment and early gene expression. Thus, Zelda possesses some key characteristics of a pioneer factor. Unexpectedly, chromatin at a large subset of Zelda-bound regions remains open even in the absence of Zelda. The GAGA factor-binding motif and embryonic GAGA factor binding are specifically enriched in these regions. We propose that both Zelda and GAGA factor function to specify sites of open chromatin and together facilitate the remodeling of the early embryonic genome.

[Supplemental material is available for this article.]

Although it is widely accepted that chromatin structure is re-configured during early embryonic development, little is known about the factors that direct this process. These changes in chromatin structure accompany the transition from a specified germ cell to a population of pluripotent cells, which occurs rapidly following fertilization. At this time the zygotic genome is not transcribed, and maternally contributed mRNAs and proteins control embryonic development. Only at later cell cycles is widespread transcription initiated (Newport and Kirschner 1982; Tadros and Lipshitz 2009). The degradation of maternally deposited mRNAs is coordinated with the transcriptional activation of the zygotic genome during the maternal-to-zygotic transition (MZT). This fundamental transition is conserved among metazoans and is essential for development.

In Drosophila melanogaster, early development is characterized by a series of 13 rapid synchronous nuclear divisions. Approximately 2–3 h after fertilization, at the 14th nuclear cycle, the division cycle slows and widespread zygotic transcription initiates. This marks the end of the D. melanogaster MZT. Maternally deposited zelda (zld; also known as vielfaltig) mRNA is necessary for zygotic genome activation and development beyond the MZT (Staudt et al. 2006; Liang et al. 2008). Previous work has demonstrated that loci bound by Zelda (Zld) as early as nuclear...
cycle 8 are associated with regions of open chromatin and transcription factor binding at cycle 14 (Li et al. 2008; MacArthur et al. 2009; Harrison et al. 2011). Indeed, Zld binding at early time points is a robust predictor of subsequent transcription factor binding (Harrison et al. 2011), and it has recently been shown that Zld-binding sites are instrumental in regulating DNA binding by the transcription factors Dorsal (DI), Twist (Twi), and Bicoid (Bcd) (Yanez-Cuna et al. 2012; Foo et al. 2014; Xu et al. 2014). Furthermore, it has been proposed that Zld acts to potentiate transcription factor binding by determining regions of open chromatin (Harrison et al. 2011; Satija and Bradley 2012). At regions bound by Zld in wild-type embryos, histone H3 density increases when Zld is depleted (Li et al. 2014), supporting this hypothesis. Additionally, chromatin accessibility as assayed by DNase I accessibility is correlated with levels of Zld binding to the brinker (brk) and short gastrulation (sog) enhancers (Foo et al. 2014). Nonetheless, it is unknown whether Zld is required for open chromatin at all of the thousands of loci to which it binds. Furthermore, whether Zld-mediated chromatin accessibility facilitates transcription factor binding remains to be determined.

Here, we directly test the role of Zld in shaping the chromatin environment during the MZT. We used formaldehyde-assisted isolation of regulatory elements (FAIRE) (Giresi et al. 2007; McKay and Lieb 2013) to perform genome-wide profiling of open chromatin in embryos lacking maternal Zld (zld<sup>M</sup>).

**Results**

Zld establishes or maintains regions of open chromatin

We have previously shown that Zld-bound regions are highly correlated with DNA accessibility (Harrison et al. 2011). To test the function of Zld in establishing or maintaining these regions of open chromatin, we performed FAIRE on 2–3 h embryos with wild-type levels of Zld (yw) and embryos depleted for maternally contributed Zld (zld<sup>M</sup>) (Liang et al. 2008). Obtaining embryos depleted for maternal Zld requires generating germline clones using heat-shock-induced mitotic recombination (Chou et al. 1993; Liang et al. 2008). Thus to control for any influence of this protocol on chromatin accessibility, we generated germline clones in our yw control strain in parallel with our zld mutant strain. Immunostaining confirmed the successful generation of embryos lacking Zld (Supplemental Fig. S1). We sequenced and analyzed three biological replicates of the zld<sup>M</sup> embryos and two replicates of the yw control embryos. Regions enriched by FAIRE in our 2–3 h yw control embryos correlated well with the regions enriched in 2–4 h wild-type (OreR) embryos (cf. yw control FAIRE to OreR FAIRE; Spearman’s rho = 0.75) (Fig. 1A; Supplemental Fig. S2; McKay and Lieb 2013). Differences between the two samples are likely the result of the different developmental time points at which the samples were collected, as well as any effects from the induction of germline clones.

Because active cis-regulatory regions are correlated with chromatin accessibility (Fisher et al. 2012), we focused our analysis on the high-confidence open regions. Specifically, we took the top 5000 peaks in our zld<sup>M</sup> data set (MACS adjusted –log10 P-value = 39) and controlled for differences in data quality between the experimental and control by similarly selecting the top 5000 peaks from the yw control (MACS adjusted –log10 P-value = 18). To determine how chromatin accessibility changed when maternal Zld was removed, we took the union of the top 5000 peaks from both of our data sets (resulting in 6042 peak regions along the fly genome) and used edgeR to identify differentially accessible

Figure 1. Zld is required to maintain or establish discrete regions of open chromatin. (A) Normalized FAIRE-seq and ChIP-seq read profiles as labeled on the left for two genomic regions. FAIRE data for yw and zld<sup>M</sup> embryos (this study). FAIRE data for 2–4 h OreR (wild-type) embryos from McKay and Lieb (2013). ChIP data for Zld from Harrison et al. (2011), for Bcd from Xu et al. (2014), and for GAF from Negre et al. (2011). Genes are shown at the bottom with arrows to indicate direction of transcription. Boxes indicate different classes of FAIRE peaks: blue box, differential, Zld-bound; dark orange box, constitutive, Zld-bound; and light orange box, constitutive, not Zld-bound. (B) Scatter plot of the FAIRE signal from yw embryos versus the FAIRE signal from zld<sup>M</sup> embryos. Black dots indicate the union set of regions identified by FAIRE in both yw and zld<sup>M</sup> embryos. Colored dots indicate differential peaks identified by edgeR. Colors represent P-values (≤0.05) as indicated by the scale. (C) Pie charts showing the genomic distribution of FAIRE peaks, Zld-binding sites, and CAGGTAG motifs to promoters, genes, introns, and intergenic regions as shown.
Zelda shapes chromatin accessibility at the MZT

Zld binds to promoters and enhancers of genes expressed through the MZT (Fig. 1C; Harrison et al. 2011; Nien et al. 2011). To assess which genomic regions might be particularly dependent on Zld for chromatin accessibility, we determined the distribution of FAIRE peaks that were specific to the yw control (yw differential). FAIRE peaks that were accessible in both yw and zldM embryos (constitutive), and FAIRE peaks specific to the zldM embryos (zldM differential) (Fig. 1C). The observed distribution of FAIRE peaks that require Zld (yw differential) was similar to the distribution of regions bound by Zld in vivo and of CAGGTAG motifs (Fig. 1C), suggesting that Zld functions to establish or maintain chromatin accessibility at both promoters and enhancers. In contrast, the peaks specific to the zldM (zldM differential) showed a genomic distribution substantially different from Zld binding and CAGGTAG motifs, with a strong enrichment in intergenic regions.

Zld is not essential for chromatin accessibility at many Zld-bound loci

During the initial analysis of our FAIRE data, we identified three classes of FAIRE peaks that we had expected to identify. First, fitting with the predicted role of Zld as a pioneer-like factor, we identified Zld-bound loci that required Zld for chromatin accessibility. Second, we identified a large class of FAIRE peaks that did not bind Zld or require Zld for accessibility. Chromatin accessibility in these regions likely resulted from the activities of other proteins or from inherent DNA-sequence structure. Third, we identified a small number of regions that depend on Zld for accessibility but are not Zld bound, which are likely due to indirect effects of Zld depletion. However, our analysis unexpectedly revealed, in addition to these three classes, a large class of FAIRE peaks that overlapped Zld-bound regions but remained accessible in zldM embryos. Thus, while Zld was required for chromatin accessibility at 540 loci, there were nearly three times as many loci (1537) that were bound by Zld but did not require Zld occupancy for accessibility.

For further analysis, we therefore divided the 5000 top FAIRE peaks from our yw embryos into four categories: differential, Zld-bound (402 peaks); constitutive, Zld-bound (1537 peaks); differential, not Zld-bound (138 peaks); and constitutive, not Zld-bound (2923 peaks) (Fig. 2A). Examples of these different classes are highlighted in the regulatory regions surrounding both dpn and sog (Fig. 1A). The average FAIRE signals from the differential and constitutive peaks were generally similar. However, the differential peaks showed a slightly lower level of FAIRE signal, especially those differential peaks that did not overlap Zld-bound regions (differential, not Zld-bound) (Fig. 2B). As defined, the FAIRE peaks for the differential class are substantially decreased in the zldM embryos (Fig. 2B). Additionally, there was no detectable difference between the average FAIRE signals from constitutive regions either bound or not bound by Zld (Fig. 2B). Thus, the strength of the FAIRE signal is unlikely to explain the differences between these four classes.

When we used sequence surrounding the FAIRE peaks to predict nucleosome occupancy (Kaplan et al. 2009), we did not identify a predicted region of nucleosome depletion at the FAIRE peaks in any of the four classes (Fig. 2C). On the contrary, we found that sequences underlying FAIRE peaks are predicted to have higher nucleosome occupancy, consistent with previous observations (McKay and Lieb 2013). This analysis suggests that the underlying sequence alone does not explain the open chromatin identified by

---

Table 1. Enrichment of Zld-binding motifs and in vivo Zld-binding sites (with Zld) in FAIRE peaks

|                  | CAGGTAG | CAGGTA | Total |
|------------------|---------|--------|-------|
| **yw differential** |         |        |       |
| Total            | 45%     | 244    | 67%   | 361   | 540   |
| With Zld         | 61%     | 244    | 87%   | 351   | 402   |
| Without Zld      | 0%      | 0      | 7%    | 10    | 138   |
| **Constitutive** |         |        |       |
| Total            | 8.3%    | 370    | 20%   | 900   | 4460  |
| With Zld         | 21%     | 321    | 45%   | 692   | 1537  |
| Without Zld      | 1.7%    | 49     | 7%    | 208   | 2923  |
| zldM differential|         |        |       |
| Total            | 0.7%    | 1      | 6%    | 9     | 145   |

| Without Zld      | 1%      | 1      | 3%    | 4     | 123   |

Without Zld indicates no in vivo bound ZLD was identified by ChIP-seq (Harrison et al. 2011).
FAIRE at any of these regions and that active mechanisms are likely working to create or maintain chromatin accessibility. To better define the features that determine chromatin accessibility in the early embryo, we focused our analysis on characterizing these classes of FAIRE peaks.

A large number of promoters do not require Zld for accessibility

Many factors are known to shape chromatin accessibility so we were not surprised to identify a relatively large class of FAIRE peaks that were unchanged in the absence of Zld and that did not possess Zld-binding sites (constitutive, not Zld-bound; n = 2923). When we analyzed the distribution of these regions throughout the genome, we noted they were highly enriched for promoter regions with ~70% of these FAIRE peaks being localized to promoters (Fig. 2D). Promoters, especially of transcriptionally active genes, are known to be relatively nucleosome free in a wide variety of species (Lee et al. 2007; Schones et al. 2008; Weiner et al. 2010; Thomas et al. 2011; Valouev et al. 2011). In zebrafish, well-positioned nucleosome arrays appear at promoters during zygotic genome activation in a transcription-independent fashion, suggesting that active mechanisms may shape nucleosome occupancy at promoters during early development (Zhang et al. 2014). When we searched for motifs enriched among these constitutively open peaks, all k-mers identified were highly AT rich (Supplemental Table 1). AT-rich sequences were also enriched when we analyzed all FAIRE peaks lacking Zld compared with all FAIRE peaks with Zld bound. AT-rich sequences are associated with decreased nucleosome occupancy and have also been shown to be enriched at promoters (Sekinger et al. 2005; Hughes et al. 2012). Because the underlying sequence does not predict any inherent decrease in nucleosome occupancy at FAIRE peaks that are independent of Zld binding (constitutive, not Zld-bound) (Fig. 2C), we suggest the identification of the AT-rich sequence motif in these regions likely results from the fact that this sets of peaks is enriched for promoters and does not by itself explain the open chromatin at these regions.

Zld-mediated chromatin accessibility is associated with early gene expression

Our analysis of the top FAIRE peaks demonstrated that there were two classes of accessible chromatin regions bound by Zld: those that required Zld for accessibility (differential, ZLD-bound; n = 402) and those that did not (constitutive, Zld-bound; n = 1537). To begin to differentiate between these two classes of Zld-bound loci, we used ChiP-seq data to determine the relative strength of Zld binding at nuclear cycle 14 (Harrison et al. 2011). Constitutive peaks with Zld bound (constitutive, Zld-bound) had on average threefold lower Zld ChiP-signal than those that were dependent on Zld for accessibility (differential, Zld-bound) (Fig. 3A). This shows that regions highly occupied by Zld in vivo are more dependent on Zld for establishing or maintaining chromatin accessibility than those less-occupied sites (see also Supplemental Fig. S3). We have previously shown that levels of Zld binding are correlated with the timing of gene expression; regions with higher Zld ChiP-seq signal are expressed earlier in embryonic development (Harrison et al. 2011). This suggests that regions that depend on Zld for accessibility may be enriched near genes that require Zld for expression.

To test the functional impact of Zld-mediated chromatin accessibility on gene expression, we performed RNA-seq from single embryos and compared stage 5 zld<sup>M</sup> to <i>yw</i> controls. We then associated FAIRE peaks with the nearest gene and identified what percentage of these FAIRE-associated genes require Zld for robust expression. Because Zld is known to act as a transcriptional activator (Liang et al. 2008), we focused on genes whose expression decreased by greater than twofold in the <i>zld</i><sup>M</sup> embryos. The analysis shows that 48% of genes associated with Zld-dependent FAIRE peaks (differential, Zld-bound) had a greater than twofold decrease in expression in the absence of Zld compared with only 18% for all FAIRE peaks (Fig. 3B). Those regions that do not depend on Zld for accessibility (constitutive, Zld-bound) were also enriched near genes that require Zld for expression, but to a lesser degree than those genes near regions that require Zld for open chromatin (differential, Zld-bound). However, the large amount of maternally supplied RNA in the early embryo masked any changes in expression of genes transcribed both maternally and zygotically. Thus, our RNA-seq only identified changes in gene expression for those genes that are exclusively zygotically expressed. For this reason, the actual numbers of down-regulated genes in the <i>zld</i><sup>M</sup> embryos may be larger than reported. To independently verify these results, we repeated our gene expression analysis using published microarray data (Liang et al. 2008) and similarly demonstrated that those regions that require Zld for accessibility were...
enriched near genes that require Zld for expression (Supplemental Fig. S4).

Zld influences expression of both a small number of genes expressed early in the MZT, as well as a large number of genes expressed at nuclear cycle 14. To determine if Zld-mediated accessibility might specifically drive expression of either one of these sets of genes, we used a high-temporal resolution data set to examine the relationship between Zld-mediated chromatin accessibility and the timing of gene expression (Lott et al. 2011). Genes were grouped based on their timing of initial expression (Li et al. 2014), and we analyzed the correlation between Zld-mediated changes in gene expression and FAIRE signal for 83 genes expressed at nuclear cycles 10–11 (C) or 91 genes expressed at late nuclear cycle 14 (D). $r = \text{Spearman’s correlation coefficient.}$

We recently mapped the location of nine histone modifications at four different developmental times spanning the MZT using ChIP-seq (Li et al. 2014) and demonstrated that acetylation of three different lysines on two different histones (H3K18, H3K27, and H4K8) correlated with Zld binding, especially early in development (Li et al. 2014). Thus we speculated that Zld-mediated chromatin accessibility might correlate with specific histone modifications. To further investigate the connection between chromatin accessibility and early gene expression, we examined the relationship between chromatin accessibility and histone modifications during the MZT. We analyzed the enrichment of acetylation and methylation marks around our four classes of FAIRE peaks (Fig. 4; Supplemental Fig. S6). Prior to widespread zygotic genome activation (at cycles 8 and 12), H3K18ac and H4K8ac were enriched on nucleosomes surrounding the Zld-bound regions that require Zld for accessibility (differential, Zld-bound) (Fig. 4). Similar enrichment was not evident at constitutively open regions or those that lack Zld binding (constitutive, Zld-bound; constitutive, not Zld-bound, differential, not Zld-bound) (Fig. 4). Thus, Zld-mediated chromatin accessibility, and not Zld-binding in general, is correlated with early histone acetylation. We previously demonstrated that these early acetylation marks are associated with early expressed genes (Li et al. 2014), strengthening the connection between regions that require Zld for accessibility and early gene expression. Furthermore, H3K18ac levels are decreased in zld$^{M}$ embryos (Li et al. 2014), demonstrating that Zld is required for H3K18 acetylation at specific regions. Together with our FAIRE data, this suggests that Zld may potentiate chromatin accessibility and early gene expression by increasing histone acetylation.

**Regions that require Zld for chromatin accessibility also require Zld for Bcd binding**

One mechanism by which Zld may activate gene expression is by facilitating transcription factor binding. We have previously demonstrated that early Zld binding is predictive of where transcription factors will later bind (Harrison et al. 2011), and it has been recently reported that Zld promotes binding of the transcription factors Twi, Dl, and Bcd to DNA (Yanez-Cuna et al. 2012; Foo et al. 2014; Xu et al. 2014). To determine if Zld enabled binding of these proteins by creating open regions of chromatin, we reanalyzed a published ChIP-seq data set identifying Bcd-binding sites in both wild-type embryos and those lacking maternal zld (Xu et al. 2014). Previous analysis had shown that Bcd binding is partially redistributed when Zld is absent. Specifically, Bcd binding in the mutant was decreased at a large number of sites that overlap with Zld-bound regions (Xu et al. 2014). Comparing our four
classes of peaks with the Bcd ChIP-seq data set demonstrated that Bcd binds preferentially to Zld-bound loci, both those that require Zld for accessibility and those that do not (Fig. 5A), and the average Bcd ChIP-signal at these two classes of Zld-bound regions is approximately equivalent (Fig. 5A). We identified a preferential reduction in Bcd binding at the differential peaks with Zld bound (differential, Zld-bound) compared with the constitutively open peaks with Zld bound (constitutive, Zld-bound) upon Zld depletion (Fig. 5B). This is demonstrated by the regulatory regions of dpn and sog (Fig. 1A). In these examples, promoter proximal FAIRE peaks do not require Zld for accessibility or Bcd binding (dark orange box), while neighboring enhancers lose both chromatin accessibility and Bcd binding in the absence of Zld (blue box). This shows that Zld-dependent Bcd binding is correlated with Zld-mediated chromatin accessibility and not just with Zld binding. Together this suggests that Zld facilitates transcription factor binding through the establishment or maintenance of open chromatin.

Collective binding by a large number of transcription factors does not distinguish between Zld-bound FAIRE classes

In addition to being associated with regions of open chromatin, another feature correlated with Zld-bound loci is occupancy by a large number of transcription factors (Li et al. 2008; MacArthur et al. 2009; Roy et al. 2010; Kvon et al. 2012). These regions have been termed highly occupied target (HOT) regions and have been identified in a wide variety of organisms (Moorman et al. 2006; The ENCODE Project Consortium 2007; Li et al. 2008; MacArthur et al. 2009; Gerstein et al. 2010; Roy et al. 2010; Negre et al. 2011). Thus it was possible that Zld-bound regions that do not require Zld for accessibility are maintained in an open chromatin state by binding of a large number of additional factors. To determine if this was the case, we analyzed the number of transcription factors bound in vivo to each of the four classes of FAIRE peaks. As expected, we showed that FAIRE peaks overlapping Zld-bound regions were enriched for binding by more than 10 transcription factors (constitutive, Zld-bound and differential, Zld-bound) (Fig. 6A). On average there were 2.5 times as many transcription factors present at Zld-bound FAIRE peaks than at FAIRE peaks that were not Zld bound (Fig. 6A). Thus, among regions of chromatin accessibility, Zld binding is correlated with those loci that are bound by a large number of transcription factors. Nonetheless, we found no obvious difference in the number of transcription factors bound when we compared Zld-bound peaks that depend on Zld for accessibility (differential, Zld-bound) to those that do not require Zld (constitutive, Zld-bound). This was also the case when we controlled for the fact that constitutive, Zld-bound peaks are enriched for promoters compared with differential, Zld-bound peaks by further subdividing each class by genome annotation (Supplemental Fig. 7). Thus, these data demonstrate that binding by a large number of transcription factors is not what functionally distinguishes these classes of Zld-bound regions and that some other feature must allow the chromatin to remain accessible in the absence of Zld at those regions that remain constitutively open.

Constitutively open Zld-bound loci contain GAGA motifs and are preferentially bound by GAGA factor

Because binding by a large number of transcription factors did not functionally distinguish between the two Zld-bound FAIRE classes, we proposed that binding by a specific transcription factor might maintain chromatin accessibility at constitutive, Zld-bound peaks in the absence of Zld. To determine potential factors, we identified motifs enriched in the DNA sequences underlying the FAIRE peaks. For both classes of peaks with Zld bound (differential and constitutive), we showed, as expected, that the most highly

Figure 4. Early histone acetylation is enriched around loci that require Zld for chromatin accessibility. (A,B) Distribution of ChIP-seq signals for H3K18ac (A) and H4K8ac (B) surrounding individual classes of FAIRE peaks at specific nuclear cycles during the early stages of embryonic development. Colors indicate the different FAIRE classes. Plots are centered on the FAIRE peak and oriented relative to the transcription start site of the nearest gene.

Figure 5. In the absence of Zld, Bcd binding is preferentially lost at those regions that lose chromatin accessibility. (A,B) Average Bcd binding in wild-type embryos (A) and embryos lacking maternal Zld (B) for each class of FAIRE peaks. Colors indicate the different FAIRE classes.
enriched motif was the canonical Zld-binding motif, CAGGTA (Fig. 6B; Supplemental Table 1). For the differential Zld-bound peaks, the next most highly enriched k-mers were overlapping or related to this canonical Zld-binding site (Supplemental Table 1; ten Bosch et al. 2006; Liang et al. 2008; Harrison et al. 2011; Nien et al. 2011; Struffi et al. 2011). However, for the constitutively open Zld-bound peaks, there was a strong enrichment for GAGA motifs (Fig. 6B; Supplemental Table 1), suggesting that these regions may be occupied by GAGA factor (GAF; encoded by the gene Trithorax-like [Trl]) in addition to Zld (Wilkins and Lis 1997). Importantly, GAF binding is strongly correlated with chromatin accessibility, and GAGA motifs are enriched in HOT regions (Lu et al. 1993; Kvon et al. 2012; Slattery et al. 2014). Because GAF-binding motifs are known to be enriched at promoters, it was possible that the identification of GAF-binding motifs in constitutive, Zld-bound peaks was a function of the fact that 39% of these peaks were in promoter regions compared with only 18% for the differential, Zld-bound peaks (Fig. 2D). Thus, we directly determined the enrichment of the GAF-binding motif in the constitutive, Zld-bound versus the differential, Zld-bound peaks for promoters, intergenic regions, intronic regions, and coding regions. We found that in all cases there was a significant enrichment of the GAF-binding motif in the constitutive, Zld-bound peaks. This enrichment was most significant at the intronic and intergenic peaks. Comparing GAGA motif enrichment in constitutive versus differential Zld-bound FAIRE peaks, we demonstrated that at intronic regions, 62% of constitutively accessible Zld-bound regions contained GAGA motifs, while only 25% of the introns that depended on Zld for accessibility (differential, Zld-bound) contained the motif ($P = 10^{-15}$). In intergenic regions, 20% of constitutively accessible Zld-bound regions had GAGA motifs in comparison to none of the differential, Zld-bound intergenic peaks ($P < 10^{-8}$). These analyses demonstrate that the GAF-binding motif is specifically enriched in the constitutive, Zld-bound regions independently of where in the genome these peaks are located.

Consistent with this sequence enrichment, GAF binding, as assayed by ChIP-seq in 0- to 8-h embryos (Negre et al. 2011), is enriched in those regions that are constitutively accessible and bound by Zld (constitutive, Zld-bound). Specifically, 52% (796/1537) of constitutively open Zld-bound regions overlap GAF peaks, compared with only 15% (59/402) of regions that depend on Zld for open chromatin (Fig. 6C, $P < 0.0001$). Thus both the GAF-binding site and embryonic GAF binding are specifically enriched at Zld-bound loci that remain accessible in the absence of Zld. Furthermore, only 28% (829/2923) of constitutively open regions that do not bind Zld overlap GAF-binding sites, indicating that in addition to GAF, other transcription factors may be required for open chromatin. Together, these data suggest that a subset of Zld-bound regions that do not change in accessibility in the zld$^{−}$ embryos remain open due to co-occupancy by GAF.

**Discussion**

We have used FAIRE to identify regions of open chromatin in the early embryo and determine the role of Zld in establishing or maintaining chromatin accessibility. We demonstrate on a genome-wide level that Zld is instrumental in defining specific regions of open chromatin. Furthermore, this Zld-mediated chromatin accessibility dictates both transcription factor binding and early gene expression. Unexpectedly, we discovered that most open chromatin regions to which Zld is bound do not absolutely require Zld for chromatin accessibility. At these regions, Zld may function redundantly with GAF to determine the chromatin state. We suggest that Zld directly mediates the very earliest gene expression by facilitating chromatin accessibility. At cycle 14, when thousands of genes are transcribed, Zld and GAF may coordinate to determine both regions of open chromatin and levels of gene expression.

**Zld-mediated chromatin accessibility facilitates transcription factor binding and early gene expression**

Zld is known to be instrumental in regulating expression of both the very first set of zygotic genes transcribed after fertilization, as well as a large set of genes transcribed at cycle 14. Zld is already bound to thousands of loci at cycle 10, including those that will not be activated until four nuclear cycles later during the major wave of genome activation (Harrison et al. 2011). This suggests that early Zld binding is poised genes for later activation. Nonetheless, it remains unclear what differentiates the small subset of Zld-bound loci that are transcribed early from the hundreds of Zld-bound genes activated at cycle 14. Here we demonstrate regions that require Zld for chromatin accessibility are correlated with the subset of genes transcribed prior to cycle 14 and with histone

**Figure 6.** GAF likely functions with Zld to define chromatin accessibility in the early embryo. (A) Mean number of transcription factors (TFs) bound to each class of FAIRE peaks. Colors indicate the different FAIRE classes. Error bars, SD. (B) Position weight matrices for the motifs enriched in the FAIRE peaks for each class compared with all of the top 5000 FAIRE peaks identified in yw embryos. Hypergeometric $P$-values are shown below each motif. The top three motifs for each class are shown (for additional motifs, see Supplemental Table 1). (C) Percentage of FAIRE peaks in each class that overlap a GAF-binding site as identified by ChIP-seq in 0- to 8-h embryos (Negre et al. 2011). Hypergeometric $P$-value is shown.
Zld-mediated transcriptional activation may be potentiati- ed by the subsequent binding of additional transcription factors. Early Zld binding is a robust predictor of where multiple additional transcription factors will later bind (Harrison et al. 2011). More recently, it has been shown that Zld is required for the DNA binding of three different transcription factors: Twi, Dl, and Bcd (Yanez-Cuna et al. 2012; Foo et al. 2014; Xu et al. 2014). Additionally, transgenic versions of the hmr and sog enhancers show a correlation between the number of Zld-binding sites and both DI binding and DNase I accessibility (Foo et al. 2014). Thus, prior work has clearly demonstrated a role for Zld in mediating transcription factor binding, but the mechanism by which Zld served this function was unclear. Here we demonstrate that Bcd binding is lost in zld<sup>5007</sup> embryos preferentially at those regions that depend on Zld for chromatin accessibility. These data show that Zld potentiates transcription factor binding through the establishment or mainte-
nance of open chromatin, and this is likely to be important for Zld-mediated transcriptional activation (Fig. 7).

The mechanism by which Zld establishes or maintains chro-
matin accessibility remains unknown. Unlike the pioneer fac-
tor FOXA1, which can bind open chromatin by binding through a winged-helix domain (Cirillo et al. 1998, 2002), the Zld DNA-
binding domain does not resemble that of a linker histone. Instead, Zld binds DNA through a cluster of four zinc fingers in the C terminus (Struffi et al. 2011; Hamm et al. 2015). In addition, Zld is a large protein with no recognizable enzymatic domains that activates transcription through a low-complexity protein domain (Hamm et al. 2015). Thus, Zld likely facilitates open chromatin through interactions with cofactors, and it is possible that recruitment of different cofactors to distinct Zld-bound loci could partially explain the differential requirement on Zld for chromatin acces-
sibility in the early embryo.

Zld binding but not Zld-mediated chromatin accessibility is a defining feature of HOT regions

HOT regions, loci that are bound by a large number of different transcription factors, have been identified in multiple organisms, including worms, flies, and humans (Moorman et al. 2006; The ENCODE Project Consortium 2007; Li et al. 2008; MacArthur et al. 2009; Gerstein et al. 2010; Roy et al. 2010; Negre et al. 2011). Unexpectedly, these HOT regions are not strongly enriched for the DNA-sequence motifs bound by the transcription factors that define them (Moorman et al. 2006; MacArthur et al. 2009; Gerstein et al. 2010; Roy et al. 2010). Instead, HOT regions are asso-
ciated with open chromatin, suggesting that chromatin accessi-

![Figure 7](https://www.genome.org)

**Figure 7.** Model for the role of Zld in defining chromatin accessibility at the MZT. (A) Zld determines chromatin accessibility at early embryonic enhancers, allowing other TFs access to their binding sites. (B) At a large subset of regions, Zld binds chromatin but is not required for accessibility. GAF facilitates open chromatin at regions that remain accessible in zld<sup>5007</sup> embryos, allowing transcription factors to bind to these loci. (C) Promoter regions are enriched among those regions that do not require Zld for accessibility.
genes expressed during cycle 14 (Fig. 3D). Instead, our data suggest that at loci associated with this later gene expression, GAF is functioning together with Zld to regulate chromatin accessibility and gene expression. Maternally deposited GAF is required for robust transcription and nuclear divisions during the MZT (Bhat et al. 1996; Lagha et al. 2013). GAF is thought to mediate transcription, at least in part, through a role in the establishment of poised polymerase (Shopland et al. 1995; Bhat et al. 1996; Lee et al. 2008). The fact that poised polymerase is not established until cycle 13 (Chen et al. 2013; Blythe and Wieschaus 2015) supports our model that GAF is required specifically for gene expression at cycles 13–14. Thus, we suggest that Zld-dependent early embryonic enhancers may be unique in that they rely only on Zld for chromatin accessibility. Although there are likely additional factors involved, our data demonstrate that later in development, Zld and GAF likely function together to define the chromatin landscape of the early embryo.

Pioneer factors as drivers of zygotic genome activation

Pioneer factors are a specialized class of transcription factors that bind nucleosomal DNA and initiate chromatin remodeling, allowing the recruitment of additional transcription factors (Iwafuchi-Doi and Zaret 2014). Zld binding is strongly driven by DNA sequence, much more so than the binding of other transcription factors (Harrison et al. 2011). This observation combined with our FAIRE data and analyses demonstrates that Zld exhibits many of the characteristics of a pioneer factor as defined by Iwafuchi-Doi and Zaret (2014): (1) engaging chromatin prior to gene activity, (2) establishing or maintaining chromatin accessibility to facilitate transcription factor binding, and (3) playing a primary role in cell reprogramming. Additional properties have been shown for classical pioneer factors, including remaining bound to the mitotic chromosomes (i.e., bookmarking) and binding to nucleosomal DNA (Cirillo et al. 2002; Sekiya et al. 2009; Kadauke et al. 2012; Caravaca et al. 2013). It will be important to determine whether Zld shares these characteristics with other pioneer factors.

Pioneer factors, such as FOXA1, can bind to closed chromatin and subsequently increase accessibility of the target site (Cirillo et al. 2002). However the chromatin of the early embryo may provide a unique environment with little compacted chromatin. Heterochromatin formation is not observed until the 14th nuclear cycle (Foe and Alberts 1983). Chromatin-bound H3 levels increase through the MZT, and histone modifications indicative of silent genes, such as H3K27 trimethylation, are not evident until there is widespread activation of the zygotic genome (Li et al. 2014). Thus, while Zld binds to genes prior to zygotic genome activation, this activity may not require binding to compacted chromatin. It may be that Zld is distinctive in the timing of its expression rather than in its chromatin-binding properties and that the sequence-driven binding of Zld is a property of the open chromatin and rapid nuclear divisions that characterize the earliest stages of embryonic development.

Despite the fact that we have demonstrated a critical role for Zld in determining chromatin accessibility at hundreds of genomic regions, our data show that this role is limited to specific regions associated with the earliest-expressed embryonic genes. Other factors, such as GAF, likely work redundantly with Zld to define chromatin accessibility during the MZT. The coordinated function of multiple factors in determining chromatin structure and genome activation is not without precedent. It has recently been demonstrated that homologs of the core pluripotency factors, Nanog, Pou5f3 (previously known as Pou5f1 and Oct4), and Sox19B (a member of the Sox8.1 family), act analogously to Zld during the zebrafish MZT to drive genome activation (Lee et al. 2013; Leischesning et al. 2013). Furthermore, Pou5f3 and Sox2 are known to be pioneer factors instrumental in reprogramming differentiated cells to a pluripotent state (Soufi et al. 2012, 2015). Together, these data suggest that chromatin remodeling in the early embryo requires the function of multiple factors, and this activity facilitates the transition from the specified germ cells to the pluripotent cells of the early embryo.

Methods

Fly strains

Embryos lacking maternally supplied Zld were generated according to the method described by Liang et al. (2008). zld<234 FRT19A/FM7 females were crossed with y w sn P(mini w+, ovoD1-26g5 FRT19A, hsFLP122/Y males and allowed to lay for 24 h. The resulting offspring were heat-shocked twice for 30 min at 37°C with a 24-h interval between (at ~24–48 h and 48–72 h after laying) to generate germline clones. In parallel, y w FRT19A females were crossed with y w sn P(mini w+, ovoD1-26g5 FRT19A, hsFLP122/Y males, and the offspring were heat-shocked to serve as paired controls. Since only females with the desired germline clones should produce embryos, non-heat-shocked offspring from each cross were preserved and allowed to mature to check for escapers. Any crosses that produced embryos without heat-shock (escapers) were discarded.

Immunostaining

Embryos depleted for maternal Zld and paired yw controls were dechorionated and fixed in 3 mL fixation buffer (1.3x PBS, 67 mM EGTA at pH 8), 1 mL 37% formaldehyde, and 5 mL heptanes for 25 min. Vitelline membranes were removed with methanol. Embryos were rehydrated and stained using anti-Zld antibodies (Harrison et al. 2011) along with DM1A anti-tubulin (Sigma) as a positive control. Goat anti-rabbit Alexa-488 and goat anti-mouse Alexa-688 were used as secondary antibodies (Life Technologies).

FAIRE

Embryos ranging in age from 2 to 3 h were collected, dechorionated, and crosslinked for 10 min with 3:1 heptane:fix solution at room temperature. Following washing, embryos were flash-frozen in liquid nitrogen and stored at ~80°C. FAIRE was performed on ~0.1 g of embryos, as previously described by McKay and Lieb (2013) with the following exceptions. The homogenized embryos were filtered through Miracloth (EMD Millipore). After resuspension in lysis buffer (10 mM Tris-Cl at pH 8, 100 mM NaCl, 1 mM EDTA, 2% Triton X-100, 1% SDS), the nuclei were subjected to four rounds of bead beating with 0.5-mm glass beads. The chromatin was sonicated three times for 30 sec using a Branson sonifier 250 at a power setting of 1.5 to achieve a size range of 200 bp–1 kb.

Single-embryo RNA preparation

Embryos depleted for maternal Zld and paired yw controls were dechorionated and analyzed under halocarbon oil to determine stage. Individual paired stage 5 embryos were selected, and oil was removed. Embryos were lysed in TRIzol (Life Technologies)
supplemented with 150 µg/mL glycogen, and RNA was prepared according to the manufacturer’s instructions.

**Sequencing and data analysis**

High-throughput sequencing libraries were prepared by the University of Wisconsin Biotechnology Center DNA Sequencing Facility (FAIRE) and by Jacqueline Villalta (RNA). Libraries were prepared from both FAIRE-enriched DNA and from sonicated genomic DNA to serve as input material. The libraries were sequenced using the Illumina HiSeq 2000 platform. The total reads for yw were 42,524,780 and for zld<sup>MK</sup> were 50,462,591. The sequence data were processed essentially as previously described (McKay and Lieb 2013). Briefly, reads were aligned to the genome using Bowtie 2 (Langmead and Salzberg 2012) with the “classic analysis.” The input file consisted of a table of FAIRE read counts for each yw and zld<sup>MK</sup> replicate intersecting the union set of the top 5000 FAIRE peaks. FAIRE peaks with a P-value lower than 0.05 were called as differential.

Data for Bcd binding in wild-type and zld<sup>MK</sup> embryos were from GSE55256 (Xu et al. 2014). GAF binding was from GSE23537 (Negr et al. 2011). Histone modification data were obtained from GSE8935 (Li et al. 2014). Microarray expression data for wild-type and zld<sup>MK</sup> embryos were from GSE11231 (Kuang et al. 2008). Zfd-binding sites were from GSE30757 (Harrison et al. 2011). Data for RNA Pol II binding during the MZT were obtained from GSE41703 (Chen et al. 2013).

**Peak classification**

FAIRE peaks were classified into four functional groups based on their location. Peaks located −500 to +150 bases from a known transcription start site were classified as promoter peaks. Peaks overlapping coding regions were classified as genic or intronic, and the remaining peaks classified as intergenic.

**Motif analysis**

The DNA sequence in FAIRE peaks was analyzed using SeedSearcher software by Barash (2019). Specifically, we enumerated over all possible k-mers (ranging from length three to eight, while allowing one or two wildcards in specific positions). Each k-mer was then scored using a differential hypergeometric score, comparing the number of motif occurrences within a set of peaks to the overall number of occurrences within a background set of control sequences. Here we compared each group of FAIRE peaks (constitutive or differential, with or without in vivo Zld or GAF binding) to the remaining of the 5000 high-activity yw FAIRE peaks. All reported k-mers are highly significant after corrections for multiple hypothesis testing.

**Data access**

The FAIRE-seq and RNA-seq data from this study have been submitted to the NCBI Gene Expression Omnibus (GEO: http://www.ncbi.nlm.nih.gov/geo/) under accession number GSE65837.
