**Abstract.** We study the excitonic dynamics of a driven quantum dot under the influence of a phonon environment, going beyond the weak exciton–phonon coupling approximation. By combining the polaron transform and time-local projection operator techniques, we develop a master equation that can be valid over a much larger range of exciton–phonon coupling strengths and temperatures than in the case of the standard weak-coupling approach. For the experimentally relevant parameters considered here, we find that the weak-coupling and polaron theories give very similar predictions for low temperatures (below 30 K), while at higher temperatures we begin to see discrepancies between the two. This is because, unlike the polaron approach, the weak-coupling theory is incapable of capturing multiphonon effects, while it also does not properly account for phonon-induced renormalization of the driving frequency. In particular, we find that the weak-coupling theory often overestimates the damping rate when compared to the polaron theory. Finally, we extend our theory to include non-Markovian effects and find that, for the parameters considered here, they have little bearing on the excitonic Rabi rotations when plotted as a function of pulse area.

1. Introduction

Semiconductor quantum dots (QDs) provide a promising setting in which to explore the interplay of coherent control and decoherence in the solid state. Spatial confinement of charge carriers gives rise to an atomic-like discrete energy level structure within the dot region [1]–[3], which allows for the selective probing of particular excitonic (electron–hole pair) transitions [4, 5]. This has led to demonstrations of fundamentally quantum mechanical effects, such as laser-driven excitonic Rabi rotations [6]–[16] and two-photon interference in QD emission [17]–[20]. Moreover, optical preparation, control and readout of a single self-assembled QD spin has been achieved [21]–[27], while various forms of coupling between closely spaced dots have been observed and characterized [28]–[32].

Such experimental progress clearly demonstrates the feasibility of creating and manipulating both excitonic and spin quantum coherence in QD samples. However, despite this, QD charge carriers are often still strongly influenced by their surrounding solid-state environment. Although the resulting decoherence processes must generally be mitigated in order for QDs to be used in, for example, quantum information processing devices [33]–[40], they also open up intriguing opportunities for exploring system–environment interactions in the solid state. The combination of strong optical-dipole transitions, well-developed control techniques and relatively pronounced environmental interactions allows QDs to be used to study important open system effects that may be more difficult to observe in, for instance, atomic systems.

As an example, the damping of excitonic Rabi rotations in single self-assembled semiconductor QDs has been demonstrated to be driving dependent [6]–[12, 15]. Owing to the large variation in QD type, growth strategy and experimental setup, a number of possible decoherence channels may be responsible for such behaviour. Two prominent mechanisms are off-resonant excitation of the wetting layer [15, 41, 42] and coupling to lattice vibrations (phonons) [11, 12, 43]–[46]. In particular, recent experiments have provided compelling evidence that interactions with longitudinal acoustic (LA) phonons via deformation potential coupling dominates the damping of (ground-state) excitonic Rabi rotations in optically driven InGaAs/GaAs QDs [11, 12]. Furthermore, while it might be hoped that certain decoherence sources could be suppressed by careful selection of samples and experimental techniques,
ultimately self-assembled QDs are embedded in a host matrix. Interactions with phonons thus constitute an intrinsic limitation on the level of coherence seen in their excitonic transitions [43]–[51]. As such, a range of theoretical approaches have previously been developed to investigate the effects of phonon interactions on the coherent manipulation of excitons in QDs. Examples include perturbative expansions of the QD–phonon coupling, resulting in master equation descriptions of both Markovian [11, 12, 46, 52] and non-Markovian [43, 53, 54] nature, correlation expansions [44, 55, 56] and non-perturbative, numerically exact techniques that rely on the calculation of the path integral [45].

The aim of this paper is to extend the master equation approach to QD exciton–phonon interactions beyond the weak-coupling regime in which it is commonly used [57]. The formalism is attractive because in many regimes analytical expressions are obtainable, and when they are not, it is not computationally expensive. We present theoretical results describing the phonon-induced damping of a resonantly driven QD using a polaron transform [47, 58, 59] plus time-local master equation technique [57, 60]. Our theory exploits a perturbative expansion in the polaron-transformed representation, rather than in the system–bath interaction itself. As we shall show, under certain conditions this allows us to identify a perturbation term that is small over a much larger range of parameters than in the weak-coupling approach [58]. In particular, our master equation is able to account for ‘non-perturbative’ effects not captured in a weak-coupling treatment, such as multiphonon processes and phonon-induced renormalization of the driving pulse. This is particularly important in exploring the exciton dynamics at elevated temperatures (above 30 K for the parameters we consider), where such effects may become important. Furthermore, we also extend the master equation to the non-Markovian regime.

We focus particularly on comparing this theory to the weak-coupling Markovian technique used in [11, 12] to provide good fits to both the phonon-induced damping and energy shifts of the observed Rabi rotations. We find that for low temperatures (below 30 K) the weak coupling and polaron theories predict essentially the same excitonic dynamics, indicating that multiphonon and renormalization processes are unimportant. However, as the temperature is increased, we find surprisingly that the weak-coupling theory can overestimate the phonon-induced damping rate when compared to the polaron approach. This is consistent with the weak-coupling fits to the highest temperature plots in [12]. We also show that for the laser pulse durations used in [11] and [12], the inclusion of non-Markovian effects within our formalism has almost negligible influence on the Rabi rotations when plotted as a function of pulse area.

This paper is organized as follows. In section 2, we introduce a model describing the QD system and its interactions with the phonon environment, and also define the polaron transformation. Section 3 outlines our master equation derivation together with a discussion of the regimes in which we expect it to be valid. In sections 4.1 and 4.2, we consider resonant Rabi rotations, driven both by a Gaussian laser pulse and constant driving, and compare the weak-coupling and polaron theory predictions. In section 4.3, we investigate non-Markovian effects, while in section 5 we give a brief discussion and summarize our results.

2. Model and polaron transformation

We consider a single QD modelled (as in [11, 12]) as a two-level system with ground state |0⟩ and single-exciton state |X⟩, separated by an energy ω0. The dot is driven by a laser of frequency ωl, with Rabi frequency Ω(t), and is coupled to a phonon bath represented by an infinite collection of harmonic oscillators with frequencies ωk and creation (annihilation)
operators \( b_k^\dagger (b_k) \). The system-plus-bath Hamiltonian takes the form (for \( \hbar = 1 \))

\[
H = \omega_0 |X \rangle \langle X| + \Omega(t) \cos \omega_l t (|0 \rangle \langle X| + |X \rangle \langle 0|) + \sum_k \omega_k b_k^\dagger b_k + |X \rangle \langle X| \sum_k (g_k b_k^\dagger + \Omega(t) B_k^\dagger + g_k^* b_k).
\]

(1)

where the exciton–phonon couplings are denoted by \( g_k \). Moving to a frame rotating at the laser frequency \( \omega_l \) and performing a rotating-wave approximation on the driving term, we obtain

\[
H_{\text{RWA}} = \delta |X \rangle \langle X| + \frac{\Omega(t)}{2} (|0 \rangle \langle X| + |X \rangle \langle 0|) + \sum_k \omega_k b_k^\dagger b_k + |X \rangle \langle X| \sum_k (g_k b_k^\dagger + \Omega(t) B_k^\dagger + g_k^* b_k).
\]

(2)

where \( \delta = \omega_0 - \omega_l \) is the detuning of the laser from the excitonic transition energy. The rotating-wave approximation can be justified here as both the Rabi frequency \( \Omega(t) \) and detuning \( \delta \) are generally small in comparison to \( \omega_l \).

To move into the appropriate basis for the subsequent perturbation theory, we now apply a unitary polaron transformation to \( H_{\text{RWA}} \) [47, 58]. This transformation displaces the bath oscillators when the QD is in its excited state; we shall explore in the following section how this can lead in many situations to a smaller perturbation term than a weak-coupling treatment of the exciton–phonon interaction in equation (2). The transformed Hamiltonian is defined by

\[
H_P = e^S H_{\text{RWA}} e^{-S},
\]

where

\[
S = |X \rangle \langle X| \sum_k (\alpha_k b_k^\dagger - \alpha_k^* b_k),
\]

(3)

with \( \alpha_k = g_k / \omega_k \). Hence, we may write

\[
e^{\pm S} = |0 \rangle \langle 0| + |X \rangle \langle X| \prod_k D(\pm \alpha_k),
\]

(4)

where \( \prod_k D(\pm \alpha_k) = e^{\pm \sum_k (\alpha_k b_k^\dagger - \alpha_k^* b_k)} \) is the product of the displacement operators \( D(\pm \alpha_k) \). Defining the Pauli matrices in the \(|0\rangle, |X\rangle \rangle \) basis as \( \sigma_x = |X\rangle \langle 0| + |0\rangle \langle X| \), \( \sigma_y = i(|0\rangle \langle X| + |X\rangle \langle 0|) \), and \( \sigma_z = |X\rangle \langle X| - |0\rangle \langle 0| \), we find that our polaron-transformed Hamiltonian reads [58, 59]

\[
H_P = \frac{\delta'}{2} \sigma_z + \frac{\Omega_x(t)}{2} \sigma_x + \sum_k \omega_k b_k^\dagger b_k + \frac{\Omega(t)}{2} (\sigma_x B_x + \sigma_y B_y) ,
\]

(5)

where the detuning is now \( \delta' = \omega_0' - \omega_l \), defined in terms of the bath-shifted QD transition energy \( \omega_0' = \omega_0 - \sum_k \omega_k |\alpha_k|^2 \), and we have ignored an irrelevant term proportional to the identity.

Bath-induced fluctuations are now described by the Hermitian combinations

\[
B_x = \frac{1}{2} (B_+ + B_- - 2B)
\]

(6)

and

\[
B_y = \frac{1}{2i} (B_+ - B_-),
\]

(7)

where \( B_\pm = \prod_k D(\pm \alpha_k) \), and \( B = \langle B_\pm \rangle \) is the expectation value of the bath displacement operators.

Importantly, the driving term in equation (5) has now been renormalized by a factor equal to this expectation value: \( \Omega_x(t) = \Omega(t) B \). For a phonon bath in thermal equilibrium at inverse temperature \( \beta = 1/k_B T \), we find

\[
B \equiv \langle B_\pm \rangle = \exp \left[ - (1/2) \sum_k |\alpha_k|^2 \coth(\beta \omega_k / 2) \right].
\]

(8)
For models of the type studied here, the system–bath interaction is entirely characterized by the spectral density $J(\omega) = \sum_{k} \beta_{k}[\delta^{2}(\omega - \omega_{k})]$ [61]. We are specifically interested in the coupling of bulk LA-phonons to our QD exciton, shown to dominate the dephasing dynamics in [11], and we therefore take a spectral density in the continuum limit of the form [11, 12, 49, 52, 62]

$$J(\omega) = \alpha \omega \varepsilon^{2}e^{-(\omega/\omega_{c})^{2}},$$

(9)
giving $B = \exp[-(1/2) \int_{0}^{\infty} d\omega (J(\omega)/\omega^{3}) \cosh(\beta \omega / 2)]$. The coupling constant $\alpha$ (here having units of $s^{2}$) captures the strength of the exciton–phonon interaction and is dependent on bulk quantities of the QD sample [11]. The exponential cut-off with frequency $\omega_{c}$ arises from the form factor of the carrier wavefunctions [49, 62]. For excitons in self-assembled QDs it is proportional to the inverse of the carrier localization length, which for simplicity we assume to be the same for both electrons and holes.

It is important to note that, apart from the rotating-wave approximation on the driving, we have made no further approximations in our manipulations leading from equations (2) to (5). We have simply put the Hamiltonian in a form that clearly separates the effects of the QD–phonon coupling into renormalization of QD parameters, through $\Omega_{x}(t)$ and $\omega_{0}'$, and bath-induced fluctuations, through the last term in $H_{p}$.

3. Master equation derivation

Utilizing our transformed representation of the QD Hamiltonian, we shall now derive a master equation describing the driven QD exciton dynamics under the influence of the phonon environment. To proceed, we separate the polaron-transformed Hamiltonian such that $H_{p}(t) = H_{0P}(t) + H_{IP}(t)$. Here, $H_{0P}(t) = H_{SP}(t) + H_{BP}$, with bath Hamiltonian $H_{BP} = \sum_{k} \omega_{k} b_{k}^{\dagger} b_{k}$, and the time-dependent system part

$$H_{SP}(t) = \frac{\delta}{2} \sigma_{z} + \frac{\Omega_{x}(t)}{2} \sigma_{x},$$

(10)

while

$$H_{IP}(t) = \frac{\Omega_{y}(t)}{2} (\sigma_{x} B_{x} + \sigma_{y} B_{y})$$

(11)
is the interaction Hamiltonian, to be treated as a perturbation. Moving to the interaction picture with respect to $H_{0P}(t)$ yields an interaction Hamiltonian in the (polaron-transformed) interaction picture of the form

$$H_{IP}(t) = U_{0P}^{\dagger}(t) H_{IP}(t) U_{0P}(t),$$

(12)

where $U_{0P}(t) = U_{SP}(t)e^{-iH_{0P}t}$, with

$$U_{SP}(t) = T \exp \left[ -i \int_{0}^{t} dv H_{SP}(v) \right].$$

(13)

Here, the Schrödinger and interaction pictures have been chosen to coincide at time $t = 0$, while the time-ordering operator $T$ is necessary as, in general, $H_{SP}(t)$ does not commute with itself at two different times. We therefore write the interaction Hamiltonian as

$$H_{IP}(t) = \frac{\Omega_{y}(t)}{2} \left( \tilde{\sigma}_{x}(t) \tilde{B}_{x}(t) + \tilde{\sigma}_{y}(t) \tilde{B}_{y}(t) \right),$$

(14)

where $\tilde{\sigma}_{l}(t) = U_{SP}^{\dagger}(t) \sigma_{l} U_{SP}(t)$ and $\tilde{B}_{l}(t) = e^{iH_{0P}t} B_{l} e^{-iH_{0P}t}$, for $l = x, y$. 

New Journal of Physics 12 (2010) 113042 (http://www.njp.org/)
We now follow the standard projection–operator procedure, outlined in [57], to derive a time-local master equation for the reduced system density operator, $\tilde{\rho}_{SP}(t)$, in the polaron frame interaction picture. Considering the QD to be initialized in its ground state, with the bath initially in thermal equilibrium, $\rho_B(0) = \rho_B = e^{-\beta \sum_k \omega_k |k\rangle \langle k|}/\text{tr}_B(e^{-\beta \sum_k \omega_k |k\rangle \langle k|})$, we see that the initial system–bath density operator, $\chi(0) = \langle 0|0\rangle \rho_B$, is unaffected by transformation into the polaron representation, i.e. $\chi_P(0) = e^\delta \chi(0)e^{-\delta} = \langle 0|0\rangle \rho_B = \chi(0)$. Hence, taking a thermal equilibrium state of the bath as a reference state and treating $\tilde{H}_{IP}(t)$ to second order, we find a homogeneous equation [57, 60]

$$\frac{\partial \tilde{\rho}_{SP}(t)}{\partial t} = -\int_0^t ds \text{tr}_B([\tilde{H}_{IP}(t), [\tilde{H}_{IP}(s), \tilde{\rho}_{SP}(t)\rho_B]])$$

(15)

describing the dynamics of the excitonic system in the polaron frame, under the influence of the phonon bath. Substituting in for $\tilde{H}_{IP}(t)$ from equation (14), we obtain

$$\frac{\partial \tilde{\rho}_{SP}(t)}{\partial t} = -\frac{\Omega(t)}{4} \int_0^t ds \Omega(s) \left([\tilde{\sigma}_x(s), \tilde{\sigma}_s(s)\tilde{\rho}_{SP}(t)]\Lambda_x(\tau) + [\tilde{\sigma}_y(s), \tilde{\sigma}_s(s)\tilde{\rho}_{SP}(t)]\Lambda_y(\tau) + \text{H.c.}\right),$$

(16)

where H.c. refers to the Hermitian conjugate, and we have made use of the stationarity of the bath reference state to write

$$\langle \tilde{B}_l(t)\tilde{B}_l(s)\rangle_B = \langle \tilde{B}_l(\tau)\tilde{B}_l(0)\rangle_B = \Lambda_l(\tau),$$

(17)

with $\tau = t - s$. We note also that owing to the form of $B_x$ and $B_y$, correlation functions of the type $\langle \tilde{B}_l(\tau)\tilde{B}_{l'}(0)\rangle_B$ for $l \neq l'$ are identically equal to zero. Using $J(\omega) = \sum_k |g_k|^2 \delta(\omega - \omega_k)$ allows us to write the relevant correlation functions in the continuum limit as

$$\Lambda_x(\tau) = \frac{B^2}{2} (e^{\phi(\tau)} + e^{-\phi(\tau)} - 2),$$

(18)

$$\Lambda_y(\tau) = \frac{B^2}{2} (e^{\phi(\tau)} - e^{-\phi(\tau)}),$$

(19)

where

$$\phi(\tau) = \int_0^\infty d\omega \frac{J(\omega)}{\omega^2} \left(\cos \omega \tau \coth(\beta\omega/2) - i \sin \omega \tau\right).$$

(20)

Now, moving back to the Schrödinger picture and making the change of variables $s \rightarrow t - \tau$, we obtain

$$\dot{\rho}_{SP}(t) = -\frac{i}{2} [\delta' \sigma_z + \Omega_r(t)\sigma_x, \rho_{SP}(t)] - \frac{\Omega(t)}{4} \int_0^t d\tau \Omega(t - \tau) \left([\sigma_x, \sigma_x(t - \tau, t)\rho_{SP}(t)]\Lambda_x(\tau) + [\sigma_y, \sigma_y(t - \tau, t)\rho_{SP}(t)]\Lambda_y(\tau) + \text{H.c.}\right),$$

(21)

where $\sigma_i(s, t) = U_{SP}(t) U^\dagger_{SP}(s) \sigma_i U_{SP}(s) U^\dagger_{SP}(t)$. Equation (21) is a non-Markovian master equation describing the QD exciton dynamics in the polaron frame for a time-dependent laser-driving pulse envelope $\Omega(t)$, and valid to second order in $H_{IP}(t)$.
3.1. Markov approximation

While we could use equation (21) directly as a basis for numerical simulation of the exciton dynamics (and we shall in fact do so in section 4.3), a great deal of insight into the system behaviour can be gained through the simplifications allowed by the Markov approximation. To make a Markov approximation in the present case, we let the upper limit of integration in equation (21) go to infinity under the assumption that the bath correlation functions \( \Lambda_1(\tau) \) decay on a timescale that is short compared to that of the system dynamics we would like to capture. Given this, we may also approximate

\[
U_{SP}(t - \tau, t) \approx \exp \left[ i H_{SP}(t) \tau \right],
\]

while replacing \( \Omega_1(t - \tau) \) by \( \Omega_1(t) \) in the integral in equation (21). We may then write

\[
\sigma_x(t - \tau, t) \approx \delta' \cos \eta \tau \sigma_x + \frac{\delta' \sin \eta \tau \delta' \Omega_1(t)(1 - \cos \eta \tau)}{\eta^2} \sigma_z,
\]

and

\[
\sigma_y(t - \tau, t) \approx -\frac{\delta' \sin \eta \tau \sigma_y + \Omega_1(t) \sin \eta \tau \sigma_z}{\eta}.
\]

where \( \eta = \sqrt{\delta'^2 + \Omega_1(t)^2} \).

In the following, we shall consider the case of resonant excitation, \( \delta' = 0 \), which simplifies equations (23) and (24) to \( \sigma_x(t - \tau, t) = \sigma_x \) and \( \sigma_y(t - \tau, t) \approx \cos(\Omega_1(t) \tau) \sigma_y + \sin(\Omega_1(t) \tau) \sigma_z \), respectively. We then arrive at a polaron-transformed master equation

\[
\dot{\rho}_{SP}(t) = \frac{1}{2} \left[ \Omega_1(t) \sigma_x, \rho_{SP}(t) \right] - \frac{\Omega_1(t)^2}{4} \int_0^\infty d\tau \left( [\sigma_x, \sigma_x \rho_{SP}(t)] \Lambda_x(\tau) + \cos(\Omega_1(t) \tau) [\sigma_y, \sigma_y \rho_{SP}(t)] \Lambda_y(\tau) + \sin(\Omega_1(t) \tau) [\sigma_y, \sigma_z \rho_{SP}(t)] \Lambda_y(\tau) + H.c. \right),
\]

which we shall use to explore the dynamics of a resonantly driven QD beyond the weak exciton–phonon coupling regime. For constant driving, equation (25) is of a familiar Born–Markov form in the polaron frame\(^4\).

3.2. Regimes of validity

Having derived equations (21) and (25) perturbatively in the polaron frame, we should expect their validity to be limited in some manner. Recall that the polaron transformation displaces the bath oscillators in reaction to a change of state of the QD. Intuitively, we would therefore expect the polaron-transformed representation to be applicable when the bath is able to react on a timescale shorter than, or similar to, that on which the QD exciton itself evolves. Since the timescale on which the bath reacts is set approximately by the inverse of the cut-off frequency \( \tau_B \sim 1/\omega_c \), we would therefore expect equation (21) to work best in the regime \( \Omega/\omega_c < 1 \). Additionally, the Markov approximation made in deriving equation (25) limits its validity to timescales greater than \( \tau_B \).

\(^4\) However, upon transformation back into the original (or ‘lab’) frame, changes in the QD state can have an influence on the phonon bath. Specifically, the bath state is not stationary in the original frame, and the system–bath state is not generally separable.
To put these considerations on a slightly more quantitative footing, we can make a rough estimate of the regime of validity of our perturbative expansion by considering the magnitude of the perturbative terms in the master equation, namely \((\Omega^2/4)\Delta_\gamma(\tau)\) \cite{57,60}, for constant driving \(\Omega(t) = \Omega\). For example, consider the upper bound on the magnitude of \(\Delta_\gamma(\tau)\), given by \(|\Delta_\gamma(0)| = (1/2)(1 - B^4)\). Bearing in mind that \(\Lambda(\tau)\) tends to zero on a timescale of the order of \(1/\omega_c\), we see that we want \((\Omega^2/4)(|\Delta_\gamma(0)|/\omega_c) = (\Omega^2/8\omega_c)(1 - B^4)\) to be small in the sense that terms higher than second order in \(H_{IP}\) may be neglected in the master equation expansion. Since \(\langle H_{IP} \rangle = 0\), the next term is of fourth order, and its magnitude can be estimated in a similar manner by \((\Omega^2/4)^2(|\Delta_\gamma(0)|^2/\omega_c^2)\). Thus, ignoring numerical factors, we find that the fourth-order term is small in comparison to the second order, provided that the condition
\[
\left(\frac{\Omega^2}{\omega_c}\right)^2 (1 - B^4) \ll 1 \tag{26}
\]
is satisfied\(^5\). In line with our previous intuition, this condition tells us that in the scaling limit \((\Omega/\omega_c \ll 1)\) we expect our treatment to be valid well beyond a standard weak system–bath coupling approach, such that we can explore both the weak \((B \approx 1, \text{ small } \alpha \text{ and/or low } T)\) and strong \((B \ll 1, \text{ large } \alpha \text{ and/or high } T)\) system–bath coupling regimes, as well as reliably interpolate between these two extremes \cite{58}. Outside the scaling limit, our approach should remain valid provided that the system–bath coupling is small enough, or the temperature low enough, such that the inequality of equation (26) is still satisfied.

To demonstrate how the polaron approach generally allows a larger regime of parameter space to be explored than a standard weak-coupling treatment, we can also apply the above reasoning to assess the regime of validity of such a weak-coupling master equation. In this case, we have a weak-coupling correlation function \(\Lambda_W(\tau) = \int_0^\infty d\omega J(\omega)(\cos(\omega \tau)\coth(\beta \omega/2) - i \sin(\omega \tau))\) \cite{46}, which again falls to zero on a timescale of the order of \(1/\omega_c\). Hence, in a similar manner to before, we estimate the second-order perturbation to be roughly of magnitude \(|\Lambda_w(0)|/\omega_c\), while the fourth order is then \(|\Lambda_w(0)|^2/\omega_c^2\). We then find the condition
\[
\frac{|\Lambda_w(0)|}{\omega_c^2} \ll 1, \tag{27}
\]
as an estimate of the range of validity of the weak-coupling approach.

Considering first the zero-temperature limit, we find that \(\Lambda_w(0) \sim \alpha \omega_c^4\), where we use the QD spectral density given in equation (9). Hence, at zero temperature, our condition implies that a weak exciton–phonon coupling treatment should be adequate for describing the QD excitonic dynamics provided that
\[
\alpha \omega_c^2 \ll 1. \tag{28}
\]
However, as the temperature is increased, the magnitude of \(\Lambda_w(0)\) increases too, and we therefore expect the weak-coupling treatment to worsen. Approximating \(\coth(\beta \omega/2) \approx 2/(\beta \omega)\), we find that
\[
\frac{\alpha \omega_c}{\beta} \ll 1 \tag{29}
\]
or \(\alpha \omega_c^2/(\beta \omega_c) \ll 1\), which is clearly a harder criterion to fulfill than the zero-temperature condition. Hence, for a given system–bath coupling strength \(\alpha\) and cut-off frequency \(\omega_c\), as the
\(^5\) Considering the magnitude of \(\Lambda_\gamma(\tau)\) instead leads to a similar condition, which gives essentially the same regime of validity.
temperature of the bath is increased, a weak-coupling treatment of the system–bath interaction becomes a worse approximation.

Although we should be wary of reading too much into numerical values obtained from these rough validity conditions, for the system studied in [11, 12] we can take $\alpha = 0.027\text{ ps}^2$ and $\omega_c = 2.2\text{ ps}^{-1}$ extracted through fits to the data, which gives $\alpha\omega_c^2 \approx 0.1$. Hence, we might expect a weak-coupling treatment to be valid at low temperatures for this QD system, as borne out by the excellent agreement between experimental data and theory in [11, 12]. However, by a temperature of 50 K, we find $|\Lambda_W(0)/\omega_c^2| \approx 0.4$, such that the weak-coupling approximation is now becoming dubious. In contrast, for the same parameters and taking $\omega_c = 1\text{ ps}^{-1}$, we find that the polaron condition equation (26) gives $(\Omega/\omega_c)^2(1 - B^2) \approx 0.03$ at $T = 0$, increasing up to $(\Omega/\omega_c)^2(1 - B^2) \approx 0.15$ at $T = 50$ K. In fact, we shall show below that it is around temperatures of 30 K and above that we begin to see significant differences between the weak-coupling and polaron treatments of our driven QD, signifying (in this case) that the system is beginning to move out of the weak-coupling regime, and both driving renormalization and multiphonon processes are starting to become important.

4. Resonant excitation dynamics

We now proceed to explore the excitonic dynamics of our QD system, focusing in particular on comparing how the polaron and weak-coupling theories capture the interplay between the driving-induced coherent population oscillations and the phonon environment as we vary the temperature. Interestingly, we shall see that as the phonon-induced damping rate naturally depends on the renormalized Rabi frequency $\Omega_0$ in the polaron theory, whereas it depends on the original Rabi frequency $\Omega$ in the weak-coupling theory, the weak-coupling approach can actually overestimate the damping rate even in the high-temperature regime where multiphonon effects are important.

Experimentally, it is generally the excitonic population $\rho_{XX}$ that is measured, through photocurrent detection [8, 11] or microcavity-assisted photon emission [13, 14], for example. Here, we express the solutions to our Markovian master equation through the Bloch vector, defined in the polaron frame as $\alpha_p = (\alpha_x, \alpha_y, \alpha_z)^T = (\langle \sigma_x \rangle_p, \langle \sigma_y \rangle_p, \langle \sigma_z \rangle_p)^T$, where $\langle \sigma_i \rangle_p = \text{tr}\sigma_{i,b}(\sigma_{i,p}(t))$, for $i = x, y, z$. Since $\sigma_z$ is invariant under the polaron transformation, $e^{\delta \sigma_i}e^{-\delta} = \sigma_z$, we see that in the original (lab) frame $\alpha_c = \text{tr}\sigma_{i,b}(\sigma_{i,c}(t)) = \text{tr}\sigma_{i,b}(\sigma_{i,p}(t)) = \alpha_p$, and the Bloch vector elements along $z$ are equivalent in the two representations. Hence, $\rho_{XX} = (1 + \alpha_z)/2 = (1 + \alpha_p)/2$, and we may work entirely in the polaron frame provided we are only interested in population dynamics.

From equation (25) we find that the polaron frame Bloch vector evolves according to

$$\dot{\alpha}_p = M(t) \cdot \alpha_p + b(t),$$

where

$$M(t) = \begin{pmatrix}
- (\Gamma_z - \Gamma_y) & 0 & 0 \\
0 & -\Gamma_y & -\Omega_x(t) \\
0 & (\Omega_x(t) + \lambda) & -\Gamma_z
\end{pmatrix},$$

and $b(t) = (-\kappa, 0, 0)^T$. Here,

$$\Gamma_y = \frac{\Omega(t)^2}{2}\gamma_y(t),$$

New Journal of Physics 12 (2010) 113042 (http://www.njp.org/)
\[ \Gamma_e = \frac{\Omega(t)^2}{4}(\gamma_y(\Omega_e(t)) + \gamma_z(-\Omega_e(t)) + 2\gamma_x(0)), \]

\[ \lambda = \frac{\Omega(t)^2}{2}(S_y(\Omega_e(t)) - S_y(-\Omega_e(t))), \]

\[ \kappa = \frac{\Omega(t)^2}{4}(\gamma_y(\Omega_e(t)) - \gamma_y(-\Omega_e(t))), \]

where

\[ \gamma_1(\omega) = 2\text{Re}[K_1^{(p)}(\omega)] \]

and

\[ S_1(\omega) = \text{Im}[K_1^{(p)}(\omega)], \]

written in terms of the polaron response function

\[ K_1^{(p)}(\omega) = \int_0^\infty d\tau \, e^{i\omega \tau} \Lambda_1(\tau). \]

Note that as we are solely interested in the exciton population dynamics it suffices to consider only the Bloch equations for \( \alpha_y \) and \( \alpha_z \) since, in the resonant case, that for \( \alpha_x \) becomes decoupled.

The polaron theory developed here will be compared to the Born–Markov weak-coupling treatment presented in \[11, 12\]. With the weak-coupling theory, we again find that the equation of motion for \( \alpha_x \) is decoupled, while \( \alpha_y \) and \( \alpha_z \) obey

\[ \dot{\alpha}_y = -\Gamma_W \alpha_y - (\Omega(t) + \lambda_W)\alpha_z, \]

\[ \dot{\alpha}_z = \Omega(t)\alpha_y, \]

The damping rate and energy shift can be expressed in our current notation as

\[ \Gamma_W = \frac{1}{4} (\gamma_W(\Omega(t)) + \gamma_W(-\Omega(t))), \]

\[ \lambda_W = \frac{1}{2} (S_W(\Omega(t)) - S_W(-\Omega(t))), \]

respectively, with the weak-coupling correlation function given by

\[ \Lambda_W(\tau) = \int_0^\infty J(\omega) d\omega (\cos \omega \tau \coth(\beta\omega/2) - i \sin \omega \tau). \]

We can evaluate \( \Gamma_W \) in closed form, giving

\[ \Gamma_W = \frac{\pi}{2} J(\Omega(t)) \coth(\beta\Omega(t)/2). \]

Hence, the weak-coupling rate displays a linear temperature dependence in the high-temperature regime \[11\] and, as mentioned previously, is dependent on the original Rabi frequency \( \Omega(t) \) as opposed to the bath-renormalized value. Furthermore, we see that there is no pure-dephasing contribution to the weak-coupling rate in the Born–Markov approximation, in contrast to the terms \( \gamma_x(0) \) appearing in the polaron theory through \( \Gamma_y \) and \( \Gamma_z \).

We also point out that in the derivation of equations (39) and (40), no secular approximation is made \[57\]. The corresponding master equation is therefore not of Lindblad form and does not guarantee a completely positive, trace-preserving map. As such, for certain parameters, it is possible that equations (39) and (40) predict unphysical behaviour. In fact, we shall see in the following sections that this is indeed the case for high enough temperatures.
Figure 1. Excitonic population as a function of driving pulse area (in units of \(\pi\)), for temperatures ranging from 5 to 75 K, where each curve has been offset by an increasing integer for clarity. Blue solid lines are calculated using the polaron approach, while red dashed lines are calculated using weak-coupling theory. Parameters: \(\alpha = 0.027\) ps\(^2\) and \(\omega_c = 2.2\) ps\(^{-1}\).

4.1. Time-dependent driving

Having outlined some of the similarities and differences between the weak-coupling and polaron transform approaches, we shall now compare their respective predictions in the case of resonant driving with a Gaussian pulse envelope. Rather than looking at the dynamics in the time domain, we shall instead explore oscillations in the excitonic population (Rabi rotations) as a function of varying pulse area, \(\Theta = \int_{-\infty}^{\infty} \Omega(t) dt\), for fixed pulse duration, as is common experimentally. We therefore consider a Gaussian pulse of fixed width \(\tau\) but varying peak magnitude, centred around \(t = 0\), and described by \(\Omega(t) = (\Theta / 2\tau \sqrt{\pi}) \exp[-(t / 2\tau)^2]\). Starting at a time \(-t_0\) well before the pulse (i.e. \(t_0 \gg \tau\)), we initialize the QD in its ground state: \(\alpha_p = \alpha = (0, 0, -1)\). We then numerically solve the Bloch equations (equation (30) in the polaron case and equations (39) and (40) in the weak-coupling case) to find the state of the system at any time \(t\) satisfying \(t \gg \tau\), such that the pulse has effectively ended.

Figure 1 shows the final excitonic population, \(\rho_{XX}\), calculated from the polaron and weak-coupling theories as described above, as a function of total pulse area, \(\Theta\) (in units of \(\pi\)), for
temperatures ranging from $T = 5$ to 75 K (each plot has been offset by an increasing integer for clarity). We use experimentally determined values of the exciton–phonon coupling strength and cut-off frequency, $\alpha = 0.027$ ps$^2$ and $\omega_c = 2.2$ ps$^{-1}$, respectively [12], and a Gaussian driving pulse of width $\tau = 4$ ps. Note that for the largest pulse areas studied here the ratio $\Omega/\omega_c$ has a maximum value of $\sim 1.2$.

At low to intermediate temperatures ($T < 30$ K), we see that the weak-coupling and polaron theories agree very closely in their predictions for the population dynamics, consistent with the excellent agreement found previously between experimental observations and the weak-coupling theory in this regime [11, 12]. Importantly, the two theories predict almost exactly the same dependence of the Rabi rotation damping rate and frequency shift on increasing temperature and pulse area, provided the temperature does not increase much above 30 K. As expected, the phonon-induced damping is strongly driving dependent, with oscillations becoming almost totally suppressed at high pulse areas for all but the lowest temperatures.

Perhaps the most striking feature apparent from figure 1, however, is that the weak-coupling theory tends to overestimate the damping effect of the phonons at higher temperatures when compared to the polaron theory. In fact, as we shall see below in the case of constant driving, provided $\Omega/\omega_c \sim 0.7$ or smaller, the weak-coupling theory predicts a larger damping rate than the polaron theory at all temperatures for the realistic parameters studied here.

At the single-phonon level, this difference can be attributed directly to the temperature-dependent suppression of the driving pulse that occurs in the polaron-transformed Hamiltonian (see equation (5)). Among other things, this has the consequence that the rates appearing in the polaron Bloch equations are to be evaluated at the (smaller) renormalized pulse strength $\Omega_\tau(t)$, rather than at the bare pulse strength $\Omega(t)$ as in the weak-coupling theory. The resulting effect can be seen clearly by expanding the relevant polaron rates $\Gamma_\tau$ and $\Gamma_\zeta$ (in equations (32) and (33), respectively) up to their single-phonon terms. We then find a damping rate of precisely the same form as in the weak-coupling theory,

$$\Gamma_{1-ph} = \frac{\pi}{2} J(\Omega_\tau(t)) \coth (\beta \Omega_\tau(t)/2),$$

although evaluated at the renormalized $\Omega_\tau(t)$, as expected. For low pulse areas, we can approximate $\Gamma_{1-ph} \approx (\alpha x/2)\Omega_\tau(t)^3 \coth(\beta \Omega_\tau(t)/2)$. Hence, for single-phonon processes at least, the lessening of the damping rate in the polaron theory is simply due to the fact that we are sampling the spectral density at a lower frequency, since $\Omega_\tau(t) < \Omega(t)$. Any differences would then become more pronounced at higher temperatures, since this is when $\Omega_\tau$ most differs from $\Omega$.

In the full polaron theory, however, the situation is of course much more complicated than this simple analysis would suggest. To begin with, we have no particular reason to expect the single-phonon rate of equation (45) to be valid over a larger temperature range than the weak-coupling rate of equation (44), so the sampling of the spectral density at different frequencies in the two theories cannot be the whole story. Looking again, for example, at the full polaron rate $\Gamma_y$ (which in fact disappears in the single-phonon approximation), we see from equations (18), (32), (36) and (38) that it may be written as

$$\Gamma_y = \Omega(t)^2 \text{Re} \int_0^\infty d\tau \Lambda_\tau(t) = \frac{\Omega(t)^2}{2} \text{Re} \int_0^\infty d\tau (e^{\phi(t)} + e^{-\phi(t)} - 2).$$

$^6$ Note that due to phonon-induced frequency shifts the maxima and minima of the curves in figure 1 are not expected to occur at integer multiples of $\pi$.

$^7$ We do not enter the undamping regime predicted in [45] for the parameters considered here.
Thus, in determining the overall size of the full polaron rates at higher temperatures, there additionally exists competition between the multiphonon effects accounted for by the exponentiation of the phonon propagator \( \phi(\tau) \), which increases the rate in comparison to the single-phonon approximation, and the overall factor proportional to \( \Omega_c(t)^2 \), which again acts to decrease it with increasing temperature.

A further feature to draw out from the comparison presented in figure 1 is that while the polaron theory predicts physical behaviour at all temperatures considered, for the highest temperature \( T = 75 \text{ K} \) the weak-coupling theory actually predicts unphysical behaviour, since \( \rho_{XX} \) becomes negative for pulse areas \( \Theta \sim \pi \). This behaviour can be related to an overestimate of the phonon-induced frequency shift in the weak-coupling analysis at high temperatures, and will again be discussed in more detail below for the case of constant driving.

### 4.2. Constant driving

In order to put the arguments outlined in the previous section on a more formal footing, it is useful to consider the dynamics of the QD system for constant driving, in which case an analytic form can be given for the population difference, \( \alpha_z = \rho_{XX} - \rho_{00} \). We construct a second-order differential equation for the time evolution of \( \alpha_z \) in both the polaron and weak-coupling theories.

From equation (30), we find for the polaron theory (using \( \alpha_z^p = \alpha_z \))

\[
\ddot{\alpha}_z + (\Gamma_y + \Gamma_z) \dot{\alpha}_z + (\Omega_t(\Omega_e + \lambda) + \Gamma_y \Gamma_z) \alpha_z = 0,
\]

which has the solution (for \( \alpha_z(0) = -1 \))

\[
\alpha_z(t) = -e^{-\Gamma_p t/2} \left( \cos(\xi_p t/2) + \frac{\Gamma_p}{\xi_p} \sin(\xi_p t/2) \right),
\]

with damping rate

\[
\Gamma_p = \Gamma_y + \Gamma_z = \frac{\Omega^2}{4} (\gamma_y(\Omega_e) + \gamma_y(-\Omega_e) + 4 \gamma_y(0))
\]

and oscillation frequency

\[
\xi_p = \sqrt{4 \Omega_e(\Omega_e + \lambda) - (\Gamma_z - \Gamma_y)^2}.
\]

On the other hand, equations (39) and (40) give for the weak-coupling theory

\[
\ddot{\alpha}_z + \Gamma_w \dot{\alpha}_z + \Omega(\Omega + \lambda_w) \alpha_z = 0,
\]

which has a solution of exactly the same form,

\[
\alpha_{zW}(t) = -e^{-\Gamma_{W} t/2} \left( \cos(\xi_{W} t/2) + \frac{\Gamma_{W}}{\xi_{W}} \sin(\xi_{W} t/2) \right),
\]

although this time with the weak-coupling damping rate \( \Gamma_w \) of equation (44), and oscillation frequency

\[
\xi_w = \sqrt{4 \Omega(\Omega + \lambda_w) - \Gamma^2_w}.
\]

In the constant driving case, we may therefore directly compare the rate \( \Gamma_p \) and frequency \( \xi_p \) in the polaron theory to the weak-coupling expressions \( \Gamma_w \) and \( \xi_w \), respectively.

In figure 2(a), we plot the damping rates \( \Gamma_p \) and \( \Gamma_w \), along with the single-phonon expansion of the polaron rate (\( \Gamma_{1-ph} \) of equation (45)), as a function of temperature for an
Figure 2. (a) Temperature dependence of the weak-coupling rate $\Gamma_W$ (red dashed curve), polaron rate $\Gamma_P$ (blue solid curve) and single-phonon expansion of the polaron rate $\Gamma_{1-\text{ph}}$ (green dotted curve), where we have evaluated each rate at $\Omega = 0.5 \text{ ps}^{-1}$. (b) Dependence of the polaron damping rate $\Gamma_P$ (blue solid curves) and weak-coupling damping rate $\Gamma_W$ (red dashed curves) on the driving frequency $\Omega$. The two sets of curves correspond to temperatures of $T = 5\text{ K}$ and $75\text{ K}$, as indicated. Parameters: $\alpha = 0.027 \text{ ps}^2$, $\omega_c = 2.2 \text{ ps}^{-1}$.

arbitrarily chosen value of the constant driving, $\Omega = 0.5 \text{ ps}^{-1}$. For these parameters, the weak-coupling approximation is indeed shown to predict a larger rate for all values of $T$. Furthermore, there is a significant difference between the full polaron rate ($\Gamma_P$) and its single-phonon expansion ($\Gamma_{1-\text{ph}}$) above temperatures of about 10–15 K, indicating that multiphonon effects are becoming important. Hence, in this regime, even though the weak-coupling rate is still too large, we cannot simply fix it by replacing $\Omega \rightarrow \Omega_c$ in $\Gamma_W$ (i.e. taking $\Gamma_W \rightarrow \Gamma_{1-\text{ph}}$) as this neglects important multiphonon processes. Note also that while the weak-coupling rate varies linearly with temperature above a few kelvins, the single-phonon expansion does not, despite having a very similar form, due to the temperature dependence inherent to $\Omega_c$.

In figure 2(b), we show how the polaron and weak-coupling rates vary with the strength of the driving frequency $\Omega$, for low and high temperatures. As observed experimentally [11, 12], we see a clear and strong dependence on the driving strength for both temperature regimes, and in both the weak-coupling and polaron theories. It is also interesting to note that around $\Omega/\omega_c \sim 0.7$ in the high-temperature case, the polaron and weak-coupling rates cross, indicating that above this value the hierarchy of rates discussed with reference to figure 2(a) no longer holds.

We emphasize again that, as in the case of time-dependent driving, there are two important effects present in the polaron theory that are not captured by the weak-coupling treatment and that become increasingly relevant as the temperature is increased. Firstly, there are multiphonon contributions, which tend to increase the damping rate, as can clearly be seen by comparing the full polaron rate to its single-phonon expansion in figure 2(a). Secondly, the interaction of the QD exciton with the phonon bath causes a reduction in the effective driving field. For $\Omega/\omega_c < 1$, this tends to decrease the damping rate, as can be seen from figure 2(b).

We are also now in a position to explain the origin of the unphysical behaviour predicted by the weak-coupling theory at 75 K (see figure 1). In figure 3, we again plot the excitonic population as a function of pulse area, but this time for a constant driving pulse of 14 ps duration, which is roughly equal to the full-width at half-maximum (FWHM) of the Gaussian pulse used.
in figure 1. Note that for $T = 75 \text{K}$, the excited state again takes on unphysical negative values in the weak-coupling theory for pulse areas $\Theta \sim \pi$ (right-hand side plot (b)). To see how this comes about, we must consider the weak-coupling oscillation frequency $\xi_W$ of equation (53). For $\Gamma_W > 4\Omega(\Omega + \lambda_W)$, we find that $\rho_{XX}$ can take on negative values when $\lambda_W < -\Omega$, i.e. when the correction to the driving frequency is larger than the frequency itself, the weak-coupling theory discussed here breaks down. As mentioned previously, this can ultimately be attributed to the fact that no secular approximation was made in the derivation of the weak-coupling Bloch equations, which therefore have a corresponding master equation that is not of Lindblad form [57].

Let us now consider the frequency shift in slightly more detail. In the weak-coupling theory, we find from equations (42) and (43) that

$$\lambda_W = \Omega \mathcal{P} \int_0^\infty d\omega \frac{J(\omega) \coth(\beta \omega/2)}{\Omega^2 - \omega^2},$$

where $\mathcal{P}$ indicates that the Cauchy principal value should be taken, and we have made use of the identity $\int_0^\infty e^{i\omega s} ds = \pi \delta(\omega) + \mathcal{P}(i/\omega)$. Since we expect the weak-coupling theory to break down in the high-temperature limit, we can evaluate $\lambda_W$ analytically by approximating $\coth(x) \approx x^{-1}$ in the integrand of equation (54). In doing so, we find that

$$\lambda_W \approx -\frac{\Omega \sqrt{\pi} \alpha \omega_c}{\beta} (1 - 2(\Omega/\omega_c)F(\Omega/\omega_c)),$$

where $F(x) = \exp[-x^2] \int_0^1 \exp[y^2]dy$ is the Dawson integral. The condition $\lambda_W < -\Omega$, which determines when we expect unphysical behaviour from the weak-coupling theory, then becomes

$$\beta < \sqrt{\pi} \alpha \omega_c,$$

where we take the limit $\Omega/\omega_c \ll 1$. For the parameters of figure 3(b), we then expect to obtain unphysical behaviour when $T > 72 \text{K}$, in good agreement with the actual dynamics. We note that while equation (56) may give a bound on when the limits of the weak-coupling theory

Figure 3. Exciton population as a function of pulse area for constant driving: (a) using polaron theory; (b) using weak-coupling theory. The different curves in each plot correspond to temperatures ranging from 5 to 75 K in steps of 10 K, with lower temperatures coloured blue and higher temperatures red (the arrows indicate increasing temperature). Parameters: pulse duration = 14 ps, $\alpha = 0.027 \text{ps}^2$ and $\omega_c = 2.2 \text{ps}^{-1}$. 
are met, its degree of accuracy may become poor well before this condition is satisfied (see equation (29) and the discussion there).

Turning to the low-temperature regime, where the weak-coupling theory remains physical, we have seen previously that by expanding the full polaron damping rate to its single-phonon terms we may recover the weak-coupling damping rate, although evaluated at a renormalized frequency (compare equations (44) and (45)). In order to complete the picture, we shall now show a similar equivalence between the polaron and weak-coupling frequency shifts at the single-phonon level. Expanding equation (34) to first order in \( J(\omega) \), we find the single-phonon approximation to the polaron frequency shift, \( \lambda \to \lambda_{1-\text{ph}} \), where

\[
\lambda_{1-\text{ph}} = \Omega_{\lambda}^2 P \int_0^\infty \frac{d\omega}{\omega^2} \frac{J(\omega) \coth(\beta \omega/2)}{(\Omega_2^2 - \omega^2)}. \tag{57}
\]

However, this is not quite the whole story since, in the polaron theory, the driving frequency is shifted both by \( \lambda \) and at the Hamiltonian level through \( \Omega \to \Omega_r \). Ultimately, it is the observables, such as the population difference, that are the physically meaningful quantities to consider. Inspection of the frequencies \( \xi_\lambda \) in equation (50) and \( \xi_W \) in equation (53) therefore tells us that we should compare \( \Omega_r(\Omega_r + \lambda) \) in the polaron theory to \( \Omega(\Omega + \Delta \Omega) \) in the weak-coupling theory, as we know that \( \Gamma_z - \Gamma_y \approx \Gamma_W \) at the single-phonon level. Expanding \( \Omega_r(\Omega_r + \lambda) \approx \Omega(\Omega + \Delta \Omega) \), where

\[
\Delta \Omega = \Omega \int_0^\infty d\omega \frac{J(\omega)}{\omega^2} \coth(\beta \omega/2) \left( \frac{\omega^2 + \Omega_2^2(B^2 - 1)}{\Omega_1^2 - \omega^2} \right). \tag{58}
\]

Expanding the remaining factors of \( B \) and occurrences of \( \Omega_r \) to first order in \( J(\omega) \) we find that equation (58) reduces to equation (54) (i.e. \( \Delta \Omega \to \lambda_W \)); in the weak-coupling limit, the polaron and weak-coupling theories therefore predict the same correction to the driving frequency.

4.3. Non-Markovian effects

Finally, we shall now relax the Markov approximation made in section 3.1 to investigate non-Markovian effects on the QD exciton dynamics [43]–[45], [53]–[56], within the polaron frame [60]. Referring to equation (21), and considering the case of constant driving for simplicity, we find that our non-Markovian master equation may be written as

\[
\dot{\rho}_{SP}(t) = -\frac{i}{2} \left[ \delta'(\sigma_z + \Omega_r \sigma_x, \rho_{SP}(t)) + \frac{\Omega_z^2}{4} \int_0^t d\tau (\sigma_z(t - \tau, t) \rho_{SP}(t)) \Lambda_x(\tau) 
+ [\sigma_y, \sigma_y(t - \tau, t) \rho_{SP}(t)] \Lambda_y(\tau) + \text{H.c.}. \right]. \tag{59}
\]

Avoiding the Markov approximation thus corresponds to the introduction of time-dependent rates and energy shifts in our master equation [57].

We determine Bloch equations from equation (59) in exactly the same way as the Markovian case. Considering resonant excitation, \( \delta' = 0 \), and inserting \( \sigma_x(t - \tau, t) = \sigma_x \) and \( \sigma_y(t - \tau, t) = \cos(\Omega_r \tau) \sigma_y + \sin(\Omega_r \tau) \sigma_z \) (which are exact for constant driving), we find an equation of motion for the polaron frame Bloch vector identical to equations (30)–(35) but with \( \Omega(t) \to \Omega, \Omega_r(t) \to \Omega_r \), and all \( \gamma_l(\omega) \) and \( S_l(\omega) \) replaced with the time-dependent quantities

\[
\gamma_l(\omega, t) = 2\text{Re} \left[ \int_0^t e^{i\omega \tau} \Lambda_l(\tau) d\tau \right]. \tag{60}
\]
Figure 4. Exciton population dynamics in the time domain calculated with (solid blue curves) and without (dashed black curves) a Markov approximation. The insets show the non-Markovian decay rates (dashed red curves) approaching their constant Markovian values (solid orange lines). Parameters: $\alpha = 0.027$ ps$^2$, $\omega_c = 2.2$ ps$^{-1}$, $\Omega = 2$ ps$^{-1}$. Temperatures: (a) $T = 10$ K and (b) $T = 50$ K.

\[
S_i(\omega, t) = \text{Im} \left[ \int_0^t e^{i\omega \tau} \Lambda_i(\tau) d\tau \right],
\]

respectively. For the model we consider here, the difference between the non-Markovian and Markovian polaron frame dynamics is entirely captured in equations (60) and (61). The Markov approximation simply corresponds to pushing the upper integration limits to infinity. We can therefore make the immediate observation that we should expect the Markovian and non-Markovian dynamics to deviate most at short times, since this is when $\gamma_l(\omega, t)$ differs significantly from $\gamma_l(\omega, \infty)$ (and similarly for $S_l(\omega, t)$ and $S_l(\omega, \infty)$). These deviations should be most pronounced when $\Lambda_i(0)$ is greatest in magnitude, since this maximizes the difference between the Markovian and non-Markovian rates (and energy shifts), and decays on a long timescale (set by $1/\omega_c$), as this increases the time over which the non-Markovian rates (and energy shifts) reach their Markovian limits.

To show that this is indeed the case, in figure 4 we plot the excitonic population of our QD as a function of time (rather than pulse area). For this figure we take the relatively large value of $\Omega = 2$ ps$^{-1}$, so that the excitonic system evolves appreciably within the phonon bath correlation time, and in figure 4(a) we consider a low-temperature regime of $T = 10$ K. For these parameters non-Markovian effects are most pronounced at short times, as expected, although it is generally fairly difficult to distinguish between the two theories, especially beyond $t \sim 10$ ps. In the inset, we plot the non-Markovian generalization of the polaron theory decay rate (see equation (49))

\[
\Gamma_P(t) = \frac{\Omega^2}{4} (\gamma_x(\Omega_r, t) + \gamma_y(-\Omega_r, t) + 4\gamma_x(0, t)),
\]

which rapidly approaches its Markovian limit on a timescale $\sim 1$ ps.

We can enhance short-time non-Markovian effects by considering higher temperatures, as this increases the difference between the Markov and non-Markov rates and energy shifts on the bath correlation timescale (although it does not change the timescale on which the Markov
limit is reached). This is shown in figure 4(b), where we again compare Markovian and non-Markovian dynamics, but now at the higher temperature of $T = 50 \, \text{K}$. Non-Markovian effects are indeed more pronounced at short times in this case, and as shown in the inset, the Markov and non-Markov rates do differ more significantly at short times, although the Markov limit is again reached on a similar timescale to that at 10 K. Once more, beyond 5–10 ps there is very little to distinguish the Markovian and non-Markovian dynamics.

The inclusion of non-Markovian effects within the polaron frame master equation can therefore affect the population dynamics at short times ($\sim 5 \, \text{ps}$ and below), but makes very little difference on longer timescales. When plotting excitonic Rabi rotations as a function of pulse area, as in figures 1 and 3, it is only the final exciton population that is measured. For the parameters of figure 3, for example, this corresponds to reading out the excited state population after 14 ps. Even for the relatively large Rabi frequencies used in figures 4(a) and (b), we see that non-Markovian effects are almost negligible on this timescale. Furthermore, at larger temperatures, for which short-time non-Markovian effects seem to be more noticeable, the damping is more pronounced, so that the steady state is reached sooner. Hence, since short-time behaviour is not captured in the pulse area plots of figures 1 and 3, neither are non-Markovian effects (remember that in figure 1 the pulse FWHM is close to 14 ps). In fact, if we plot the exciton population as a function of pulse area using our non-Markovian polaron master equation (equation (59)) for the same parameters as figure 3(a), we find that it is almost indistinguishable from the Markov version on the scale shown in that figure. Hence, our theory predicts that (for the parameters considered here) in order for polaron frame non-Markovian signatures to be evident in pulse–area plots, FWHM pulse durations on the sub-5 ps timescale should be used, much shorter than those in the experiments performed in [11, 12].

We comment that Markovian and non-Markovian excitonic dynamics could also be explored within a time-non-local master equation formalism [57, 58]. To do so, one would replace the reduced density operator at time $t$, $\tilde{\rho}_{\text{SP}}(t)$ in equation (15), with its value instead at time $s$. This generally results in a master equation of convolution type, which is best solved in Laplace space. The dynamics are then determined by the properties of the poles and branch cuts of the Laplace transform of $\alpha_s(t)$, which will have contributions corresponding to both Markovian and non-Markovian processes. Approximating the poles as in [58] corresponds to including Markovian effects only, and should therefore be equivalent to our Markovian treatment. It would be interesting to relax this approximation, in particular to include branch cut contributions, and compare the resulting dynamics to the time-local approach used in this section, since it is expected that both approaches should approximate the true dynamics to the same degree of accuracy [57]. We note, however, that a time-dependent driving field is likely to cause complications in the time-non-local approach, since it would reduce the applicability of the convolution theorem.

5. Discussion and summary

Inspired by recent experimental observations [11, 12], we have investigated the excitonic dynamics of a resonantly driven QD under the influence of dephasing due to its interactions with an acoustic phonon environment. We have developed a combined polaron transform, time-local master equation approach to the problem, which accounts for non-perturbative effects such as multiphonon processes and phonon-induced driving renormalization. We have also extended the theory to the non-Markovian regime. We have found that for low temperatures ($< 30 \, \text{K}$), the
weak-coupling theory presented in [11, 12] is in excellent agreement with the polaron master equation dynamics. However, as the temperature is increased, we find that the weak-coupling treatment begins to overestimate the damping rate, compared to the polaron theory prediction. In fact, it is interesting to note that in [12] it was reported that a weak-coupling fit to the data slightly overestimates the damping for temperatures > 40 K, consistent with our findings. For these temperatures, the non-perturbative aspects of the polaron theory are becoming important. Renormalization of the Rabi frequency tends to decrease the damping rate, while multiphonon processes act to increase it above the single-phonon level (see equations (44), (45) and (49) for the weak-coupling rate, the single-phonon approximation to the polaron rate and the full polaron rate, respectively). Deviations from the weak-coupling theory should be even more pronounced at higher temperatures (above the highest temperature of ~ 50 K explored in [12]), although other decoherence mechanisms could also come into play in this regime.

We also considered the important role of energy-shift terms in the weak-coupling and polaron theories. These terms, analogous to the Lamb shift in energy levels of atomic physics, are responsible for driving- and temperature-dependent shifts in the exciton population oscillation frequency, as also reported in [12]. While, in general, the energy shifts are necessary for a full description of the dynamics, at high temperatures (> 72 K for the parameters studied here) we find that in the weak-coupling theory they give rise to unphysical behaviour, and we therefore set a bound on the applicability of this approach. On the other hand, the polaron theory suffers no such limitation in this regime.

Finally, we explored the role of non-Markovian effects within the polaron frame, and found that they are predominantly a short-time phenomenon for our experimentally relevant parameters. Hence, they should have little bearing on pulse area plots of Rabi rotations if the pulse duration is long on the bath correlation timescale [6, 8, 9, 11]. Note that this implies that, under the same excitation conditions, non-Markovian effects are also negligible in pulse area plots in the weak-coupling theory at low temperatures, since the polaron and weak-coupling approaches agree well in this regime. In order to enhance the visibility of non-Markovian effects, shorter duration pulses or longer bath correlation times are required.

Acknowledgments

We thank Andrew Fisher, Sougato Bose, Brendon Lovett, Erik Gauger and Andrew Ramsay for helpful discussions, comments and suggestions. This work was supported by the EPSRC.
